200–1a,b	17 October	Complete maxilla; 16 teeth. Right M_1
211–1	20 October	Right proximal femur fragment
228–1	27 October	Diaphysis of right femur
241–14	22 December	Left lower molar
266–1	16 November	Mandibular corpus; left P_3–M_1, right P_3–M_3
277–1	19 November	Left mandibular corpus; C–M_2
288–1	24 November	Partial skeleton: occipital and parietal fragments; mandibular corpus with left P_3, M_3, right P_3–M_3, mandibular condyles; right scapula fragment; right humerus; proximal and distal left humerus; proximal and distal right and left ulnae; proximal and distal right radius; distal left radius; left capitate; 2 phalanges; 6 thoracic vertebrae and fragments; 1 lumbar vertebra; sacrum; left innominate; left femur; proximal and distal right tibia; right talus right distal fibula; numerous rib fragments.

The distal femur is undistorted, and both condyles are complete and intact. It is small, with the lateral condyle measuring 39.0 mm anteroposteriorly and 18.9 mm mediolaterally. This fragment demonstrates a number of anatomical details which are intimately related to bipedal locomotion[8,9]: the bicondylar angle is rather high, the lateral lip of the patellar groove is raised and the lateral condyle flattened and elongated.

The associated proximal tibia is intact except for some slight abrasion around the periphery of the superior articular surface. It also is small, the total preserved articular surface measuring 50.7 mm mediolaterally and 33.0 mm anteroposteriorly. The tibial tuberosity is pronounced and is limited proximally by the transverse groove; the soleal line is distinct on the posterior surface of the shaft and the interosseous membrane attachment is indicated by a roughened line on the medial aspect of the shaft; the head is slightly retroflexed with only minor tibial torsion; and the intercondyloid eminence is prominent with well developed intercondyloid fossae.

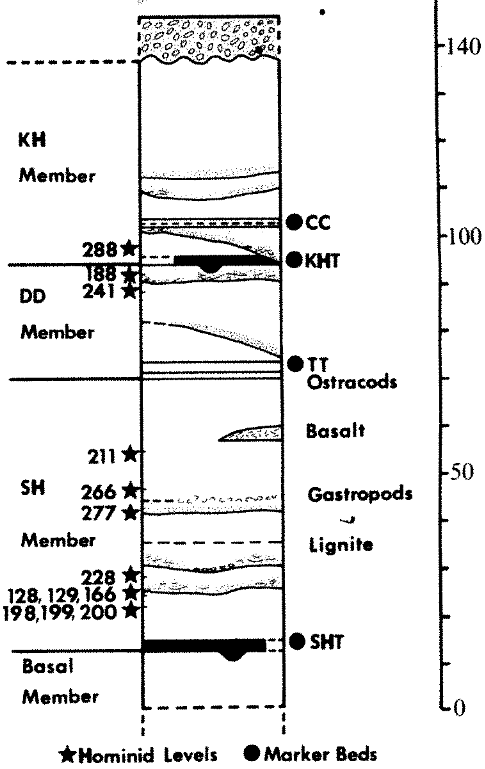

Fig. 2 Stratigraphic positions of Hominid Horizons. ★, Hominid levels; ●, marker beds.

A heavily eroded temporal fragment (AL 166–9) constitutes the only other hominid discovery from the 1973 field season. The specimen derives from a sandstone horizon a few metres stratigraphically above the level of the postcranial material. The temporal has been extensively eroded, with most of the petrous portion broken away, and extensive pneumatisation is exposed in the mastoid and zygomatic regions. The mandibular fossa is broad and flat, bordered by a postglenoid process, but open anteriorly with only a slight articular tubercle. There is a prominent entoglenoid process on the medial wall which is broken exposing a large pneumatisation. The mastoid is large and globular. The external auditory meatus is oval in section with a thick tympanic plate.

1974 hominid discoveries

Our sample of the Hominidae has been greatly augmented with additional field work. The 1974 investigations yielded

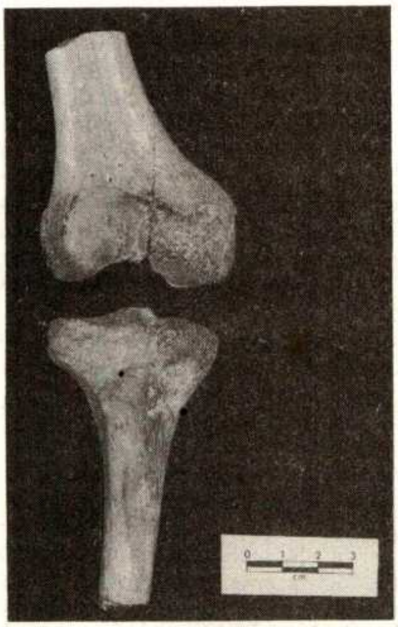

Fig. 3 Anterior view of AL 129–1a and 1c

remains of 10 additional individuals represented by dental, cranial and postcranial elements, including a remarkably intact partial skeleton.

Stratigraphically just below the 1973 hominid discoveries, one complete (AL 200–1) and one half maxilla (AL 199–1) (see Fig. 4) were recovered by Ato Alemayehu Asfaw within 15 m of one another and from the same mudstone horizon.

The AL 200 specimen is an undistorted palate with full dentition and an associated right M_1. The general pattern of dental wear is interesting, in that the incisors exhibit extensive 'ribbon like' wear and dentine exposure relative to the postcanine teeth. In addition, the canines and the P^3s have suffered antemortem enamel chippage on their buccal surfaces during the specimen's lifetime. The tooth rows of AL 200 are subparallel and the arch is relatively long. The anterior portion of the arch is broad to accommodate the large central incisors and marked diastemata occur between the lateral incisors and the canines. The palate is shallow, becoming somewhat deeper posteriorly.

In lateral view this specimen exhibits pronounced alveolar prognathism. The zygomatic root is situated above the first molar, the maxillary sinuses are large and the lower nasal margin is guttered.

The right half maxilla is smaller in size and is less complete, with C–M^3, as well as both incisor sockets and the I^2 root. The dentition is smaller than that of AL 200 (Table 2), but the similarity in morphological detail is striking. Although the incisors are lacking, it is apparent from the root sockets that the anterior portion of the arch was broad and somewhat squared-off as in AL 200. The specimen is broken close to the midline exposing the incisive canal. The palate is shallow and the greater palatine foramen is present. The inferior nasal margin is not sharp and in lateral view alveolar prognathism is well developed. The maxillary sinus is large and the zygomatic root is situated above the distal portion of the first molar.

A partial mandible (AL 266–1) was located in a horizon of sandy clay, ~ 10 m stratigraphically below the basalt flow[5]. This specimen includes the complete right corpus with P_3–M_3, the symphysis with canine and incisor roots, and a portion of the left corpus with P_3–M_1 (Table 3). The dentition is moderately worn with the third molar having just come into occlusion and showing only minor wear facets. The anterior portion of the dental arch is rounded and the dental rows are straight and slightly divergent posteriorly. The post-incisive planum is only moderately developed and the corpus in the region of M_1 is 21.7 mm thick and 31.0 mm deep.

A right mandibular fragment (AL 188–1) containing M_2–M_3 and roots of P_3–M_1, was collected from a sandstone horizon immediately below KHT. The molars are heavily worn. The mandible exhibits some wind abrasion, but it is possible to estimate a thickness of 20.7 mm and a depth of ~ 32.0 mm in the region of M_1.

AL 277–1, a fragmentary left mandible containing C–M_2 and sockets for I_1–I_2, is derived from a sandstone horizon. It is broken just to the right of the midline and distal to M_2. The occlusal wear is heavy with the canine worn flat. Anteriorly the fragment gives the impression of being deep, measuring ~ 41.0 mm just distal to P_3. A prominent post-incisive planum is present, as well as a slight inferior mandibular torus. The inferior surface of the symphysis is flattened and has distinct mental spines. The corpus exhibits slight eversion.

An interesting left half mandible (AL 198–1) was recovered from a mudstone horizon, stratigraphically equivalent to AL 199 and AL 200. The specimen is broken near the midline with the I_1 socket and the root for I_2 preserved. The C–P_4 and M_1–M_2 are present, with a retained deciduous molar located distal to the P_4. The deciduous nature of this tooth is confirmed by a radiograph demonstrating a widely divergent root system. Substantial occlusal wear is evident on P_4–M_2. The corpus is broken just distal to M_2, exposing a portion of the mesial root of M_3 immediately superior to the mandibular canal. The mandible is lightly built, being 16.0 mm thick and 31.9 mm deep at M_1.

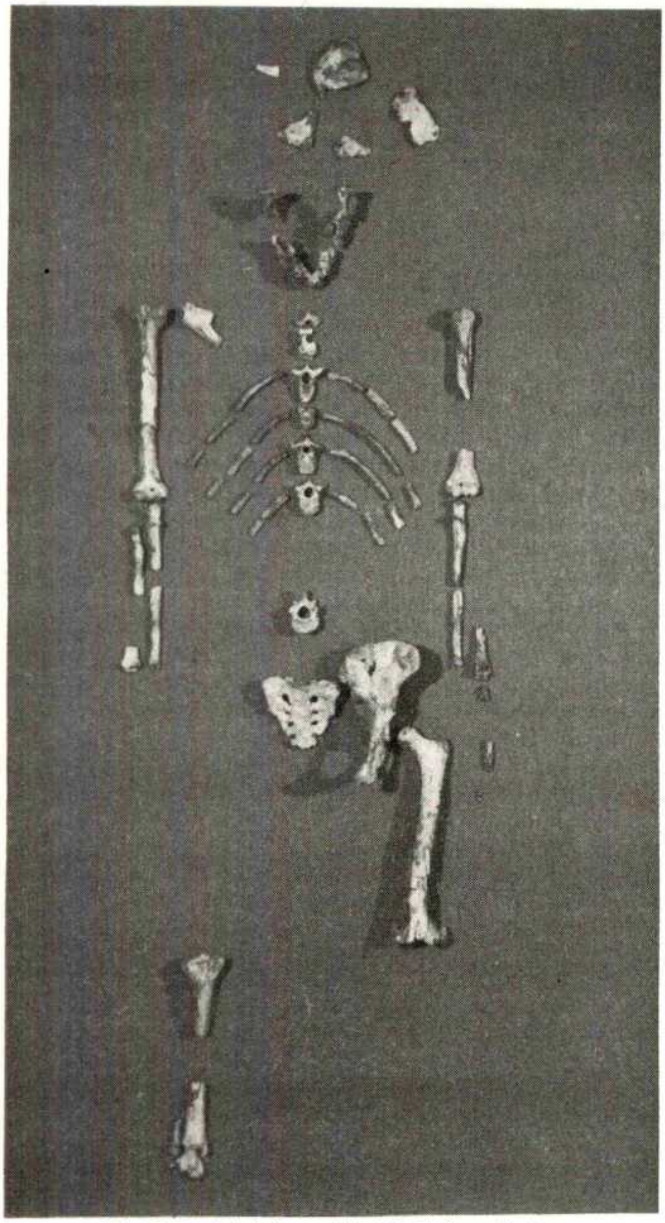

Fig. 5 Partial skeleton (AL 288–1) from Hadar

It exhibits some modelling and the inferior margin is thin and not bulbous.

During screening operations, three additional teeth were located at this locality: a right I_2 (AL 198–18), a left I^2 (AL 198–17a) and a left I^1 (AL 198–17b). The interproximal facets on the upper incisors match perfectly, suggesting that they are from the same individual. Because of the close association of these teeth with the AL 198 mandible, we tentatively assign them to the same individual.

Stratigraphically just below the basalt flow a fragmentary right proximal femur (AL 211–1) was collected. The specimen is somewhat abraded with the head and neck missing and most of the greater trochanter. The neck is very flattened, no trochanteric flare is present, the intertrochanteric line is weakly expressed, the spiral line is well developed and the lesser trochanter is not visible from the anterior aspect. The specimen is quite large and fairly robust.

AL 228–1 is a distal portion of a femoral diaphysis recovered from a sandstone. It is not large, but exhibits strong development of the linea aspera. It is smaller than AL 129–1A.

The partial skeleton

The discovery on November 24 of a partial skeleton (AL 288–1; see Fig. 5) eroding from sand represents the most outstanding hominid specimen collected during the 1974 field season. The stratigraphic horizon yielding the skeleton is situated just above the KHT, which has not yet been dated. Fossil preservation at this locality is excellent, remains of delicate items such as crocodile and turtle eggs and crab claws being found. It is obvious that this discovery provides us with a unique opportunity for reconstructing the anatomy of an early hominid in far more detail than has been previously possible. Extensive descriptive and comparative studies are projected for the AL 288 partial skeleton and will provide us with details of stature, limb proportions, articulations and biomechanical aspects. Three weeks were devoted to intensive collecting and screening to ensure the recovery of all bone fragments from the site. Laboratory preparation and analysis has only just begun, and in this report it is possible to mention only a few salient points.

The mandible is not heavily built; it is 30.0 mm deep and 19.0 mm thick in the region of M_1. The M_3s are fully erupted and occlusal wear facets are just appearing. The symphysis is intact with a slight post-incisive planum. Although the incisor crowns are absent, it is apparent that this region was quite small. The remaining dentition is small and not very worn. The P_3s are interesting with a sloping buccal surface and almost no development of a metaconid. The form of the dental arch as well as the body of the mandible is distinctly V-shaped.

The cranium is not sufficiently complete to estimate cranial capacity. The cranial bones are thin, exhibit no sutures (internally or externally) and no marked development of nuchal or temporal musculature is present.

The left innominate is complete, although it is somewhat distorted in the pubic region and particularly in the area of sacral articulation. In size the specimen resembles Sterkfontein (Sts) 14; the ilium, however, gives the appearance of being higher, and the anterior border is relatively straight. A strongly developed anterior inferior spine is apparent. The acetabulum is shallow when compared with modern man and with Sts 14. The sciatic notch is broad, the subpubic angle obtuse and the pubis exhibits a pronounced vental arc, all of which suggests the skeleton belonged to a female. When viewed from the superior aspect, the base of the sacrum is divided into thirds, with the diameter of the sacral body equal to each of the alae. This again suggests that AL 288 was female.

A complete left femur is associated with the innominate, but the distal portion is badly crushed. Its total length has been estimated at 280 mm but may be slightly revised when the distal end is reconstructed. The femur has minimal trochanteric flare, the neck is anteroposteriorly flattened, an intertrochanteric line is present and the lesser trochanter is not visible from the anterior aspect.

The proximal right tibia is nearly identical in size and morphology to AL 129–1b. The distal tibia is associated, and articulates with a talus and a distal fibula.

The right humerus is complete with some crushing of the proximal end. Its total length is estimated at ~ 235 mm giving a value of 83.9 for the humeral–femoral index. The distal end possesses a marked ridge separating the capitulum and trochlea.

Significance of the Hadar hominids

Detailed studies of the Hadar hominids have just recently been initiated and definitive interpretations are not yet possible. Because of the geological antiquity, and in some instances the completeness of the specimens, however, we proffer a number of preliminary impressions concerning their phyletic affinities and resemblances to other specimens.

The partial skeleton exhibits a number of similarities to the Sterkfontein sample. Specifically, the size of the pelvis and to some degree its morphology are reminiscent of Sts 14. The shallow acetabulum and relatively high ilium, how-

Table 3 Dental measurements of AL 266–1(mm)

	Left		Right	
AL 266–1	Mesio-distal	Bucco-lingual	Mesio-distal	Bucco-lingual
P_3	9.1	10.1	9.2	10.1
P_4	8.9	11.0	9.4	10.8
M_1	12.1	11.9	12.1	12.0
M_2			13.3	14.0
M_3			15.3	13.7

ever, demonstrate certain divergences from the Sterkfontein specimen and possibly reflect a somewhat more primitive status for the AL 288 specimen. The associated V-shaped mandible is noteworthy. Leakey[10] has drawn attention to mandibular shape and has suggested that KNM-ER 1482 (Kenya National Museum, East Rudolph), and Omo 18 should be considered primitive because of their V-shaped contours. Should this prove to be a diagnostic character, it is possible that AL 288 retains more primitive features than *Australopithecus africanus*, recognised from Sterkfontein.

Previously the 1973 postcranial material has not been assigned to a taxon. It is now clear that it should probably be included in the same category as the AL 288 specimen because of the striking similarity of the proximal tibial fragments in size and morphology as well as the preserved femoral fragments. This is important because: there is now evidence of at least two individuals of a very small hominid in Hadar, and the AL 128 and 129 specimens are situated stratigraphicaly 80 m below the partial skeleton (Fig. 2).

The presence of another taxon is suggested by two other specimens in the Hadar hominid collection. AL 211–1 resembles very closely Olduvai Hominid (OH) 20 (ref. 11) as well as the two proximal femora from Swartkrans (SK 82 and SK 97). Similarities are not only in size but also in morphological detail; stout shafts, flattened necks, a lack of trochanteric flare and posteriorly facing lesser trochanters not visible in anterior view.

The temporal fragment (AL 166–9) resembles material from Swartkrans and East Rudolf which has also been assigned to a large *Australopithecus* pattern, particularly in the large bulbous mastoid process and heavy pneumatisation, as well as the broad temporal shelf. It is, however, less typical of this pattern in the broad, flat mandibular fossa and absence of a strong articular tubercle.

The close association of AL 199–1 and AL 200–1, as well as their stratigraphic equivalence, is important because of the high probability that they sample the same taxon. Except for size differences, these two specimens are remarkably similar, and suggest variation within a single taxon. The complete maxilla has large canines, broad central incisors and large posterior dentition. These characters as well as other details suggest resemblances with some *Homo erectus* material, particularly *Pithecanthropus* IV. This dental pattern is also seen in KNM-ER 1590 from East Rudolf, a specimen with large cranial capacity assigned to the genus *Homo*[10,12]. It must be recognised that other aspects of the AL 200 maxilla are 'primitive', such as the guttered nasal margin and the alveolar prognathism.

The AL 266–1 and AL 277–1 mandibles resemble, in details of the dentition and mandibular morphology, other specimens assigned to *Homo*, such as OH 7 (ref. 13) and KNM-ER 1802 (ref. 10).

On the basis of the present hominid collection from Hadar it is tentatively suggested that some specimens show affinities with *A. robustus*, some with *A. africanus* (*sensu stricto*), and others with fossils previously referred to *Homo*.

The understanding of Plio–Pleistocene hominid remains is undergoing intensive revision and re-evaluaton, and we stress that our identifications and phylogenetic interpreta- such as the guttered nasal margin and the alveolar prog- liminary. With continued collection of specimens from the three million year-old time range in Hadar and elsewhere, and with additional detailed studies and comparisons, our attempts to interpret the earliest hominds should become more clear.

Special gratitude is expressed to Y. Coppens for his assistance in preparation of this manuscript. Owen Lovejoy also provided helpful comments.

Sequence of promoter for coat protein gene of bacteriophage fd

M. Takanami, K. Sugimoto, H. Sugisaki and T. Okamoto

Institute for Chemical Research, Kyoto University, Uji, Kyoto, Japan

*The nucleotide sequence in the promoter region for the coat protein gene of phage fd has been determined. This sequence contains an endonuclease R·*Hha *cleavage site at the fifteenth nucleotide upstream from the RNA start site. Cleavage results in loss of promoter function. Comparison with the sequence of another fd promoter indicates that the longest sequence common to both was TATAAT in the region in which RNA polymerase forms a stable initiation complex.*

ELUCIDATION of the structure of DNA specifying the initiation of transcription is essential to understand the mechanism of gene expression. Although the sequences of several different promoters have been determined[1-7], the information still seems to be insufficient to define the structure essential for promoter function. In previous work in which the promoter regions were localised on the cleavage map of fd[8,9], two strong promoters were shown to be located on two separate fragments, named *HapC* and *Hap-HgaV*. The nature of these promoters was very similar: RNA polymerase binds tightly to these fragments in the presence of GTP and initiates G-start RNA with almost the same efficiency. The sequence in the promoter region on *Hap–HgaV* (named G2 promoter) has been determined[7]. In this report, the promoter region on *HapC* (named G3 promoter) was sequenced to find the sequence common to both promoter regions.

HapC contains the entire gene for the coat protein (B protein) of fd[10,11], and RNA of about 350 bases (G3 RNA) is efficiently synthesised on this fragment. This RNA contains the sequence for the coat protein (M.T. *et al.*, unpublished). Restriction endonuclease (R) *Hae*III cleaves *HapC* into two pieces: *HapC–Hae 1* and *HapC–Hae 2.* RNA of about 200 bases (G3′ RNA) is synthesised only on *HapC–Hae 1*. Comparison of the sequences of G3 and G3′ RNAs indicated that G3′ RNA was yielded by termination of G3 RNA at the R·*Hae*III cleavage site. *HapC–Hae 1* can be further cleaved by R·*Hha* into two pieces, *Hha 1* and *Hha 2*. No RNA was initiated, however, on the resulting fragments; the ability to form a stable complex with RNA polymerase was also destroyed by this cleavage. The positions of the cleavage sites and of the G3 RNA start site on *HapC* are indicated in Fig. 1. The sequences in the region preceding the G3 RNA start site and in the region in which RNA polymerase forms a stable initiation complex (RNA polymerase binding site) were determined by the following procedures.

(1) In low salt conditions, *HapC–Hae 1*-directed RNA synthesis was initiated at two additional sites, although RNA initiation at the G3 promoter was still predominant. Figure 2*a* and *b* shows autoradiographs of the low salt and high salt (0.15 M KCl) transcripts for comparison. The direction of transcription and the regions covered by these transcripts have been determined by hybridisation to fd phage (+ strand) DNA and each fragment of *HapC*. Since both the low salt transcripts, named (+)RNA·LS and (−)RNA·LS, covered the region preceding the G3 RNA start site (Fig. 1), these RNAs were further fractionated by hybridisation to each *Hha* fragment and by partial T1 RNase digestion, and the sequences of the resulting fragments were determined.

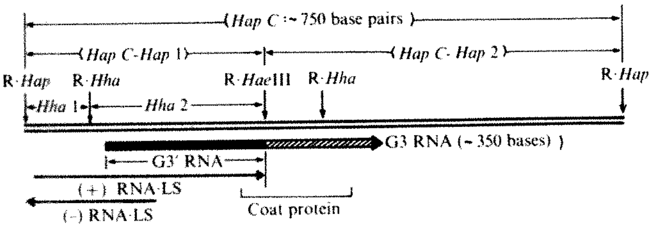

Fig. 1 Cleavage and transcription maps of the *HapC* region of fd DNA. Location of *HapC* on the cleavage map of fd DNA is given in ref. 8.

(2) *HapC–Hae 1* forms a stable initiation complex with RNA polymerase in the presence of GTP: the region protected by RNA polymerase was isolated after treatment with DNase I. In accordance with other observations[6,12–14], the isolated fragment was about 45 base pairs, as determined by gel electrophoresis. The polymerase-protected fragment was denatured by heating, and incubated in an RNA-synthesising system containing a primer oligonucleotide[12]. The resulting transcripts were fractionated by hybridisation to fd phage DNA and by gel electrophoresis, and their sequences determined.

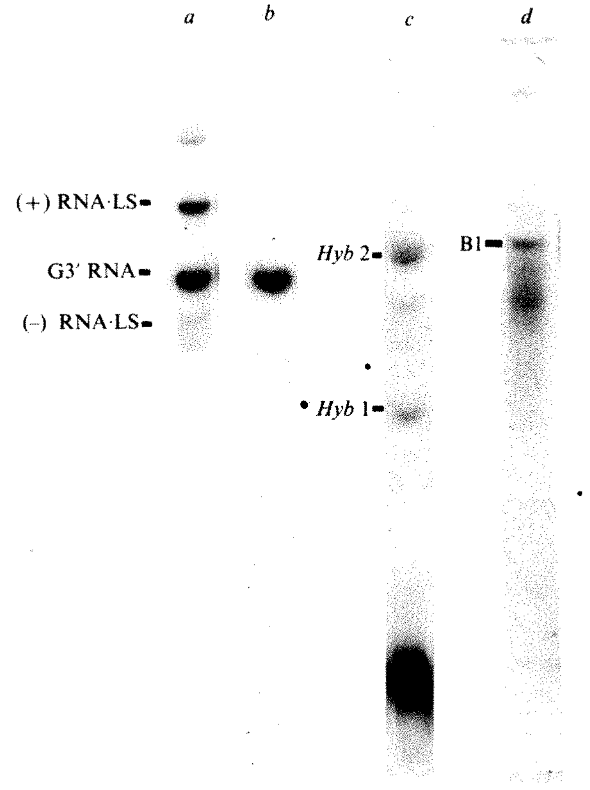

Fig. 2 Gel electrophoretic patterns of *a*, RNA formed on *HapC–Hae 1*, at low salt; *b*, RNA formed on *HapC–Hae 1* at high salt; *c*, portions of (+)RNA·LS hybridised to the R·*Hha*-digest of *HapC–Hae 1*, and *d*, RNA formed on the RNA polymerase-protected fragment. *a*, *HapC–Hae 1* (about 2 pmol) was incubated for 1 h at 37 °C in a reaction mixture (1 ml) containing 8 mM $MgCl_2$, 40 mM tris (pH 7.9), 0.1 mM dithiothreitol, 50 μM (α^{32}P)GTP and 0.2 mM each of three other NTPs, and about 15 pmol RNA polymerase. The transcripts were isolated and electrophoresed for 3 h at 150 V on a 5% polyacrylamide gel (0.6 cm × 12 cm) containing 7 M urea, as in ref. 12. *b*, RNA was synthesised on *HapC–Hae 1* and electrophoresed as in (*a*), except that 0.15 M KCl was added to the reaction mixture. *c*, RNA was extracted from the (+)RNA·LS band of (*a*) and mixed with about 10 pmol of the R·*Hha*-digest of *HapC–Hae 1* in 0.6 M NaCl–0.06M Na citrate. The mixture was heated for 5 min at 100 °C and then held for 3 h at 55 °C. After cooling, the mixture was diluted, treated with 100 units of T1 RNase for 1 h at 37 °C, and electrophoresed for 3 h at 150 V on a 10% gel[12]. *d*, *HapC–Hae 1* (about 10 pmol) was mixed with about 30 pmol of RNA polymerase in a binding mixture (1 ml) containing 8 mM $MgCl_2$, 40 mM tris (pH 7.9), 0.15 M KCl, and 0.1 mM GTP, and the portion protected from DNase digestion was isolated after treatment with DNase I, as in ref. 12. The isolated fragment was heated for 5 min at 100 °C and added to a reaction mixture (1 ml) containing 8 mM $MgCl_2$, 50 mM KCl, 40 mM Tris (pH 7.9), 0.1 mM dithiothreitol, 20 μM each (α^{32}P)GTP and the other NTPs, 10 nmol AAAC and about 10 pmol RNA polymerase. After incubation for 3 h at 37 °C, the transcripts were isolated and mixed with 50 μg of fd phage DNA in 0.9 M NaCl–0.09 M Na citrate. The mixture was heated for 5 min at 100 °C and then held for 3 h at 51 °C. The fraction hybridised to fd phage DNA was isolated by using a Millipore filter and electrophoresed for 3 h at 150 V on a 15% gel containing 7 M urea, as in ref. 12.

The procedures for preparation of fd replicative form DNA (rfDNA) and *Escherichia coli* RNA polymerase holoenzyme, and the conditions used for digestion of DNA and gel electrophoresis have been described previously[8,9,12]. For preparation of *HapC–Hae 1*, *HapC* was first isolated from the R·*Hap* digest of fd rfDNA, redigested with R·*Hae*III, and then fractionated by gel electrophoresis. R·*Hap*, R·*Hae*III and R·*Hha* were respectively prepared from *Haemophilus aphirophilus*, *H. aegyptium* and *H. haemolyticus* by the procedures described previously[15]. For sequencing, RNA was synthesised with each of four (α^{32}P) nucleoside triphosphates (NTP), and hydrolysed with T1 RNase. The resulting nucleotides were fractionated by two-dimensional chromatography on a polyethyleneimine (PEI)–cellulose plate (Macherey–Nagel)[16]. Distribution of ^{32}P in spots was determined to estimate molar yields. To analyse the sequences of oligonucleotides, each spot was digested with either pancreatic RNase or U2 RNase and chromatographed using a two-dimensional system. The nucleotides produced were further digested with T2 RNase, and the distribution of ^{32}P in nucleotides determined. The starting nucleotides were not determined, since the nucleotides con-

Fig. 3 Arrangement of T1 RNase nucleotides produced from the low salt transcripts of *HapC–Hae 1*. Nucleotide numbers correspond to those given in Table 1. As the starting nucleotides were not identified, the possible start sites of (+)RNA·LS and (−)RNA·LS are indicated in parentheses. Sites corresponding to the R·*Hha* cleavage sites are indicated by arrows.

taining triphosphate ends stayed at the origin in the conditions used for chromatography.

Sequence in region preceding G3′ RNA start site

The nucleotides produced from G3′ RNA by digestion with pancreatic and T1 RNases have been analysed, and the sequence of 130 nucleotides from the 5′ end of G3′ RNA has been determined by analysis of its partial T1 RNase digest (Fig. 3 'G3 RNA region', our unpublished observation). The sequence contains the ribosome binding site number 1 of phage f1 messenger RNA[17] in the positions 96–120. Figure 4*a* and *b* shows fingerprints of T1 RNase nucleotides produced from G3′ RNA and (+)RNA·LS for comparison. By comparing the sequences of the products, (+)RNA·LS was found to contain 22 'extra' nucleotides. The positions of the extra nucleotides and their sequences are shown in Fig. 4*b* and Table 1*a*. These nucleotides were assigned to the region preceding the G3 RNA start site. To arrange these nucleotides, (+)RNA·LS was hybridised to the R·*Hha* digest of *HapC–Hae 1*. The regions protected by hybridisation to the DNA fragments, *Hha 1* and *Hha 2*, were isolated by gel electrophoresis after treatment with T1 RNase (Fig. 2*c*). The *Hha 1* and *Hha 2* regions were digested with T1 RNase and fractionated using a two-dimensional system. Among the 22 T1 RNase nucleotides of (+)RNA·LS assigned to the left of the G3 RNA region, 17 nucleotides arose from the *Hha 1* region, as indicated in Fig. 4*c*, and the remaining nucleotides from the *Hha 2* region. The order of the T1 RNase nucleotides in the *Hha 1* region was determined by analysis of its partial T1 RNase digests and of the T1 RNase nucleotides

Table 1 T1 RNase nucleotides produced from the low salt transcripts of *HapC–Hae 1*

a, Nucleotides from (+)RNA·LS

T1a: G A (2), T1b: G C (1), T1c: G U (2), T2: AG C (1), T3a: CG A (1), T3b: CG C (1), T3c: CG G (1), T4: CAG G (1), T5: AUG A (1), T6a: UCG C (1), T6b: CUG G (1), T7: UUG U (1), T8: CUUG G (1), T9: UAACAUG G (1), T10: UUUCG C (1), T11: AUUUCG A (1), T12: UAUAAUCG C (1), T13: (AU,AC)AAAUC(C,U)CG U (1), T14: UACUUUG U (1), T15: (AC,AC,AAUUU,AUC)AG G (1).

b, Nucleotides from (−)RNA·LS

−T1a: G A (1), −T1b: G C (2), −T2a: AG A (1), −T2b: AG G (1), −T3a: CG A (4), −T3b: CG C (1), −T4: UG U (1), −T5: AAG G (1), −T6: UCG A (1), −T7: AAAG A (2), −T8: CCUG A (1), −T9: ACCUG C (1), −T10: AUUUG U (1), −T11: ACCCCAG C (1), −T12: UACAACG G (1), −T13: AAAUCCG C (1), −T14: C(C,U)CAUG U (1), −T15: AAACAAAG U (1), −T16: CCACUACG A (1), −T17: AUAAAUUG U (1), −T18: UAUCAUCG C (1), −T19: UUACUUAG C (1), −T20: (AUU,AU,ACC)AAG C (1), −T21: C(ACC,AACC,U)AAAACG A (1), −T22*: (A_{10},C_6,U_6)UG A (1), −T23: CCG (>0.5)

*Pancreatic RNase digestion yields CA, CU, UA, UC, 2UU, ACA, 2ACU, AUC, AAUA, and AAAACA.

In *a*, nucleotides assigned to the region preceding the G3 RNA start site are listed. Nucleotide numbers correspond to those indicated in Fig. 4. Nucleotides produced from (−)RNA·LS are denoted by the minus sign. Nucleotides linked to the 5′ ends are underlined. Molar yields are indicated in parentheses.

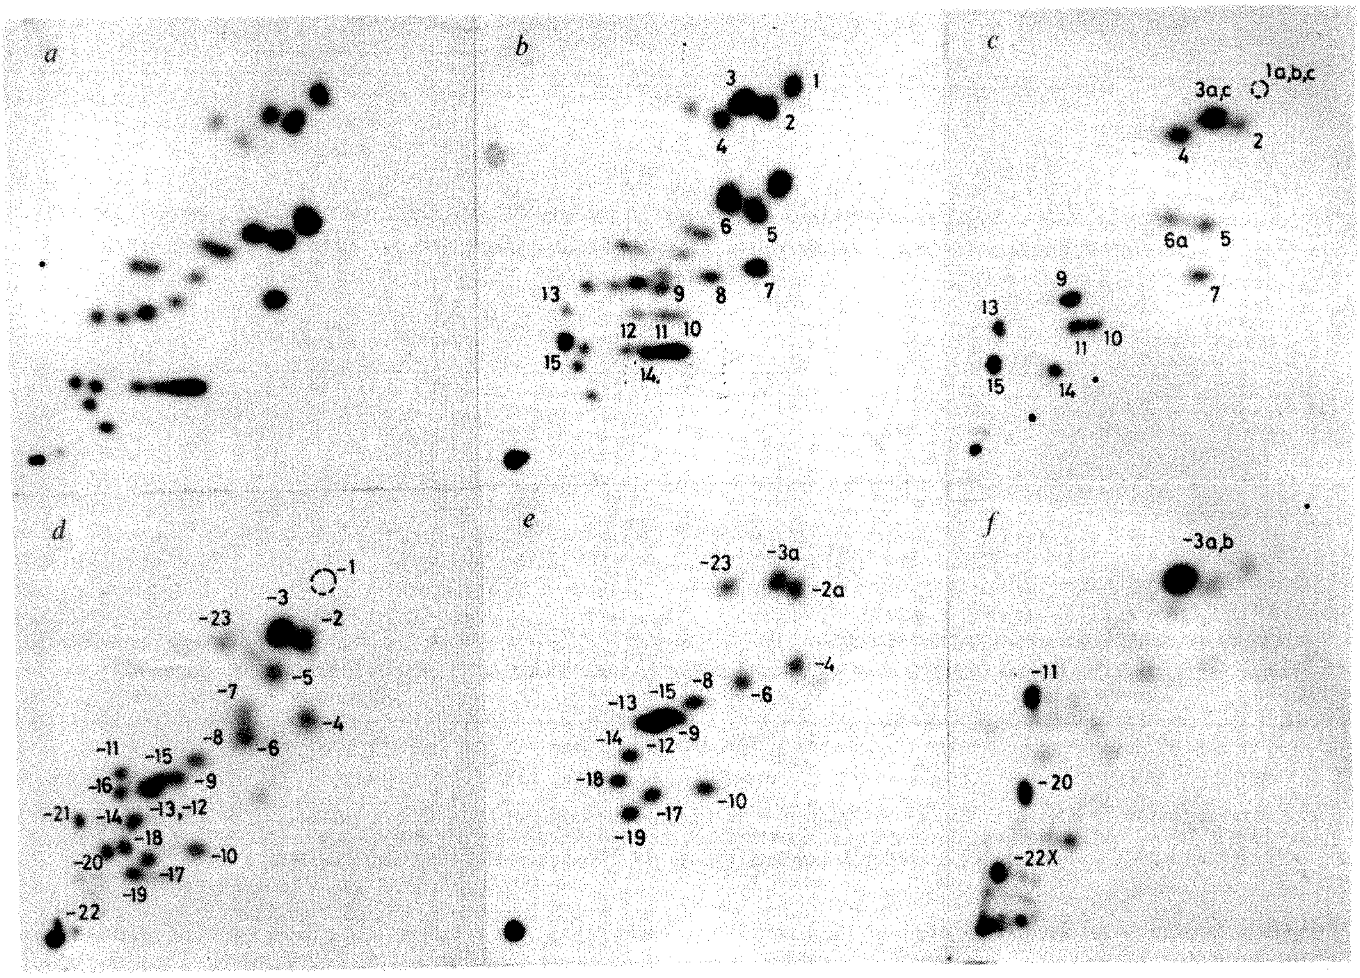

Fig. 4 Two-dimensional fingerprints of T1 RNase digests of *a*, G3′ RNA; *b*, (+)RNA·LS; *c*, portion of (+)RNA·LS hybridised to the DNA fragment *Hha 1* (Fig. 2*c*, *Hyb 1* region); *d*, (−)RNA·LS; *e*, portion of (−)RNA·LS hybridised to the DNA fragment *Hha 1*; and *f*, RNA formed on the RNA polymerase-protected fragment (Fig. 2*d*, B1 region). All RNAs have been synthesised with α-^{32}P-GTP, and the digests chromatographed on 20 × 20 cm PEI–cellulose plates, as in ref. 16. The sequences of the spots numbered are given in Table 1.

produced from the corresponding region of (−)RNA·LS (Fig. 4*e*). Although the sequences of T13 and T15 had not been deduced, a unique sequence was obtained for the *Hha 1* region by combining the sequence information on both strands (Fig. 3, '*Hha 1* region').

The five T1 RNase nucleotides remaining (T1c, T3b, T6b, T8 and T12) should be located between the *Hha 1* and G3 RNA regions. The sequence of the R·*Hha* cleavage site has been determined (ref. 18 and our unpublished observation). R·*Hha* cleaves DNA at the following sites:

↓
(5′)————pGpCpGpC————(3′)
(3′)————CpGpCpGp————(5′)
↑

This sequence should be located between the *Hha 1* and *Hha 2* regions. On the basis of this assumption and information on the nucleotides adjacent to G, the order of the five T1 RNase nucleotides can be deduced to be either (*a*) T3b:T8:T1c:T12:T6b or (*b*) T3b:T6b:T1c:T12:T8.

The T1 RNase nucleotides produced from (−)RNA·LS are shown in Fig. 4*d* and Table 1*b*, in which nucleotides from (−)RNA·LS are denoted by the minus sign. As indicated in Fig. 1, the sequence of (−)RNA·LS should be complementary to the left part of (+)RNA·LS. According to this assumption we arranged the T1 RNase nucleotides of (−)RNA·LS on the sequence of (+)RNA·LS, and 28 nucleotides were successfully ordered on the *Hha 1* and G3 regions. Although the sequences of −T14, −T21 and −T22 had not been deduced, analysis of their pancreatic RNase digests indicates that these fragments can only fit in the indicated regions (Fig. 3). −T23 was assigned to the left end of the sequence, as the yield was less than 1 mol (Table 1*b*). Only three T1 RNase nucleotides remain (−T3a, −T3b and −T20). These nucleotides were assigned to the region between the *Hha 1* and G3 RNA regions. As described above, the five T1 RNase nucleotides of (+)RNA·LS which had been assigned to the corresponding region can be ordered into two alternative sequences ((*a*) or (*b*)). The three T1 RNase nucleotides from (−)RNA·LS are only arranged on the sequence of (*a*), (see Fig. 3). This arrangement was further confirmed by analysis of the portions of (−)RNA·LS hybridised to the *Hha* fragments and of their partial T1 RNase digests. In Fig. 4*e*, the T1 RNase nucleotides produced from the *Hha 1* region of (−)RNA·LS are shown: all the nucleotides assigned to the left of the R·*Hha* cleavage site are seen. The regions covered by other RNA fragments analysed are indicated by the sidelines on the sequence in Fig. 3.

Sequence of RNA polymerase binding site

The initiation complex was formed with *HapC–Hae 1* in the presence of 0.15 M KCl, and the polymerase-protected fragment was isolated after DNase digestion. The fragment was denatured and RNA synthesis was carried out using conditions described previously[12]. AAAC was added as a primer, because RNA synthesis was significantly stimulated by this primer. The synthesised products were fractionated by hybridisation to fd phage DNA, followed by gel electrophoresis. The T1 RNase nucleotides produced from the largest RNA band (Fig. 2*d*, B1 region) is shown in Fig. 4*f*. Only six major nucleotides were identified, of which five were −T3a (2 mol), −T3b, −T11 and

Fig. 5 Comparison of sequences of *a*, fd G3 promoter; *b*, fd G2 promoter, and *c*, a promoter for *E. coli* RNA polymerase on SV40 DNA. The sequences of *b* and *c* were taken from refs 7 and 2. In *a* and *b*, nucleotides common to the polymerase binding sites of both fd promoters are boxed, and the regions with twofold symmetry are indicated by underlining (*x*, axis of symmetry). In *c*, the homologous sequence in the polymerase binding site is boxed. Arrows indicate the starting points of transcription.

−T20 in the T1 RNase products of (−)RNA·LS. The other (−T22X) contained the primer at 5′ end: the result of nearest neighbour analysis indicated that this nucleotide just fits in the region between the sixth and twentieth nucleotides of G3 RNA. It is therefore reasonable to conclude that the RNA analysed had been initiated with the primer in the middle of the −T22 region and terminated within the −T15 region on the sequence of (−)RNA·LS, as indicated in Fig. 3. The size of RNA is about equal to the approximate size of the DNA fragment isolated as the polymerase binding site. The sequence of the polymerase binding site, inferred from the RNA sequence, contains the initiation point for transcription near the centre, in accordance with the observations on other RNA polymerase binding sites[12–14].

Sequence features of fd promoter

The sequence in the promoter region for G3 RNA (G3 promoter) inferred from analysis of the low salt transcripts, is shown in Fig. 5*a*. All the information needed for promoter function should be contained in this sequence. The sequence was first compared with the sequence of fd G2 promoter determined previously (Fig. 5*b*)[7]. The longest sequence common to the two similar fd promoters, however, was only TATAAT. It is also seen that when both the promoter sequences are aligned with reference to the TATAAT sequence, a relatively high degree of homology is obtained in the polymerase binding site, as indicated in boxes in Fig. 5*a* and *b*. Any other alignment does not yield such a homology in any region. We previously noted that the G2 promoter contains regions with twofold rotational symmetry, with one located in the non transcribed region of the polymerase binding site (Fig. 5*b*)[7,12]. The G3 promoter also contains some symmetrical regions (Fig. 5*a*). Comparison of the symmetrical regions, however, does not reveal a common pattern.

In a previous paper[7], we noted that, among the promoters already sequenced[1–6], the G2 promoter sequence bears some resemblance to the sequence of a promoter for *E. coli* RNA polymerase on SV40 DNA (Fig. 5*c*) (TTNTTGNTG at around the −35th position and TATAAT in the polymerase binding site). The G3 promoter also contains some regions homologous to the SV40 promoter (GTTGT and TTGTT at positions −20 and −40 and TATAAT in the polymerase binding site). The sequence common to all three promoters, however, is only the TATAAT sequence. As has been noted by Pribnow[14], the other promoters also contain the sequences homologous to TATAAT in the corresponding region. The result therefore strongly suggests that the TATAAT sequence has an important role for the formation of the initiation complex. It is unlikely, however, that RNA polymerase directly binds to the RNA initiation site by recognising this TATAAT sequence, because the R·*Hha* cleavage of the G3 promoter five base pairs upstream from the TATAAT sequence destroys the ability to form the initiation complex. It has also been shown that RNA polymerase does not initiate RNA synthesis correctly on the isolated polymerase-binding fragment[14,19]. The exact size of the promoter is not known. In the *lac* and λ promoters, some promoter mutations locate approximately 35 base pairs upstream from the RNA start site[4,20,21]. In the λ promoters, the R·*Hin*dII cleavage site which destroys the promoter function is located 33 base pairs from the RNA start site[1,5,6]. These observations all suggest that some regions preceding the polymerase binding site are essential for promoter function. It is most likely that RNA polymerase first recognises some specific structure in such a region (recognition site) and then forms an initiation complex at the region containing the TATAAT sequence[4,14,21].

The question remains as to the basic structure at the recognition site. One possibility is that some specific sequence is involved in the primary recognition of promoter by RNA polymerase. It has been noted that both the λ and SV40 promoters contain TGTTG about 35 base pairs upstream from the RNA start site[21]. As indicated by broken lines in Fig. 5*a* and *b*, the G2 promoter contains TGATG and the G3 promoter GTTG in the corresponding region, suggesting that this sequence may have some relation to the structure of the recognition site. The *lac*[4] and tyrosine transfer RNA[24] promoters, however, do not contain this sequence. The other possibility for consideration is derived from the present finding that, except for the polymerase binding site, there was little sequence homology between two similar fd promoters. It is known that RNA polymerase has strong affinity towards single-stranded regions of DNA[22,23]. At low salt concentrations, RNA polymerase binds many sites of DNA[22] and initiates RNA synthesis at additional sites, as indicated in this and previous papers[7]. These lines of evidence would lead to a view that RNA polymerase primary interacts with regions of low transition temperature, instead of recognising a specific sequence; and if the TATAAT sequence locates at the neighbouring site, the polymerase forms a stable initiation complex. Such a primary interaction site could be either the region of high AT content or the region with twofold symmetry, as the helical structure of these regions is assumed to be unstable. In support of this possibility, all the promoters sequenced seem to have some AT-rich regions and the fd promoters contain the regions with twofold symmetry in the region preceding the polymerase-binding site, although the location and size of such regions are different with promoters. With either possibility discussed above, more information is still needed to define the basic structure at the recognition site.

Finally, we compared the sequences of two fd promoters with similar properties and found little sequence homology, except for the region in which RNA polymerase forms an initiation complex. As other lines of evidence indicate that the promoter recognition by RNA polymerase takes place at a region preceding the initiation complex site, our finding implies that a unique sequence is not involved as a key element in the promoter recognition.

Intracellular forms of Epstein–Barr virus DNA in human tumour cells *in vivo*

Tumour biopsies from Burkitt lymphoma patients, as well as human nasopharyngeal carcinoma cells growing in athymic nude mice, contain Epstein–Barr virus DNA as covalently closed circular DNA. In addition, integrated viral DNA sequences seem to be present.

EPSTEIN–BARR virus (EBV) is of great interest at present as the first virus of possible aetiological significance for certain malignant tumours in man. Two unusual human tumours are uniquely associated with EBV, the African form of Burkitt lymphoma and low-differentiated nasopharyngeal carcinoma. Patients with these tumours always have elevated serum titres against EBV-associated antigens[1,2]. Moreover, the actual tumour cells are those transformed by the virus, as they contain several copies of EBV DNA and express an EBV-associated nuclear antigen (EBNA) but lack detectable virus particles[2–5]. Although formal proof that the virus is oncogenic in man will be difficult to obtain, the notion that EBV is a tumour virus is supported by the recent findings that injection of the virus into cotton-top marmosets or owl monkeys induces fatal lymphomas[6,7], and that the virus transforms normal human B lymphocytes into immortal lymphoblastoid cell lines with great efficiency[8]. Further, in humans with certain rare forms of inherited immunodeficiency, infectious mononucleosis caused by EBV may proceed into a malignant lymphoma instead of having its usual appearance as a self-limiting lymphoproliferative disease[9,10].

Insight into the relationship between EBV and its host may be gained from studies on the state of the virus genome within the transformed cell. Such investigations have previously been limited to human lymphoid cell lines, in particular Raji cells. This line was derived from a Burkitt lymphoma biopsy over 10 yr ago[11]. A Raji cell does not produce EBV particles, but it contains 50–60 genome equivalents of EBV DNA[12]. Most of this intracellular EBV DNA is present in free form and can be separated from the larger cellular DNA by glycerol gradient centrifugation in both alkaline and neutral solution[13,14]. This non-integrated EBV DNA has been purified and shown to have a circular conformation[15,16], with both covalently closed and nicked circular DNA molecules present after isolation. Thus, the non-integrated intracellular virus DNA differs structurally from the linear duplex DNA present in virus particles, although both these DNA forms are of the same molecular weight within experimental error. In addition, integrated sequences of EBV DNA have been found in Raji cells, but it is not known if they represent complete virus genomes[17]. The isolated DNA "molecules" comprised of both viral and cellular DNA usually contain single-strand interruptions, but the actual joints between the viral and cellular DNA are alkali stable[18].

It has not been known if both integrated and circular forms of EBV DNA are also present in tumour cells *in vivo* or if one of these forms was a secondary consequence of *in vitro* cultivation. The studies on the intracellular states of EBV DNA are extended here to tumour biopsies.

Circular EBV DNA in nasopharyngeal carcinoma cells

Biopsies from patients with low differentiated nasopharyngeal carcinoma contain EBV DNA, which is located in the nuclei of the epithelial tumour cells[19,20]. Such biopsies are usually small and heavily infiltrated with lymphocytes that do not contain EBV DNA, and they are therefore less

†On leave from Institut für klinische Virologie, Universität Erlangen-Nürnberg, Erlangen, West Germany.

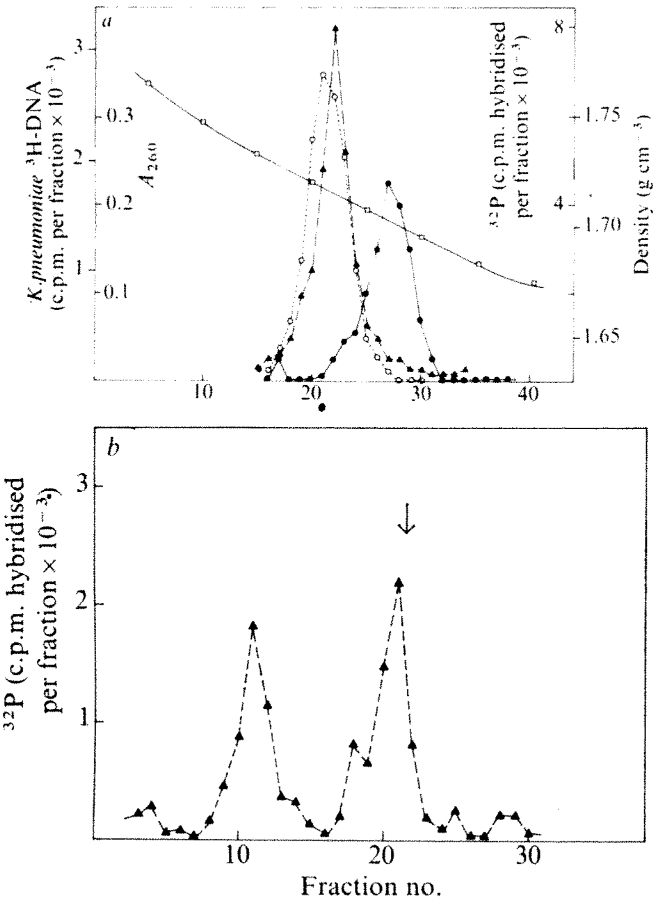

Fig. 1 Separation of EBV DNA and cellular DNA in lysates of nasopharyngeal carcinoma cells. A human tumour (M.M., 1.5 g) growing in a nude mouse was excised, finely minced with a pair of scissors in 6 ml of 0.15 M NaCl–0.01 M Tris-HCl–0.001 M $MgCl_2$–0.0005 M $CaCl_2$ (*p*H 7.2) at 0 °C, and the cells were disintegrated by twenty strokes in a Teflon-glass hand homogeniser. Six ml of 3% Sarkosyl–0.075 M Tris-HCl–0.025 M EDTA (*p*H 9.0) were then added, and the viscous lysate was brought to 20 °C. After 40 min, 3 ml of 0.5% Pronase (preincubated for 2 h at 37 °C in 0.05 M Tris-HCl (*p*H 7.5) before use) were added, and the mixture was incubated for 2 h at 37 °C. It was then diluted with 100 ml 0.05 M Tris-HCl (*p*H 8.5), and supplemented with a density marker (*Klebsiella pneumoniae* ^{3}H-DNA, $\rho = 1.717$ g cm^{-3}) and solid CsCl to a final density of 1.714 g cm^{-3}. The material was centrifuged in eight 19-ml aliquots overlayered with paraffin oil in a Spinco 60 Ti rotor at 33,000 r.p.m. for 65 h at 20 °C. The gradients were collected through a large hole in the bottom of the tube with a closed system collection device[16] in 0.4-ml fractions. A gradient profile is shown in *a*. In each fraction, the cellular DNA was determined by A_{260} measurements, the DNA density marker by ^{3}H radioactivity, and EBV DNA sequences by hybridisation of filter-bound DNA with ^{32}P-labelled EBV complementary RNA as described[16]. The density of every fifth fraction was determined by refractometry. ●, A_{260}; ○, *K. pneumoniae* ^{3}H-DNA; ▲, EBV DNA; □, density. High density DNA from a second nasopharyngeal carcinoma (J.G.) was isolated from two gradients of the type shown in frame *a* (fractions 20–23), dialysed against 0.1 M NaCl–0.01 M Tris-HCl (*p*H 8.0)–0.001 M EDTA, concentrated twofold by packing the dialysis bag in dry polyethylene glycol 6000 for 50 min, mixed with a size marker, phage T4 ^{14}C-DNA (0.6 μg, 9,000 c.p.m.), and applied to a 37-ml glycerol gradient (10–30%) containing 1 M NaCl–0.02 M Tris-HCl (*p*H 8.0)–0.001 M EDTA. The DNA was centrifuged in a Spinco SW27 rotor at 25,000 r.p.m. for 220 min at 21 °C, and the centrifuge profile is shown in *b*. 1-ml fractions were collected, the T4 DNA marker (arrow) was localised by radioactivity measurements, and the EBV DNA sequences (▲) by hybridisation with EBV ^{32}P-cRNA. The direction of sedimentation is from right to left.

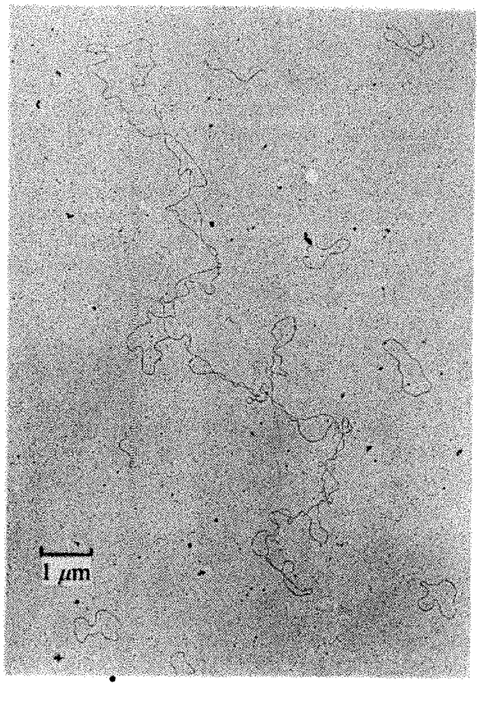
suitable for biochemical work. The tumour cells carrying EBV, however, continue to grow after implantation to congenitally athymic (nude) mice, whereas the infiltrating lymphoid cells disappear[20]. We have used such human tumours growing in nude mice to investigate the intracellular state of EBV DNA in nasopharyngeal carcinoma cells.

The M. M. and J. G. carcinomas contain about 80 and 150 EBV genome equivalents per tumour cell, respectively[20]. Tumour-carrying nude mice were transported from the Houston laboratory to Stockholm. The animals were killed, and the tumours were immediately excised and used for the preparation of high molecular weight DNA. The DNA was then fractionated by CsCl density gradient centrifugation and collected avoiding shearing forces. The EBV DNA sequences were localised by hybridisation of the individual gradient fractions with ^{32}P-labelled EBV complementary RNA. The experimental techniques are the same as those previously used with Raji cells[15–18]. A typical gradient profile is shown in Fig. 1. EBV DNA has a higher guanine–cytosine content than cellular DNA, and most of the virus DNA sequences are separated from the bulk of the cellular DNA and form a peak at a density of 1.716 g cm^{-3}. The EBV DNA peaks from two CsCl gradients were pooled and further fractionated by neutral glycerol gradient centrifugation together with phage T4 ^{14}C-DNA as an internal size marker[21]. Linear EBV DNA from virus particles sediments at 58–59S in these conditions[15,16]. In contrast, the intracellular EBV DNA sequences from the J. G. and M. M. tumours were found as two distinct peaks at about 101S and 64S (Fig. 1). The two forms of intracellular EBV DNA from the nasopharyngeal carcinoma cells sediment at 1.7 and 1.1 times the rate of linear EBV DNA from virus particles, indicating that they correspond to covalently closed circular virus DNA molecules and open circular virus DNA molecules, respectively[22]. The presence of large covalently closed circular DNA molecules was directly confirmed by electron microscopy

Fig. 2 Electron micrograph of a large, covalently closed circular DNA molecule from a nasopharyngeal carcinoma tumour (M.M.). The EBV DNA was partly purified by CsCl density gradient centrifugation and glycerol gradient centrifugation. The DNA sedimenting at 95–110S in the latter type of gradient was pooled and dialysed against 0.05 M NaCl–0.01 M Tris-HCl (*p*H 8.1)–0.005 M EDTA and spread by a modification of the microdiffusion technique avoiding the use of formaldehyde[16,25]. The small DNA circles in the figure are phage PM2 DNA molecules. In order to partially untwist the supercoiled molecules, 4 μg ml^{-1} ethidium bromide was included in the DNA–cytochrome *c* solution. For length measurements, however, only preparations without ethidium bromide were used.



(Fig. 2). Such large DNA circles have previously been found in corresponding fractions from Raji cells, but are not detected in EBV-negative human cell lines[16]. The covalently closed circular DNA molecules from nasopharyngeal carcinoma cells (J. G.) were converted to an open circular form by X-ray treatment, mixed with open circular DNA from phage PM2 (a gift from Dr R. Streeck) as an internal size marker, and used for contour length measurements on electron micrographs[16]. These EBV DNA circles were found to be 16.2–16.3 times larger than PM2 DNA molecules, corresponding to an approximate molecular weight of 104×10^6. In previous measurements on circular EBV DNA from the Burkitt lymphoma derived cell line Raji, the molecules were found to be 16.6 times larger than PM2 DNA[16], and the covalently closed and open circular forms of the virus DNA has sedimentation coefficients of 103–105S and 65S, respectively. Thus, both the contour length measurements and the sedimentation velocity data indicate that the circular EBV DNA in nasopharyngeal carcinoma cells may be slightly smaller than that in Raji cells, suggesting the presence of a different EBV subgroup or a small deletion of the virus DNA in the epithelial cells.

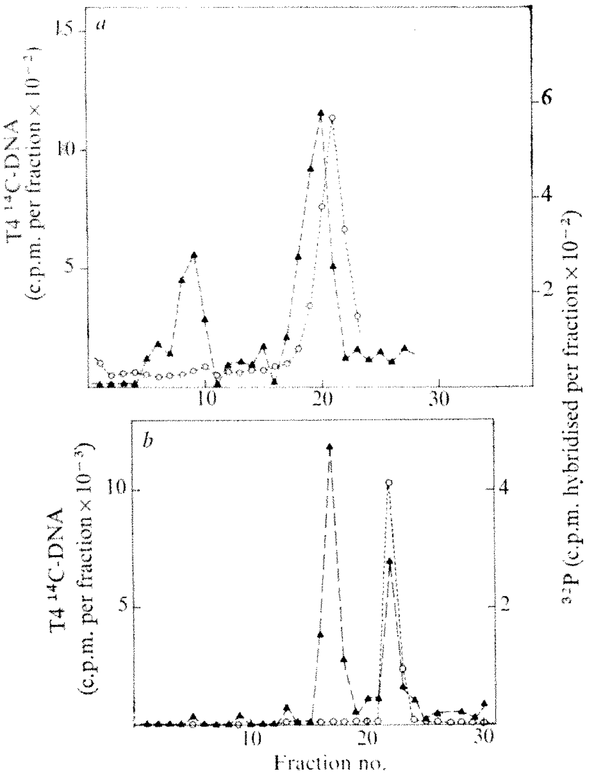


Fig. 3 Fractionation of high density DNA from a Burkitt lymphoma biopsy. The A.O. biopsy (5 g) was minced with scissors, and the material was suspended in ten volumes tissue culture medium by shaking. After 10 min at 21 °C, the material that had settled to the bottom, which consisted largely of stroma, was discarded, and suspended cells were collected by low speed centrifugation and washed in phosphate-buffered saline. The cells (10^7 cells ml^{-1}) were lysed by addition of Sarkosyl–EDTA and Pronase, and the DNA was fractionated by CsCl gradient centrifugation as in Fig. 1*a*. The high density DNA was collected and cosedimented with phage T4 DNA on a glycerol gradient as in Fig. 1*b*. The results from the latter gradient are shown in frame *a*. ▲, EBV DNA, as determined by hybridisation with EBV cRNA; ○, T4 DNA. The fractions 25–31 contained the density marker DNA from the CsCl purification step. The 105S DNA from one neutral glycerol gradient was recovered, mixed with linear ^{14}C-DNA (from phage T4), and dialysed against 1 M NaCl–0.02 M Tris-HCl (*p*H 8.0)–0.001 M EDTA for 20 h, followed by 0.05 M NaCl–0.02 M Tris-HCl (*p*H 8.0)–0.001 M EDTA for 3 h. The material was concentrated two- to threefold by packing the dialysis bag in dry polyethylene glycol 6000 for 1 h, followed by an additional 3-h dialysis against the last buffer. The DNA sample (2.2 ml) was then supplemented with 0.2 ml 0.6% propidium diiodide in 0.01 M Tris-HCl (*p*H 8.0) and 2.25 g solid CsCl. Centrifugation was carried out in a 5-ml tube overlayered with paraffin oil in a Spinco SW 50.1 rotor at 40,000 r.p.m. for 48 h at 21 °C. Fractions (0.1 ml) were collected from the bottom of the tube, and the fractions were freed from the dye by four extractions with two volumes of 90% isopropanol. Data are shown in frame *b*. ○, T4 DNA; ▲, EBV DNA, as determined by hybridisation with EBV cRNA.

Circular EBV DNA in Burkitt lymphoma biopsies

Burkitt lymphoma patients were treated by tumour excision in Nairobi. Tumour material was transported on ice to Stockholm, and was available for experimentation about 24 h after excision. Burkitt lymphoma biopsies are more homogeneous than nasopharyngeal carcinoma biopsies, and occasionally large specimens with a high proportion of living tumour cells (>80%) became available. Two such tumours were investigated, an ovary tumour from a 9-yr-old girl (A.O.) and a tumour excised from the submandibular region of a 4-yr-old boy (W.J.).

High molecular weight DNA was extracted from the Burkitt lymphoma cells and fractionated on CsCl gradients and neutral glycerol gradients. The results were quite similar to those obtained with the nasopharyngeal carcinoma cells. With material from one of the biopsies (A.O.), two distinct peaks of EBV DNA at 105S and 65S were observed by hybridisation of the glycerol gradient fractions with EBV complementary RNA (cRNA) (Fig. 3), representing covalently closed circular EBV DNA and open circular EBV DNA. In the other biopsy, a single peak of 65S EBV DNA was found, corresponding to open circular DNA. The apparent absence of covalently closed circular EBV DNA in the latter case may have been due to the introduction of single-strand breaks into the viral DNA after tumour excision, either during the transport to Stockholm or during the preparation of the lysate from the tumour.

The 105S and 65S EBV DNA fractions from the A.O. biopsy were further characterised by equilibrium density gradient centrifugation in propidium diiodide–CsCl gradients. Covalently closed circular duplex DNA has a higher density in such gradients than open circular or linear DNA[23]. Most of the EBV DNA (70%) from the 105S region banded as a distinct peak at a position typical of covalently closed circular DNA (Fig. 3), as estimated from parallel control experiments with polyoma virus DNA. The rest of the EBV DNA (30%) was found at the position of open circular and linear DNA, and was presumably due to DNA damaged during the preparation procedures. All of the 65S EBV DNA banded as open circular or linear EBV DNA.

Integrated EBV DNA

Part of the EBV DNA sequences present in Raji cells band at an anomalously light density in CsCl gradients. The densities of these viral DNA sequences remain unchanged after treatment with Pronase, sodium dodecyl sulphate, and phenol, but they appear at a heavier density after reduction of the size of the DNA preparations by shearing forces. These data indicate that integrated EBV DNA sequences are present in Raji cells[17,18]. A similar experimental approach has now been used with the tumour biopsy material studied here. In the nasopharyngeal carcinoma DNA shown in Fig. 1*a*, a small part of the total EBV DNA sequences is present under the peak of cellular DNA. To remove EBV DNA tailing into the low density region, this DNA (fractions 26–29 in Fig. 1*a*) was rebanded on a second CsCl gradient. The DNA banding at a density of 1.698–

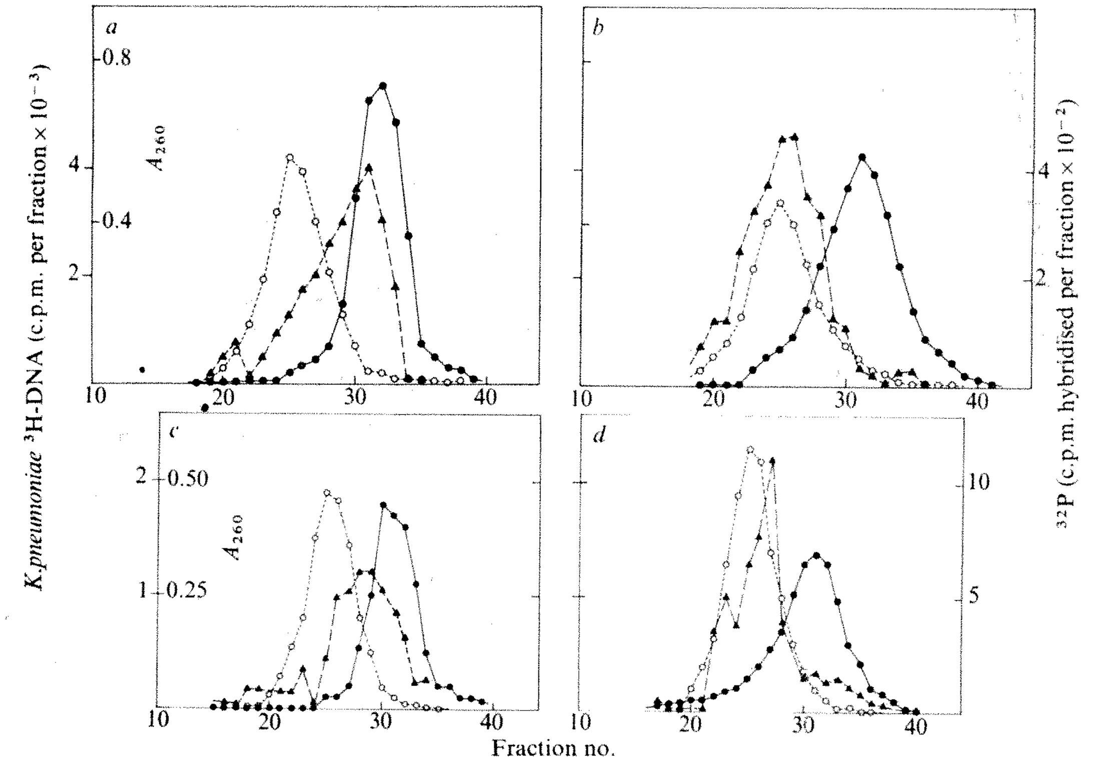

Fig. 4 Third sequential fractionation by CsCl gradient centrifugation of cellular density DNA from tumour cells. For studies on nasopharyngeal carcinoma cells, fractions 26–29 in Fig. 1*a* were rebanded in CsCl in the same experimental conditions, and the main peak of A_{260} absorbing material from the second gradient was pooled, mixed with a density marker (*K. pneumoniae* ³H-DNA), and divided in two parts. One part was sheared by three rapid passages through a No. 25 hypodermic syringe needle. The two DNA solutions were individually rebanded in CsCl in the same experimental conditions. *a*, Unsheared DNA; *b*, Sheared DNA. ●, A_{260}; ○, *K. pneumoniae* ³H-DNA; ▲, EBV DNA sequences determined by hybridisation with EBV ³²P-cRNA. The same experimental design was used with Burkitt lymphoma biopsy cells, and the data obtained with the A.O. biopsy are shown in frames *c* and *d*. After purification of cellular density DNA by two consecutive CsCl gradient centrifugation steps, the material was divided in two parts, and the size of the DNA of one part was reduced twentyfold by shearing before rebanding and hybridisation. *c*, Unsheared DNA, and *d*, sheared DNA. Symbols as in *a* and *b*.

1.708 g cm^{-3} in this gradient was supplemented with a density marker (*Klebsiella pneumoniae* ³H-DNA) and divided in two equal parts. One part was again centrifuged to equilibrium in neutral CsCi. Most of the remaining EBV DNA sequences in this DNA fraction now banded at a peak density of about 1.704 g cm^{-3}, but some EBV DNA sequences of heavier densities were still present (Fig. 4*a*). The other part of the material was reduced in size by shear treatment, and then banded in CsCl in the same conditions. In this case, the EBV DNA sequences were released to heavier densities. (Fig. 4*b*). This is the expected result if large DNA molecules containing both EBV DNA sequences and cellular DNA sequences had been fragmented by the shear treatment.

The DNA preparations from the two Burkitt lymphoma biopsies were also studied by the same techniques, and the results were essentially identical to those obtained with the nasopharyngeal carcinoma material. With both biopsies, a low density fraction of EBV DNA sequences could be isolated by three consecutive bandings in CsCl, and these viral DNA sequences were shifted to heavier densities by reduction of the size of the DNA. The data obtained with one of the biopsies (A.O.) are shown in Fig. 4. It is clear that this type of low density EBV DNA, which was first detected in lymphoid cell lines and presumably consists of integrated sequences of virus DNA, is present also in tumour biopsies of Burkitt lymphoma and nasopharyngeal carcinoma origin. Thus, the integrated viral sequences can not be ascribed to chromosome translocation events or other artefacts of long term *in vitro* culture.

Episomal state of latent EBV

In bacteria, sex factors and certain prophages can be carried both in an integrated state and as stable extrachromosomal elements in the form of circular DNA molecules. The discovery of circular EBV DNA molecules in virus-transformed human cells, free from virus particles, strongly indicates that episomes also occur among mammalian cells. Little information is available at present on the carrier states of other large animal viruses, and it seems possible that all herpesviruses may be carried as episomes during latency. The relationship between the non-integrated EBV DNA circles and the integrated EBV DNA sequences found in transformed cells remains a subject for future study.

In addition to the investigations on tumour cells, we have recently shown (to be published) that circular EBV DNA molecules are also found in EBV DNA-carrying lymphoblastoid cell lines derived from normal individuals and from infectious mononucleosis patients. A lymphoblastoid cell line derived from a normal individual also contained EBV DNA sequences with the properties of integrated DNA. No clear difference has so far been observed between the carrier state of EBV in cell lines from normal individuals and in tumour cells. A simple model in which either integrated EBV DNA sequences or circular EBV DNA molecules would only be found in tumour cells is not in agreement with the available data. It should be noted, however, that EBV-carrying lymphoblastoid cell lines derived from human blood of healthy donors have malignant potential, as they cause tumours on implantation in nude mice[24].

This investigation was supported by the US National Cancer Institute, the Swedish Cancer Society, the Swedish Natural Science Research Council, and the Stehlin Foundation for Cancer Research. The electron microscope was purchased with grants from the Swedish Work Environment Fund and the Trustees of the Knut and Alice

Wallenberg Foundation. C. K.-D. was the recipient of a fellowship from the Deutsche Forschungsgemeinschaft. G.W.B. had a short term fellowship from EMBO and is supported by the Deutsche Forschungsgemeinschaft.

New H_2O celestial sources associated with H II regions in the Southern Hemisphere

We report here the first results of a nearly complete, high-sensitivity, water vapour survey of galactic H II regions situated in the Southern Hemisphere.

A typical upper limit of about 40 Jy (1 Jy $= 10^{-26}$ W m^{-2} Hz^{-1}) was attained at the $6_{16} \rightarrow 5_{23}$ rotational transition line of the water vapour molecule (that is, a frequency of 22,235.08 MHz).

A new ruby travelling wave K-band maser receiver[1] was used at the 13.7-m Itapetinga radio telescope[2], Atibaia, São Paulo, Brazil, between November 4 and 8, 1975. The Dicke-switched system temperature was typically 350 K, including radome contribution (less than 10 K)[3] and sky contribution (less than 100 K during this season)[3]. The back-end section of the receiver consisted of a 43-channel spectrograph with 100-kHz filters. Observations were made using a combined beamswitching and 'on–on' technique.

The 13.7-m Itapetinga radio telescope has an absolute pointing accuracy better than 15″ arc, which is negligible in comparison with its 4.5′ arc beamwidth at that frequency. The aperture efficiency was redetermined using Virgo A (assuming 21.4 Jy)[4] and Venus (brightness temperature of 420 K)[5] as calibrators, and was found to be 34.5 Jy K^{-1} (that is, 54% efficiency).

Observations were carried out during the worst season for millimetric work at Itapetinga. Frequent measurements of atmospheric absorption were necessary. Optical depths were determined using the sky emission method[3], and ranged from 2.61 to 4.34 dB. All measurements were corrected for atmospheric and radome absorption, the latter being 23% at 33.2 GHz.

The most complete published surveys of new H_2O celestial sources in the Southern Hemisphere are those by Johnston *et al.*[6], and by Caswell *et al.*[7]. They reported sources having fluxes larger than or equal to about 200 Jy.

We examined all 47 of the individual H II regions with 5 GHz continuum peak brightness levels of 5 K or more, as reported by Goss and Shaver[8], and all 24 regions for which OH main-line emission has been found[9-16].

Observations were made at reported positions (Table 1), and no attempt was made to find improved H_2O positions.

Thirteen new H_2O celestial masers were found (Table 1). The spectrograph was centred at the velocities of associated OH lines, when known, otherwise at H109α recombination lines[12]. The search width for each observation was in general ± 29 km s^{-1}.

Of the sources associated with OH emission, all except H_2O 0.55−0.85 had previously been examined[6,7] for H_2O emission. It is generally accepted that sources having OH main-line emission are also likely to show H_2O emission[13]. In Fig. 1*a* we show the spectrum for the strongest source discovered in this class. Another interesting H_2O source, with three line components, is H_2O 0.55−0.85. This has been identified with RCW142 (Fig. 1*b*), a dense molecular cloud near the galactic centre[11].

The seven new H_2O sources associated with H II regions that do not exhibit OH emission, suggest the existence of a new class of celestial water vapour masers. Figure 1*c* shows the spectrum of H_2O 316.8−0.1, the most intense source found in that class during our survey. Another interesting member of that class of sources is H_2O 291.7−0.7 (Fig. 1*d*). At least one strong emission line can be observed at −32.8 km s^{-1}, with an intensity of 159 Jy superimposed on a 1.8-K continuum level. That source, and H_2O 267.9−1.1 (identified with RCW38), are known to be associated with compact protostellar

Fig. 1 *a*, H_2O 345.5+0.3, the strongest source found in association with OH main-line emission (spectrum is average of three 6-min runs); *b*, spectrum of H_2O 0.55–0.85 (RCW142), (integration time, 6 min); *c*, H_2O 216.8–0.1, the strongest source not associated with OH main-line emission (spectrum is average of two 6-min runs); *d*, H_2O 291.3–0.7, associated with the extended H II region RCW57, which contributes the 1.8-K continuum level (spectrum is the average of four 6-min runs).

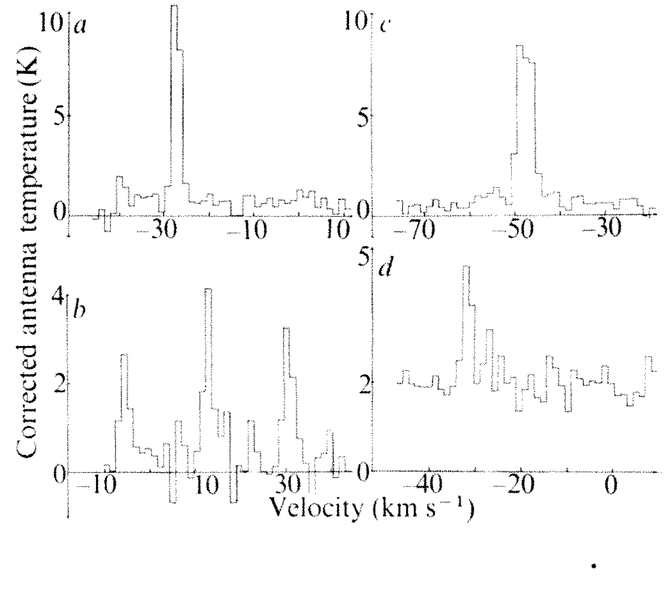

Table 1 New H_2O celestial masers in Southern Hemisphere H II regions

Galactic coordinates	H_2O line peak intensity in Jy (November 1975)	Radial velocity at peak intensity (km s^{-1} in relation to LSR)	Reference for p positions	Comments
Sources associated with OH main-line emission				
0.55−0.85	128	+11.6	11	RCW142. One 6-min run, centred at +13 km s^{-1}.
330.0−0.4	45	−67.2	9	Three 6-min runs, centred at −60 km s^{-1}.
333.2−0.1	59	−84.6	10	Two 6-min runs, centred at −90 km s^{-1}.
338.9+0.6	127	−76.3	9	Two 6-min runs, centred at −60 km s^{-1}, and −75 km s^{-1}.
345.5+0.3	359	−28.1	9	Three 6 min runs, centred at −20 km s^{-1}. See Fig. 1.
347.6+0.2	49	−83.8	9	Two 6-min runs, centred at −100 km s^{-1}. Another possible weaker line at −94.6 km s^{-1}.
Sources at regions that do not exhibit OH main-line emission				
267.9−1.1	171	− 6.1	8	RCW38. One 6-min run, centred at +2 km s^{-1}.
291.3−0.7	159	−32.8	8	Four 6-min runs, centred at −22 km s^{-1}. See Fig. 1*d*.
305.3+0.2	79	−42.7	8	Three 6-min runs, centred at −40 km s^{-1}. Another possible 53 Jy, line at −40 km s^{-1}.
316.8−0.1	290	−48.6	8	Two 6-min runs, centred at −50 km s^{-1}. See Fig. 1*c*.
326.7−0.6	70	−41.3	8	Three 6-min runs, centred at −20 km s^{-1}; two 6-min runs, centred at +5.2 km s^{-1}. Other lines at −7.0 km s^{-1} (60 Jy), −13 km s^{-1} (66 Jy), and −62 km s^{-1} (61 Jy).
332.7−0.6	58	−47.3	8	Two 6-min runs, centred at −50 km s^{-1}.
348.7−1.0	155	−12.7	8	Two 6-min runs, centred at −10 km s^{-1}. Another possbile 65 Jy line at −31.6 km s^{-1}.

infrared objects[14]. Another source found, tentatively designated as H_2O 333.0—0.4, and showing a 64-Jy line at −51.3 km s^{-1}, is possibly a confusion with a known nearby water vapour source, H_2O 333.2−0.5, which has OH main-line emission[7].

Our results are preliminary, and a detailed report is in preparation. We acknowledge technical assistance by V. Saraceni, R. Hadano and M. Shimabukuro, at Itapetinga, and by R. Erickson, N. Lariviere and S. Murray at the Haystack Observatory, Westford, Massachusetts. We also acknowledge the assistance of the Department of Physics of Campinas State University, Campinas, Brazil, for the liquefaction of helium and associated technical help needed to support the maser receiver. This research programme received support from Brazilian research agency Conselho Nacional de Desenvolvimento Cientifico e Tecnológico (CNPq) and in the US from the National Science Foundation (NSF), through a bilateral scientific agreement.

Observations of Cyg X-1 from Aryabhata

ARYABHATA, India's first artificial satellite, which was launched into a near circular orbit of 600 km altitude at an inclination of 51° on April 19, 1975, carried instruments to investigate celestial X rays in the energy range 2.5–155 keV. We report here observations of Cyg X-1 made in the range 2.5–18.75 keV, during the second orbit of the satellite, centred around 108 d 9 h 17 min 40 s UT, just before the source made a major increase in its intensity. We found a hardening in the spectrum.

We investigated this energy range with a proportional counter telescope filled with a mixture of Ar, CO_2 and He in the pressure ratio of 90:9.5:0.5 to a total pressure of 1 atm. The counter, which had a 2.5 0.0025-inch Be entrance window and an effective area of 15.4 cm^2, was fitted with cylindrical aluminium collimators for restricting the field of view to 12.5° FWHM. This telescope was mounted with its viewing direction along the spin axis of the satellite so that it could be oriented stably and operated in the pointed mode. The sighting on Cyg X-1 was made possible before the spacecraft was spin stabilised and during the time when it was performing an extremely slow spin around an axis different from the actual spin axis.

The counting rates were monitored in four energy channels: 2.5–5.4 keV, 5.4–9.8 keV, 9.8–13.8 keV and 13.8–18.75 keV, thus enabling the spectral determination of the source. Background rates were evaluated from the study of the counting rate profile as a function of time as well as their known dependence on the geographical latitude of the satellite. The attitude of the X-ray detector in space was computed using the outputs from magnetometers and Sun sensors mounted on the satellite. The excess rates corresponding to Cyg X-1 were corrected for the offset angle of the telescopic axis with respect to the

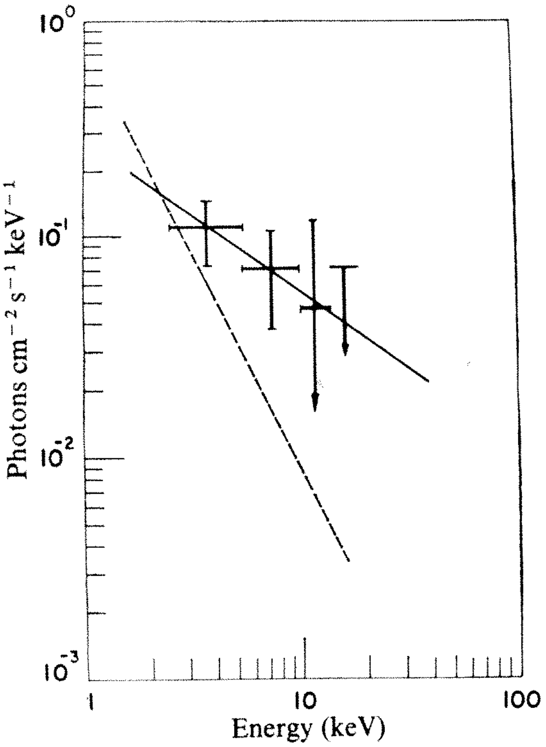

Fig. 1 The spectrum of Cyg X-1, as observed on 108 d 9 h 17 min 40 s UT (April 19, 1975), before the intensity increase. The dotted line gives the spectrum observed by Ariel V on May 13, 1975.

source direction and for the efficiency of the counter as a function of energy. The photon spectral distribution so derived is shown in Fig. 1. The spectrum shows a power law dependence with an index of ~ 0.7±0.2 in the energy interval of 2.5–13.8 keV, the estimated intensity being 0.84±0.3 photon cm^{-2} s^{-1} at the time of observation.

Cyg X-1 underwent a major upward transition in its intensity during late April 1975, as revealed by the detectors on the Ariel and ANS satellite[1-3]. This intensity transition seems to be the reverse of the one observed by Uhuru[4] in April 1971. A distinct feature of these intensity transitions is the accompanying spectral change[3], with the spectral exponent changing from the value of 1.6 observed during the normal state to 2.2 in the 'high' state. The all-sky camera on Ariel V (ref. 2) seems to place the occurrence of the intensity transition around the latter half of April 22, 1975 based on long term intensity monitoring fo this source in the 3–6-keV energy range from November 1974 to May 1975. The results presented here complement the results of the all-sky camera by providing definitive spectral information, for the first time, just before the transition. Thus, together with Ariel observations, it is now possible to examine the physical state of this X-ray source just before and just after this low–high transition. Whereas the intensity from Cyg X-1 registered by our detector in the 3–6 keV range (~ 0.3±0.1 photon cm^{-2} s^{-1}) is comparable with that of all-sky camera (~ 0.4±0.1 photon cm^{-2} s^{-1}), the spectrum observed by us is harder than the typical one for this source, even in its normal state. For purposes of comparison, the spectral nature of the source after the upward intensity transition as observed by Ariel V (ref. 3) is also shown in Fig. 1. It is, however, to be noted that the spectral hardening of this type with time scales of the order of minutes has been reported[1] previously also for Cyg X-1 in its normal state. Whether such spectral hardening forms a prelude to the transition of the source or is a property of its short term fluctuations, not necessarily related to the transition, needs further investigation.

Cyg X-1 is an interesting and complex X-ray source, probably in a binary system, where X-ray emission takes place during the mass transfer from the OB supergiant to a compact companion. This source is known to exhibit intensity variations with time scales of the order of milliseconds, minutes and even days[5,6]. Flare-like enhancements[7], sudden intensity transitions[4] and intensity dips around superior conjunction of the spectroscopic binary have also been observed.

Attempts have been made to understand the intensity transition in Cyg X-1 in terms of the variable mass accretion from the OB supergiant by the compact companion[8] and the possible instabilities in the accretion disk[9]. Dips in intensity observed in association with the superior conjunction of the binary[10], resulting in spectral hardening, can arise from discrete absorption features such as gas streams of localised character[11]. Such features can also explain short term hardening of the spectrum of the type reported here. A single self-consistent explanation that can account for all the emission characteristics of Cyg X-1 has, however, yet to emerge.

This work was supported by the Department of Space, Government of India. The launching of the Indian satellite Aryabhata was made possible through joint cooperation between the Indian Space Research Organisation and the Academy of Sciences, USSR.

Intrusions and double-diffusive convection

A STRATIFIED fluid layer in which two components contribute to the vertical density distribution need not be stable even though the net density decreases upwards. If one of the components is unstably distributed, then molecular diffusion can release its potential energy—a phenomenon known as double-diffusion convection[1]. Considerable progress has been made over the past 10 years in the study of double-diffusive convection in situations where the properties vary in one direction (vertically) only. In the ocean, horizontal advection is nearly always important and its neglect in the previous laboratory experiments makes it difficult to apply the results in a wider context. A first step in the study of two-dimensional effects in double-diffusive convection was made by Turner and Chen[2], and here I follow up one of their suggestions in detail in the hope that it may help to understand the layering which occurs when an outflow intrudes into an ambient fluid with the same density but different component concentrations[3].

Convection (when driven by double-diffusive processes) occurs in well mixed layers separated by comparatively thin regions of high density gradients, called interfaces. The interface can take either of two forms depending on whether the potential energy, which drives the motion, is provided by the component of higher or lower diffusivity. In the former case a 'diffusive' interface is formed; in the latter case a 'finger' interface[1]. Layering that can be asso-

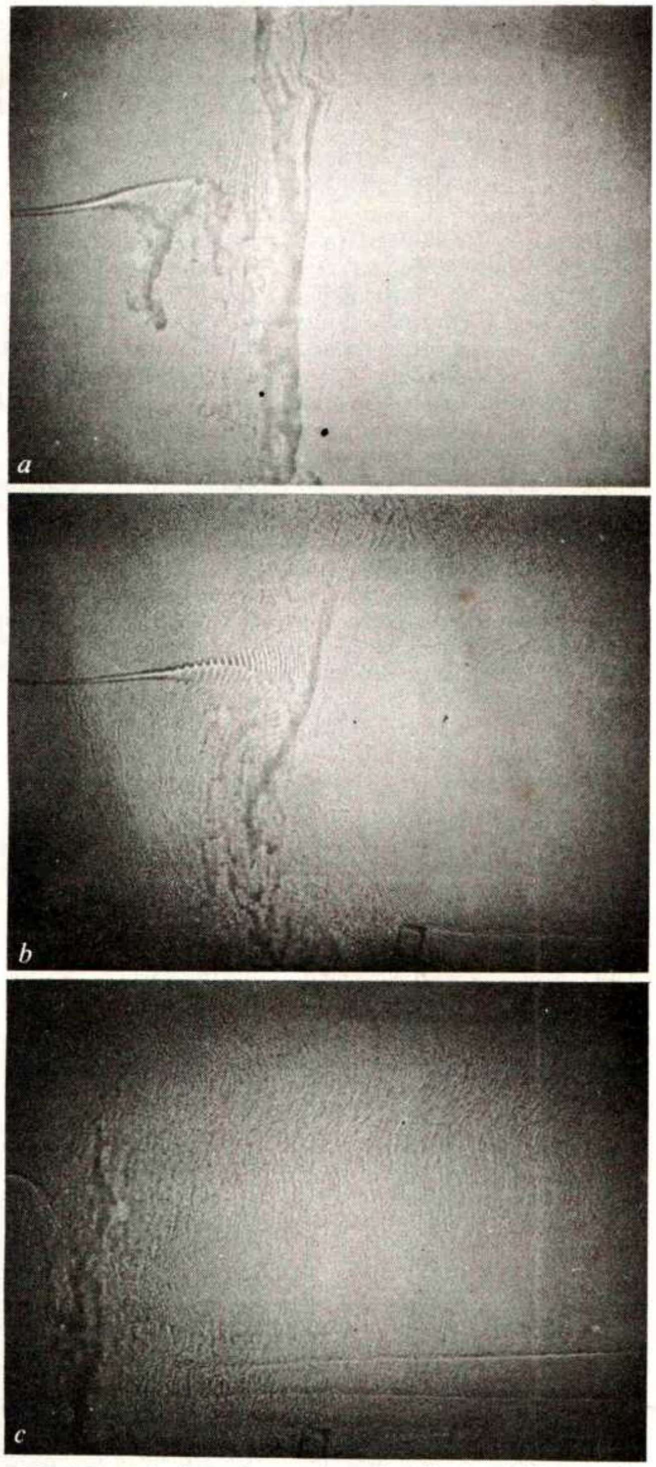

Fig. 1 The behaviour of a sugar intrusion (density, 1.180 g cm^{-3}) into a salt solution (same density): *a*, after 30 s; *b*, after 1 h; *c*, after 2 h.

ciated with both types of double-diffusive processes has now been observed in the ocean.

The experiments were performed in a transparent tank 98 cm long, 29 cm deep and 15 cm wide. The flow was observed using the shadowgraph technique. A small source (internal diameter 1 mm) was located at one end of the tank at mid-depth and the fluid was released in an approximately horizontal direction. Some preliminary experiments were performed in which a salt solution was released into an homogeneous salt solution of the same density (1.180 g cm^{-3}). The flow rate was adjusted so that the motion remained laminar. The released fluid was found to propagate smoothly across the tank with very little mixing. The same flow rate was used in all subsequent experiments.

Two types of experiment were performed, and because of their similarity only one is described in detail here. In the first type of experiment the tank was filled with an initially homogeneous salt solution with a density of 1.180 g cm^{-3}, and a sugar solution was released. The density of the sugar solution was adjusted until it too was 1.180 g cm^{-3}, and then minute adjustments were made so that when released into the salt solution it initially moved horizontally. The sugar solution was left flowing for periods of up to 3 h.

Figure 1*a* shows the behaviour of the plume after 30 s. The downward motion on the left hand side of the main vertical motions was caused by unsteadiness in turning on the intrusion. The plume becomes denser (because the diffusivity of salt is greater than that of sugar) and sinks. The immediate surroundings become less dense as they lose more salt than they gain sugar, so they rise. Thus vertical motions are generated in both upward and downward directions, thus stratifying the tank. Figure 1*b* was taken after 1 h. A diffusive interface can be seen near the bottom of the tank, and fingers can be seen growing from the top of the tank. The downward plume comprises sugar with a little salt, and as it is denser than the ambient fluid it spreads out along the base of the tank. Thus, near the base the salt gradient is destabilising, and as it is the component with greater diffusivity, a diffusive interface is formed.

The upward plume carries a reduced amount of salt (in comparison with the ambient concentration) and a little sugar. This plume spreads out on the surface. The sugar has a destabilising effect, and fingers are formed near the surface. The regular vertical striations which can be seen on the upper edge of the plume near the bending point were stationary and had the appearance of crests in a standing wave pattern. They are also evident in Figs 1*a* and 2*a*. Figure 1*c* was taken after 2 h and shows the final stage in the experiment. There is now extensive fingering in the upper half of the tank and several diffusive interfaces in the lower half. These double-diffusive processes will further stratify the fluid.

Thus, strong vertical motions are generated, carrying excess sugar to the surface ('excess' in this context means a more concentrated solution than that immediately below the surface), and reduced salt to the base of the tank. These concentration profiles provide available sources of potential energy which drive the double-diffusive processes. The vertical motions stratify the fluid and the double-diffusive processes further stratify it.

In the second type of experiment a salt solution, with a density of 1.180 g cm^{-3}, was released into a sugar solution of the same density. Again, strong vertical motions were generated; however, this time the released solution rose carrying an excess of salt to the surface, and the downward plume carried a reduced sugar concentration to the base. These concentration profiles produced diffusive interfaces at the surface of the tank, and fingers at its base. These features are illustrated in Fig. 2*a* which was taken after 1 min, and in Fig. 2*b* which was taken 2 min after the experiment ended (about 2 h after Fig. 2*a*).

The Mediterranean outflow consists of hot salty water which intrudes at its own density level into the cooler, less salty Atlantic Ocean, forming a salinity maximum at 1,200 m. Layering consistent with the finger process has been found beneath the Mediterranean outflow[3] and layering stratified in the opposite sense has been found above it. Williams[4], using a sophisticated optical system has photographed salt fingers below the Mediterranean outflow, thus increasing confidence in the double-diffusive explanation of the layering. In the Mediterranean outflow the sites for the initiation of double-diffusive convection occur at the upper and lower interfaces of the intruding wedge of hot salty water. At the upper boundary, heat is the destabilising

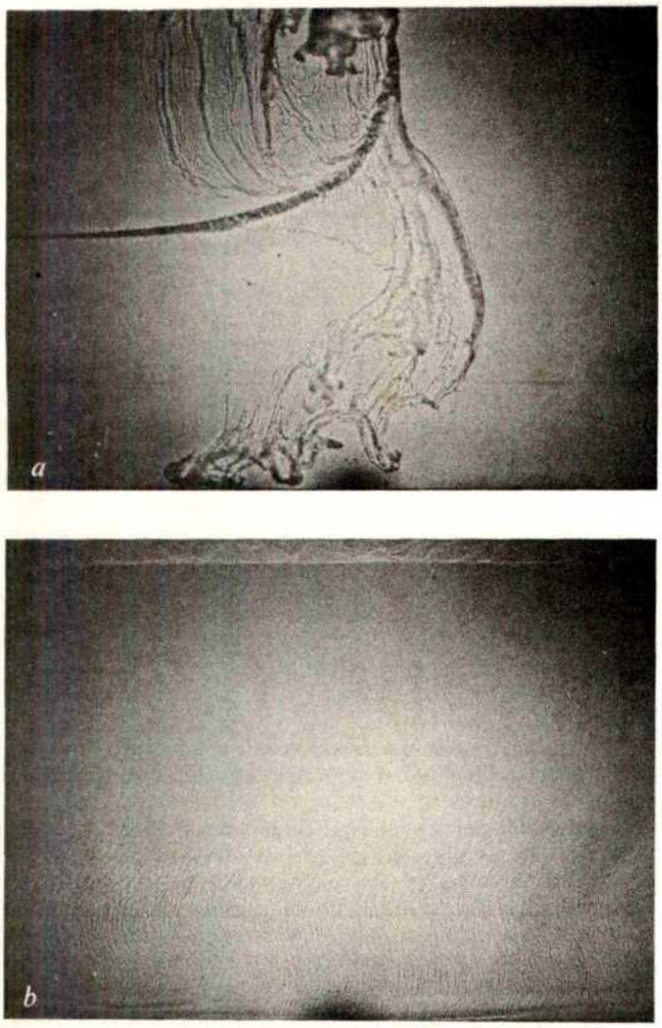

Fig. 2 The behaviour of a salt intrusion (density, 1.180 g cm^{-3}) into a sugar solution (same density): *a*, after 1 min; *b*, 2 min after end of experiment.

component giving diffusive interfaces, and at the lower boundary, salt is the destabilising component giving fingers. In the laboratory, the vertical plumes produce the destabilising gradients at the upper and lower boundaries of the tank. The oceanic situation could be modelled more accurately by using a two-component solution (initially homogeneous, then with both gradients stabilising, and finally with either gradient destabilising) and a two-component intrusion with different concentrations but the same density as at the release depth.

New Zealand temperatures since 1300 AD

THE period 1900–1935 was the coldest in New Zealand in recorded history. A climatic amelioration was experienced throughout the whole country between 1935 and 1970, with temperatures climbing by 1 °C over those years[1]. It is interesting to examine recent glacial behaviour in the light of these facts.

New Zealand west coast glaciers, such as the Fox and Franz Josef glaciers, are fast moving because of their steep gradients; they are also nourished by high precipitation rates. As a result, they respond rapidly to climatic fluctuations; however, glaciers are complex systems, so conclusions regarding climatic events must be treated cautiously. The west coast glaciers examined here descend to low altitudes (300 m) and flow rapidly, so the position of their terminal faces can be used as climatic indicators.

The recent glacial retreat shows a good relationship with running means of Christchurch mean annual temperatures, allowing for a few years' lag in the response time of the glacier (Fig. 1). Hokitika precipitation has a high correlation with Franz Josef precipitation[2]. There seems, however, to be little correlation with recent glacial movements. It seems that the west coast glaciers are not in equilibrium with the present warmer climatic regime and that they are responding by retreating rapidly. The better agreement with temperatures validates the use here of the position of the terminal face and past terminal moraines as indicators of palaeotemperatures.

A glacial advance will usually obliterate all terminal moraines in its path. The most advanced terminal moraines of the Franz Josef and Fox glaciers were laid down around 1600 AD. An advance of a greater magnitude occurred at the Franz Josef glacier at 4,730 yr BP. Since 1600 AD, a minor retreat occurred up to 1800, after which the rate of retreat was moderate; since 1934 it has been rapid (Fig. 2 and ref. 3).

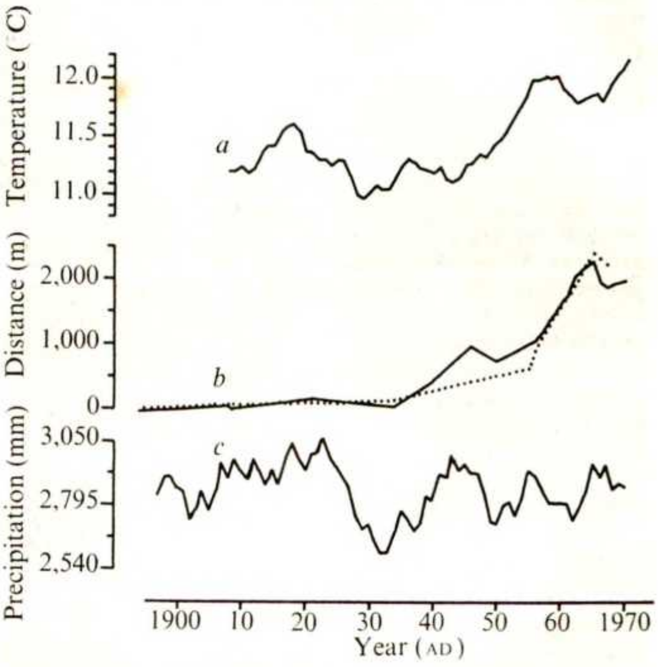

Fig. 1 Comparison of recent New Zealand west coast glacial behaviour with climatic parameters: *a*, seven-year running means of mean annual temperature at Christchurch; *b*, fluctuations of the terminal faces of the two west coast glaciers (—, Franz Josef; · · · Fox); *c*, seven-year running means of Hokitika annual precipitation.

During the period 1600–1800, the glaciers were much more advanced than at present and were also apparently in equilibrium, which indicates a climate much cooler than at present. The shrinkage of the terminal faces since 1800 suggests a climatic amelioration, and the recent rapid wasting correlates well with the recent rapid climatic warming experienced in New Zealand.

Evidence of temperature changes before 1600 AD have to be gleaned from other palaeoindicators. Wardle notes a regeneration gap occurring in New Zealand gymnosperms between 1300 and 1900 AD, with the gap being most accentuated between 1600 and 1800 AD (ref. 4). Holloway, however, postulated a climatic deterioration around 1300 to explain anomalies

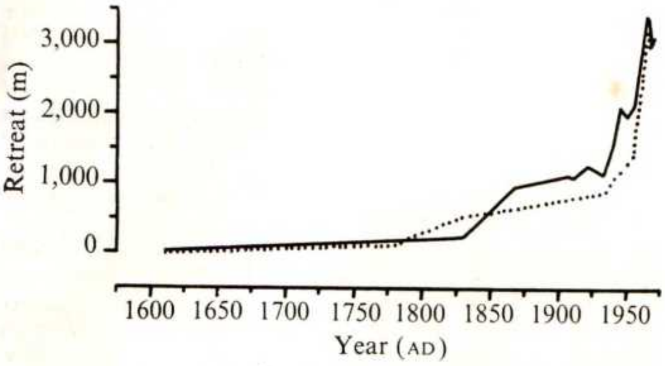

Fig. 2 Retreat of the terminal faces of the Franz Josef (—) and Fox (. . .) glaciers from their most advanced positions in the last millennium.

in the age structure of certain indigenous conifer stands on the South Island[5]. Molloy has suggested that cultural factors such as fire could have contributed to these anomalies[6]. Both Wardle and Holloway have examined forests in areas of dependable precipitation. With the coincidence between these ecological indicators and west coast glacial chronology[7], non-climatic explanations seem untenable. Thus, it seems that New Zealand experienced a climatic deterioration starting around 1300 AD. Being most severe between 1600 and 1800, it correlates well with the Little Ice Age of the Northern Hemisphere[8]. Since 1800, a slow warming has occurred, culminating in the rapid, 1 °C warming of the past 40 yr.

New Zealand palaeotemperatures seem to be similar to those of Northern Hemisphere[9] areas except during the present century, but some doubt must remain since dating was not accurate before temperature records were kept. Divergence between Northern Hemisphere and Southern Hemisphere temperatures may be a phenomenon of the past 50 yr. This assumes that New Zealand trends mimic those covering a wider area of the Southern Hemisphere. Evidence from south-eastern Australia (M. J. Coughlan, unpublished) Scott Base in Antarctica, Campbell Island, and Orcadas Island near South America at latitude 60°45′S, all demonstrate a temperature rise beginning in the 1940s.

Hydrodynamic instabilities in a lead acid battery

WE demonstrate here the feasibility of the observations of hydrodynamic instabilities in a lead acid battery during the discharge process. We use a system comprising two horizontal electrodes immersed in a transparent cell. The electrodes contain in the charged state porous PbO_2, the 'positive' electrode, and porous Pb, the 'negative' electrode. The electrodes were prepared to commercial standards using common industrial processes.

Hydrodynamic patterns in a transparent medium, with accompanying gradients of specific gravity, can be easily followed using a coherent and monochromatic light source. Specific gravity gradients in liquids are usually accompanied by parallel gradients in the index of refraction. Therefore, phase differences induced in the coherent light on passing through the medium are observed as an amplitude pattern when viewed out of the image plane. This is an interference phenomenon occurring between light waves traversing different optical paths in the medium.

The experiment was performed as follows. Light from a 5,145-Å Argon laser passes through a spatial filter and is then collimated on the $Pb–PbO_2$ transparent cell. The hydrodynamic pattern which occurs between two horizontal electrodes is projected on to a screen and recorded on photographic film. A few examples are shown in Fig. 1. The occurrence of such patterns above a certain current density during the discharge process is predictable from stability considerations. The chemical reaction during the discharge process is

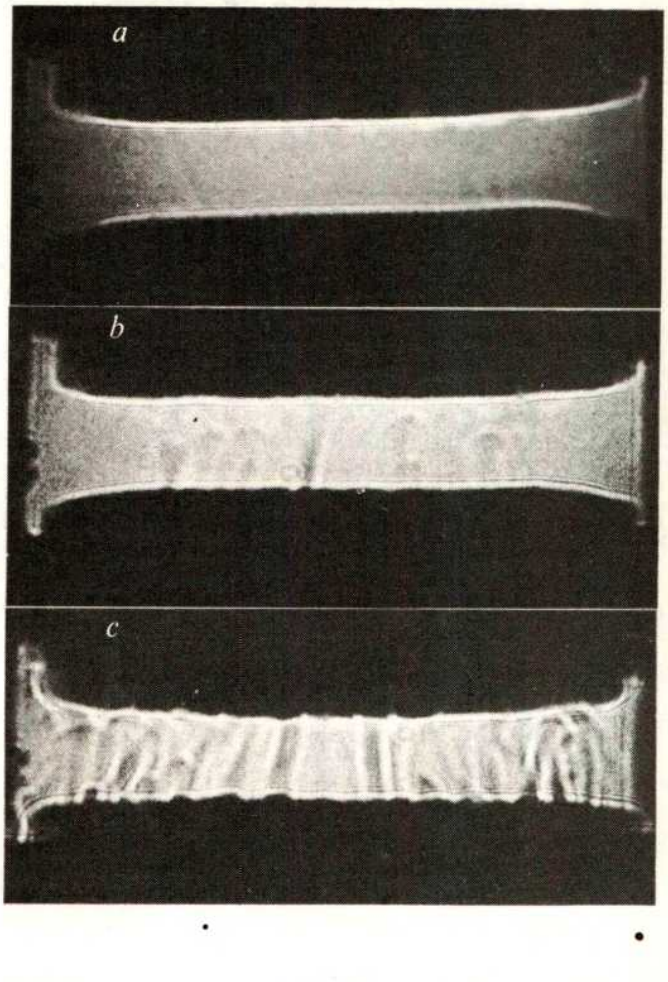
'Positive' electrode: $PbO_2 + 2e + SO_4^{2-} + 4H^+ \rightarrow PbSO_4 + 2H_2O$

(Similar reactions occur with HSO_4^- ions)

'Negative' electrode: $Pb + SO_4^{2-} \rightarrow PbSO_4 + 2e$

The electrodes therefore serve as a sink for the acid and the 'positive' electrode is a source of water. In a horizontal set-up of the electrodes at low enough currents, a steady-state profile of acid concentration, and, therefore, of density will be established. This profile is shown schematically in Fig. 2. To a first approximation a low acid concentration is established at the

Fig. 1 Hydrodynamic patterns between electrodes: *a*, $i = 0$ A cm^{-2}; *b*, $i = 6 \times 10^{-3}$ A cm^{-2}; *c*, $i = 30 \times 10^{-3}$ A cm^{-2}. All experiments performed at 25 °C.



electrodes' surfaces, and a maximum concentration is established somewhere in the electrode gap.

This distribution of density in the y direction can be sustained up to a certain gradient for a given cell geometry. The maximum current density which develops at the maximal gradient is easily calculated from the expression

$$i_{\max} = 2eD(\nabla C)_{\max}$$

where e is the elementary charge and D is the diffusion coefficient for H_2SO_4 aqueous solution. Thus, for example, with an electrode gap of 1 cm; ($y = 1$ cm) and a 1.2 g cm^{-3} acid (27% by weight), we have

$$(\nabla C)_{\max} \simeq \frac{\text{Number of carriers}}{y_0/2}$$

$$= \frac{(\text{Weight \% } H_2SO_4) \times (\text{Avogadro number})}{(\text{Molecular weight of } H_2SO_4) \times (y_0/2)}$$

$$= 3.3 \times 10^{21} \text{ carriers per cm}^2$$

$$D_{\rho=1.2} = 1.34 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$$

Therefore

$$i_{\max} = 14 \times 10^{-3} \text{ A cm}^{-2}$$

This estimation of $i_{\max}$ is really an upper limit since the y gradient of water generates a flow opposing the above current.

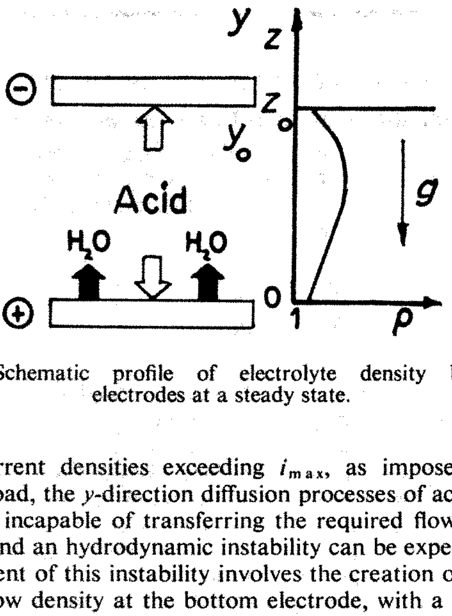


Fig. 2 Schematic profile of electrolyte density between electrodes at a steady state.

For current densities exceeding $i_{\max}$, as imposed by an external load, the y-direction diffusion processes of acid and of water are incapable of transferring the required flow rates of carriers, and an hydrodynamic instability can be expected. The development of this instability involves the creation of a water layer of low density at the bottom electrode, with a region of high density on top of it. In a gravitational field this inverted distribution of densities is discharged into patterns of ascending water and descending acid (Fig. 1).

Experimentally, an instability occurs at ~5 mA cm^{-2} and a pattern of pillars emanates from the bottom positive electrode towards the top negative electrode. The pillar pattern is of quite a regular geometrical nature and is preserved up to quite high current densities of ~0.5 A cm^{-2}. Only above that limit does the pattern break so that turbulent phenomena are observed.

We believe that the hydrodynamic instability described, and its observation, may provide a useful tool for the understanding of the performance of Pb–PbO_2 batteries at high discharge currents. The system may serve as a model to elucidate the limits imposed by hydrodynamic phenomena on the performance of the lead acid battery. It should be pointed out that the phenomena presented occur in the whole range of technically feasible discharge rates.

Tungsten trioxide as a photoanode for a photoelectrochemical cell (PEC)

THE PEC[1] has acquired popularity among researchers in the past years, mainly because of its possible use in solar energy conversion[2,3]. The major problem at present is to find a semiconductor electrode with an optical band gap (written as just band gap below) small enough to allow it to absorb a reasonably large portion of the solar spectrum, and at the same time being stable against photocorrosion. We here report that WO_3 meets these criteria although it is not very efficient at solar wavelengths.

Until now, the only material which was known to be stable as a photoanode absorbing in some region of the solar spectrum, is TiO_2, with a band gap $E_G = 3.05$ eV corresponding to a wavelength of 408 nm—on the border of the visible and ultraviolet. In the search for other stable photoanodes of smaller E_G, one criterion, which we used, is that one of the chemical elements making up the semiconductor material should be capable of reversibly changing its valence state to accommodate a hole without decomposing the semiconductor (as $Ti^{3+} \rightarrow Ti^{4+}$ in non-stoichiometric TiO_2) instead of having only one possible stable valence state in the semiconductor (as Cd^{2+} in CdS or Zn^{2+} in ZnO, both of which are decomposed by holes). WO_3, an n-type semiconductor with $E_G = 2.8$ eV, satisfies this criterion, and was selected for trial as a photoanode in a PEC.

WO_3 electrodes were prepared either by heating tungsten metal to form a layer of yellow WO_3, or by spraying ammonium tungstate on conducting glass (a gold layer on glass) and heating at ~ 500 °C to decompose the tungstate. Higher photocurrents were obtained from electrodes formed by heating the metal, but apart from the spectral response of the photocurrent, the general properties were much the same for both types of electrodes. X-ray powder diffraction of the samples showed the composition of the layers to be WO_3 with traces of lower oxides. The WO_3 electrode was connected to a platinised platinum oxygen counter electrode, and both electrodes were immersed in 1 N H_2SO_4 in a quartz cell.

In AM1 sunlight (AM1 = airmass 1, which is equivalent to directly overhead sunlight with energy of ~ 1 kW m^{-2}) photocurrents of ~ 0.2 mA cm^{-2} were obtained with WO_3 on tungsten and typically, one quarter of this for WO_3 on conducting glass. (Dark currents were $< 10^{-4}$ mA cm^{-2}.) The open circuit potential between the two electrodes increased from ~ 280 mV in the dark to 400 mV on illumination. Figure 1 shows the difference in currents obtained, in a potentiostatic experiment, between a WO_3 electrode under illumination and in the dark. The start of oxygen evolution shifted from +2.0 V (an overpotential of ~ 0.8 V) in the dark to +0.6 V (an underpotential of ~ 0.6 V) on illumination—a shift of 1.4 V.

That the photocurrent came from oxidation of water, and not photocorrosion of the WO_3 layer, is evident from two observations. First, after continuous passage of 42 C of electricity, which, if 100 per cent corrosion occurred, would correspond

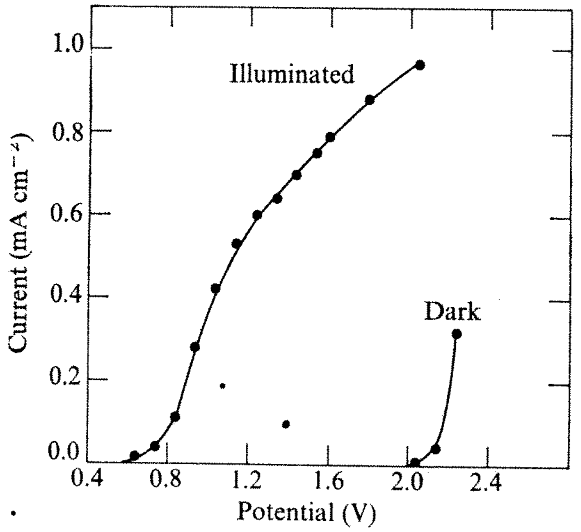

Fig. 1 Current–potential curves for a WO_3–tungsten photoanode in the dark and on illumination with light approximating to sunlight. (Measurements were made using a standard calomel electrode (SCE) as reference, and the potentials shown are adjusted to the standard hydrogen electrode (SHE) scale.)

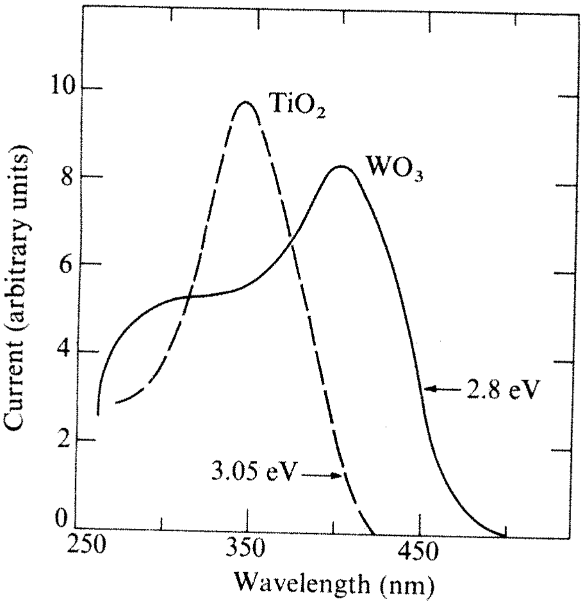
to the dissolution of 50 mg of WO_3 (assuming the hypothetical dissolution occurred by a two-electron transfer), there was no change in current, and no change in the weight of the electrode to < 0.5 mg. Second, if a strong source of light was used, so that a larger current ($\gtrsim 1$ mA cm^{-2}), was obtained, gas evolution from the electrode was clearly evident.

Besides stability, the next important property of a suitable photoanode for solar energy conversion is the ability to absorb well in the visible spectrum. Theoretically, the absorption edge for WO_3 should be shifted ~ 40 nm to the red, compared with TiO_2. The spectral response of the WO_3 electrode is compared in Fig. 2 with that for a polycrystalline TiO_2 electrode prepared by heating titanium metal in oxygen, followed by heating in hydrogen.

Fig. 2 The spectral response of the photocurrent for an electrode of WO_3 on conducting glass compared with a polycrystalline TiO_2 electrode. The positions of the wavelengths corresponding to the band gaps are arrowed (3.05 eV $\simeq$ 410 nm; 2.8 eV $\simeq$ 450 nm). The current at the peak for TiO_2 is actually considerably higher than the corresponding current for WO_3—they are shown nearly equal for purposes of clarity. (The total short-circuit current in sunlight for the TiO_2 electrode is $\sim$0.8 mA cm^{-2} compared with $\sim$0.2 mA cm^{-2} for a WO_2 electrode.)



The absorption edge for WO_3 was, in fact, shifted by ~ 50 nm. Figure 2 shows typical results obtained with WO_3 on glass. For WO_3 on tungsten, instead of the current decreasing with decreasing wavelength after the peak at 400 nm, there is a broad plateau, or slow increase, between 400 and 360 mn, followed by a sharper increase to a peak at ~ 300 nm—much like the mirror image of the curve shown. It should be stressed that the part of the curve in the visible region, 400–500 nm, is similar for both types of electrode. The difference in the ultraviolet may conceivably arise from a difference in crystallinity of the two types of WO_3. In other materials such as Si, there is a difference in spectral response between the amorphous and the crystalline states[2].

The important point arising from these preliminary results is not to suggest that WO_3 may be a serious candidate for an economical solar cell (the absorption still occurs over too small a part of the solar spectrum) but rather to show that stability against photocorrosion is not unique to TiO_2 (or other semiconductors with an even larger gap, such as Ta_2O_5, which may also be stable, but do not absorb in the solar spectrum), and that, where one more stable compound with a smaller band gap has been found, there may be others with even smaller gaps.

Effect of surface roughness on rolling friction and adhesion between elastic solids

THEORETICAL analyses of the influence of surface roughness on the adhesion of elastic solids[1,2] suggest that the introduction of roughness should reduce the adhesion to an extent governed by an adhesion parameter

$$\alpha = \left(\frac{4\sigma}{3}\right)\left[\frac{4E}{3\pi\beta^{\frac{1}{2}}\gamma}\right]^{2/3}$$

where α is the distribution of asperity heights (assumed to be Gaussian), β the mean radius of curvature of the asperities and γ is the net change in surface energy per unit area on the formation of adhesive contact. Experiment[2] bears out the theory. Here we report experiments on rolling, when we found α again to be a useful parameter. At low roughnesses, however, we found a surprising new result, that the adhesion could be greater than for smooth surfaces, and we propose an explanation for this.

Roberts and Thomas[3] and, independently, Kendall[4] had shown that in rolling friction the adhesion term may sometimes be dominant. In these circumstances the rolling friction provides a direct measure of the work required to peel apart and re-adhere the interface. This depends on the velocity, and may be thought of as the product of the surface energy and a visco-elastic term.

For smooth surfaces, the force required to separate a sphere from a flat had been shown by Johnson *et al.*[5] to be

$$P = -(3/2)\gamma\pi R$$

The reduction in the force with increasing roughness comes from the high asperities prising the surfaces apart and reducing the true area of contact. It is therefore to be expected that

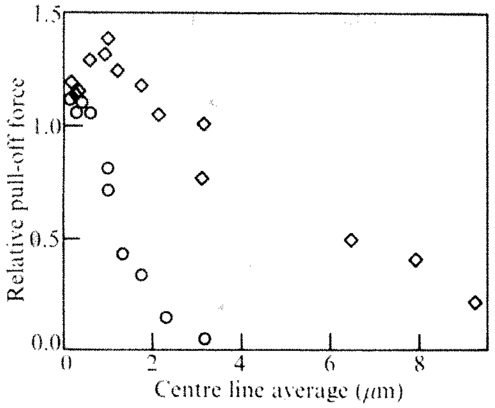

Fig. 1 Relative pull-off force for a smooth rubber surface in contact with a Perspex surface as a function of the roughness (centre line average) of the Perspex, using a crossed cylinders configuration. The pull-off force is normalised to be unity for a nominally smooth Perspex surface. ○, RTV 602 ($E = 4.9 \times 10^6$ Pa); ◇, Dow Corning XF—13-523 ($E = 6.3 \times 10^4$ Pa). In both cases the pull-off force for a smooth surface indicated a surface energy of $\gamma \simeq 100$ mJ m^{-2}. For a Gaussian distribution of asperity heights, the centre line average is a good measure of σ.

adhesion measured by rolling experiments will be affected by surface roughness in a similar way to the pull-off measurements.

We measured the adhesion during rolling at various speeds, for two rubbers, over a range of roughnesses. Perspex cylinders were roughened by blasting with fine particles. The surfaces were characterised by profilometry measurements, with data processing using established techniques[6] and thus β and σ were deduced. These cylinders were rolled down an inclined plane surface of silicone rubber and the time taken to roll 140 mm was measured electronically. The adhesion energy was determined from the weight of the cylinder and the angle of inclination. These measurements were much more reproducible (±2%) than those of Fuller and Tabor, partly because the adhesion was averaged over the whole of the surface of the cylinder and also because the time dependence was precisely specified. The greatest errors were in the surface characterisation (±10%), also depending on sampling lengths.

For the purpose of comparison with previous work the pull-off force for the various surfaces was measured using a crossed cylinders configuration. The results are shown in Fig. 1. Figure 2 shows the results for the rolling experiment, and a comparison of these two graphs shows that the effects of changing roughness and modulus are very similar in the pull-off and rolling experiments. In the case of the rolling experiments, it seems possible (except for the peak discussed below) to separate out the viscoelastic time dependence and the effect of roughness, since the normalised points for different rolling speeds fit closely over one another when the normalised adhesion $\lesssim 1$.

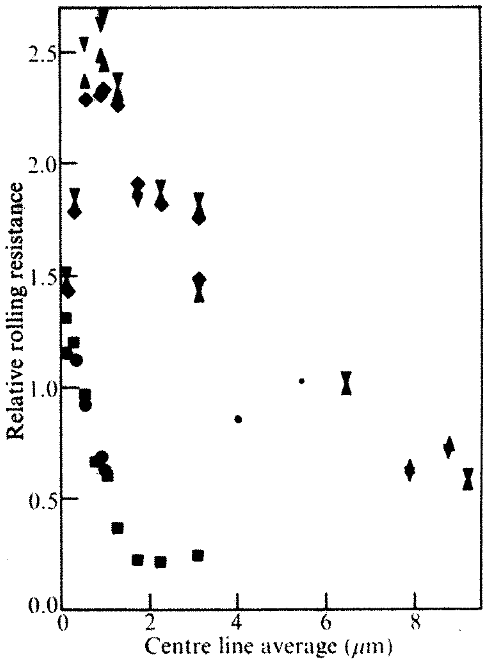

Fig. 2 Relative rolling resistance for Perspex cylinders (radius 5 mm, length 10 mm) rolling down an inclined smooth rubber surface at the following speeds (mm s^{-1}). RTV 602: ●, 2; ■, 4; Dow Corning XF—13-523; ◆, 0.5; ▲, 1; ▼, 2. The adhesion energy is the net work required for a complete cycle of adhering together and then peeling apart unit area of interface, and is deduced directly from the rolling resistance. It is markedly velocity dependent[3,4,7]. The absolute values for nominally smooth surfaces, to which the above points are normalised, are respectively (mJ m^{-2}): 600; 970; 253; 384; 612. Dusting the rubber surface with talcum powder to remove the adhesion reduced the relative rolling resistance to a very small value, indicating that bulk ploughing hysteretic losses were almost negligible in these experiments.

A new feature became apparent during these studies, however, which had previously been neither predicted nor observed. For very small roughnesses, the adhesion may be considerably

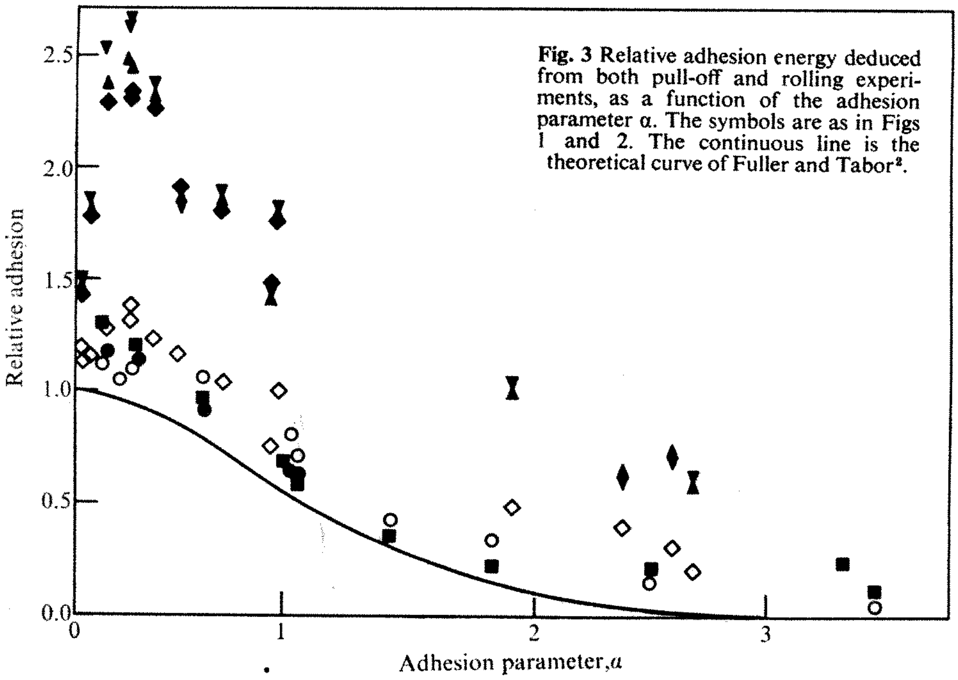

Fig. 3 Relative adhesion energy deduced from both pull-off and rolling experiments, as a function of the adhesion parameter α. The symbols are as in Figs 1 and 2. The continuous line is the theoretical curve of Fuller and Tabor[2].

greater than the adhesion with a nominally smooth surface. This effect is greatest when the effective surface energy is large and the modulus is small, and it is especially marked in the case of rolling on soft rubber. These results are shown in Fig. 3, where adhesion (normalised to the adhesion against a nominally smooth surface under the given conditions) is plotted against the adhesion parameter α. The theoretical curve of Fuller and Tabor is shown by the continuous line. The adhesion parameter seems to be a useful way of describing the influence of topography on the normalised adhesion, all the curves falling to half their maximum value when $\alpha \simeq 1$.

The increase of the adhesion for small roughnesses may be accounted for as follows: when a hard sphere is separated away from an elastic surface, there exists a minimum stable contact area. At this point the stored elastic energy is 1.4 times greater than the surface energy of the contact area. If the separation is increased quasi-statically, the rubber pulls away completely from the spherical surface, and all this elastic energy is lost. If the rate of separation is increased, then, because of viscoelastic effects, the elastic energy lost may be greater still.

For almost smooth surfaces, most of the contact areas between asperities and the rubber are smaller than the critical value and the surfaces therefore peel apart in a similar manner to perfectly smooth surfaces. For very larger roughnesses, the reduction in the true area of contact dominates. But between these two extremes a substantial proportion of the asperities may have a contact area just greater than the critical value, and therefore an increase in adhesion of up to 40% is possible. Simple analysis indicates that α should be an adequate parameter to determine the roughness at which this effect is important with the peak at $\alpha \simeq 0.2$–0.3. Comparison of these predictions with Fig. 3 is very satisfactory.

It will be noted that there is an exceptionally large increase in normalised adhesion in the case of the rolling experiments on very soft rubber. This may be due partly to the viscoelastic effect described above, and also to a snowballing of the adhesion (the extra adhesion at the rear of a rolling cylinder pushes more asperities into the rubber at the front, which increases the adhesion and so on).

A detailed account of the theory is in preparation. We wish to thank Professor D. Tabor for advice and encouragement and also Dr Whitehouse and Mr D. Kinsey of Rank Taylor Hobson for their help with the surface topography measurements. We are grateful to the SRC for an ASSIST award to G.A.D.B.

Pitting corrosion as a stochastic process

We believe that a stochastic theory originally developed to explain the fracture of solid materials under stress can be used to explain pitting corrosion. In the past (see ref. 1), both pitting potential[2] and induction time[3] have been used to select resistant alloys and to search for possible breakdown mechanisms. Studies of these and other phenomena, however, always reveal a wide scatter of data, so we have used the stochastic approach, which has proved useful in understanding time-dependent phenomena (see refs 4 and 5).

Pitting corrosion can be regarded as the failure of a two-dimensional film, which is altered over a finite time. Thus a stochastic approach is needed to explain many of the unsolved problems of pitting corrosion, such as the size effect and sweep rate sensitivity of pitting potential and the relationship between pitting potential and induction time.

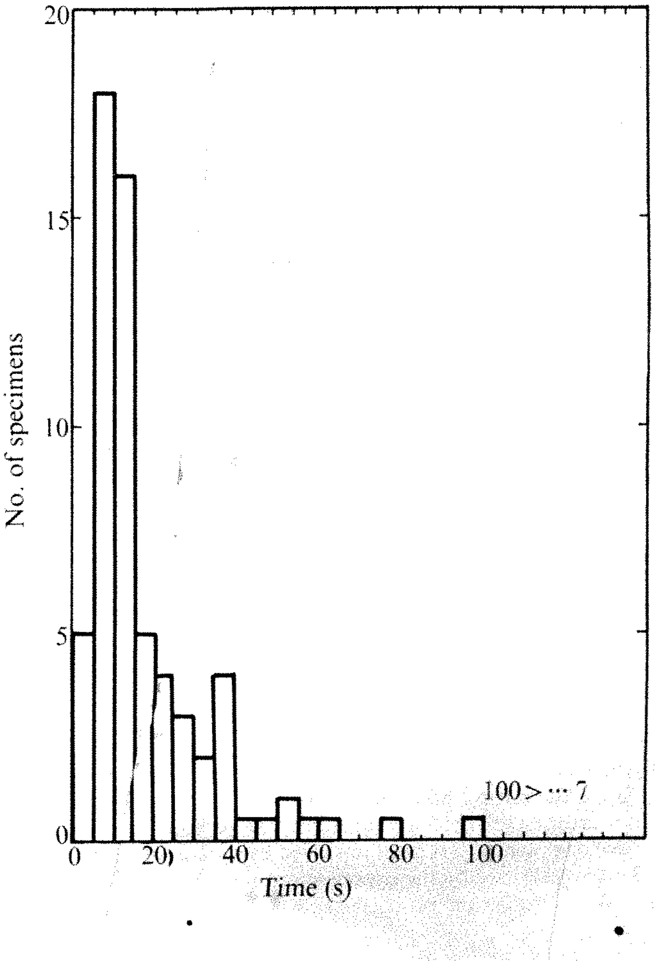
The stochastic approach requires the measurement of several series of data taken during the pitting process, in the same controlled conditions. We have developed a multichannel pitting corrosion tester which can measure the pitting potential or induction time of 12 specimens consecutively, using one potentiostat. Figure 1 is a histogram of induction time for 72 specimens of 18-8 stainless steel, the potential of which was kept constant at 0.35 V in 3.5% NaCl solution saturated with nitrogen gas at 35 °C. Though further experiments revealed that variations in pitting potential obey the normal distribution a distorted type of distribution was observed for the induction time.

This behaviour can be explained using the stochastic theory developed[4] for the brittle fracture of glass. The transition probability, $\lambda(t)$, of pit formation at any time, t, after applying the potential, is given by

$$\lambda(t)\mathrm{d}t = -\mathrm{d}P(t)/P(t) = -\mathrm{d}\ln P(t) \qquad (1)$$

where $P(t)$ is the survival probability, that is, the number of

Fig. 1 Histogram of induction time for pitting at constant potential (0.35 V) for 304 stainless steel in 3.5% NaCl solution saturated with nitrogen gas at 35 °C (72 specimens). Surface of specimens was polished with 6/0 emery paper before immersion into solution. After holding specimens in natural corrosion state for 5 min, and for further 5 min at −0.10 V to give a constant surface condition, the potential of the specimens was shifted to +0.35 V, at which potential pitting occurred after the induction time.



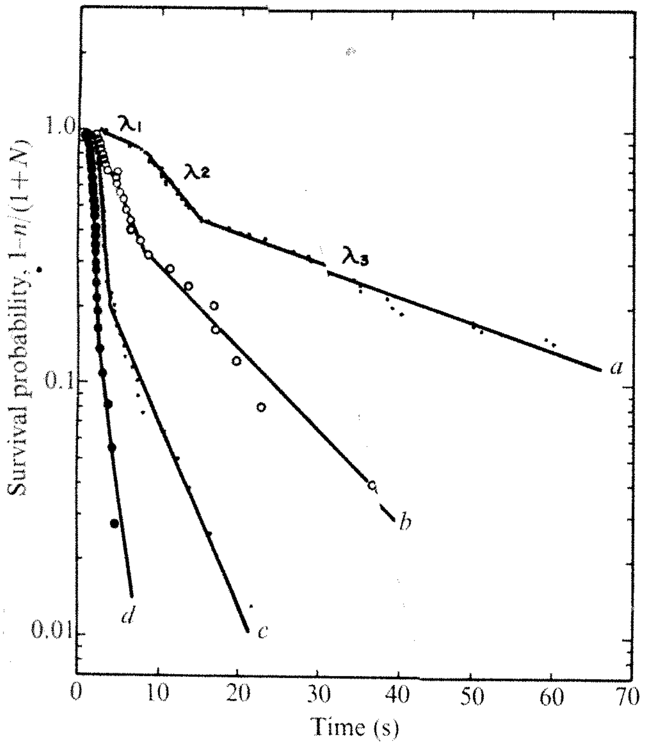


Fig. 2 Change in survival probability with time *a*, 0.35 V; *b*, 0.36 V; *c*, 0.37 V; *d*, 0.378 V. The slope of lg*P* against time gives transition probability

non-pitted specimens at time t. This equation is integrated for $P(0) = 1$, giving

$$P(t) = \exp(-\int_0^t \lambda(t)\mathrm{d}t) \tag{2}$$

Generally, $\lambda(t)$ is a function of time, but if it is not, equation (2) can be transformed to

$$\ln P(t) = -\lambda t \tag{3}$$

Equation (3) predicts a linear relationship between the logarithm of survival probability and the time elapsed after applying the potential. The survival probability is defined as $1 - n/(1+N)$, where N is the total number of specimens and n is the number of specimens failed in time t. Figure 2 shows such a plot for various potentials; the straight line which is divided into three. The slope of the lines gives the transition probability, as understood from equation (3).

The three distinct divisions could correspond to three processes causing pit formation at any one potential. The first process has the lower transition probability of λ_1, compared with λ_2 for the second process, with almost no delay. The second process begins only after a delay, in spite of the higher transition probability, λ_2. The third process has the lowest transition probability of λ_3, as shown in Fig. 2. All are highly dependent on potential, and λ_1 in the first process is described by

$$\begin{aligned}\lambda_1 &= \alpha_1(E - E_{\mathrm{crit}})\\ &= 8.20(E - 0.346)\end{aligned} \tag{4}$$

where E is the potential applied to the specimen in volts, and E_{crit} is the critical potential, at which no pitting is expected. It is interesting to note that the same linear dependence of induction time on potential has been observed by Sato *et al.*[6]. Both λ_2 and λ_3 are described by the exponential function of potential.

When transition probability is a function of potential, the most probable value of the pitting potential can be obtained using the equation[5]

$$\nu \mathrm{d}\lambda/\mathrm{d}E|_{E=\bar{E}} = \lambda^2 \tag{5}$$

which is derived by differentiation of the probability density function of pitting potential, where ν is the sweep rate of potential and $\bar{E}$ is the most probable value or mean value of pitting potential. If the first process determines the pitting potential, the sweep rate sensitivity of pitting potential can be obtained by the substitution of λ_1 into λ in equation (5)

$$\begin{aligned}\bar{E} &= (\nu/\alpha_1)^{\frac{1}{2}} + E_{\mathrm{crit}}\\ &= 0.349\nu^{\frac{1}{2}} + 0.346\end{aligned} \tag{6}$$

This predicted relationship has been confirmed in another set of experiments for determining E with changing potential sweep rates. This indicates that only the first process operates to cause pitting potential. It should also be emphasised that no paper has ever mentioned such dependence of pitting potential on the square root of the potential sweep rate. This relationship could be used to determine the value of the critical potential by extrapolating to the zero sweep rate even if the potential sweep method is used. The stochastic theory also predicts that the lowest pitting potential can be expected on the largest area of specimen. This could explain the unexpected failures which often occur in practical large scale apparatus in spite of proved resistances in laboratory tests using specimens with small areas.

Primary production of oxygen from irradiated water as an explanation for decreased radiobiological oxygen enhancement at high LET

WE report here the results of sensitive measurements of oxygen yields in water irradiated with radiation of high linear energy transfer (LET), in conditions which precluded the formation of oxygen in secondary reactions. These yields are important in radiobiology because, although small, they are sufficient to account for the decrease in value of the oxygen enhancement ratio found for biological cells irradiated by radiation of high LET compared with the value for low LET radiation.

An important feature of radiation damage to biological cells is that their sensitivity is greater in the presence of oxygen than under anoxic conditions[1,2]. For a given type of radiation the ratio of the two sensitivities, known as the oxygen enhancement ratio (OER) increases with increasing oxygen concentration. With radiation of increased LET, the anoxic sensitivity to radiation damage is increased, but the OER for a given oxygen concentration is decreased. Among the hypotheses advanced to explain these phenomena either independently, or as parts of a single mechanism, is the suggestion that the reason for decreased values of OER at high LET is the presence of oxygen

Table 1 G values of primary HO_2 and O_2

Ion or radiation	$^{60}Co\gamma$	^{4}He	^{4}He	^{14}N	^{14}N	^{14}N	^{14}N	^{14}N	^{20}Ne
Energy (MeV)	1.25	29	6	127	87	45	38	34	30
$G(HO_2)$	0.03	0.075	0.08	0.11	0.12	0.20	0.22	0.25	0.25
$G(O_2)$	0	0.0016	0.008	0.007	0.0085	0.012	0.012	–	0.031

formed in, or close to, the track of the ionising particle[3]. As a result, the radiobiological sensitivity is already raised above the hypothetical anoxic level, making further addition of oxygen less effective than with radiation of low LET, for which oxygen is not a radiolytic product. Alper and Bryant[2] have shown that the 'oxygen-in-the-track' hypothesis is superior to other hypotheses, for example, the suggestion that radicals formed in the track may recombine if sufficiently close together, thereby fixing damage without involving oxygen[4]. Experiments based on the oxygen-in-the-track hypothesis have been interpreted to quantify, by inference, an effective concentration of the oxygen present in cells along the track of energetic ^4He ions at the time of radiobiological action. Our measurements now provide direct radiation-chemical evidence that oxygen is formed as a primary product in sufficient yield to account for the decrease in OER at high LET.

Oxygen can be formed both with low and high LET radiation by the familiar bulk secondary reactions[5] of the normally accepted radiolytic products (OH, HO_2, H_2O_2, OH^-, H^+, H, H_2, e_{aq}^-) such as

$$OH + H_2O_2 \rightarrow HO_2 + H_2O \qquad (1)$$
$$OH + HO_2 \rightarrow O_2 + H_2O \qquad (2)$$
$$2HO_2 \rightarrow H_2O_2 + O_2 \qquad (3)$$

These secondary reactions are, however, suppressed by low concentrations of solutes, or are negligible in the time scale of spur and track reactions ($\leqslant 10^{-8}$ s) so that even reaction (1) cannot be invoked as an explanation for the formation of HO_2 in the track[6,7] because of its low rate constant.

Our method of preventing the occurrence of such secondary reactions and of measuring reproducibly the small primary yields of oxygen was as follows. Argon was bubbled through a suitable aqueous solution, irradiated by heavy ions from the Harwell Variable Energy Cyclotron at low currents (~ 2 nA) with adequate stirring, and then through a Hersch cell[8], the current from which gives a measure of the oxygen concentration in its own electrolyte. The area above the baseline of the graph of Hersch cell current against time obtained with constant argon flow provides a quantity proportional to the amount of oxygen formed during irradiation, which was converted to an absolute quantity by calibration with an electrolytic cell, also in the gas circuit. The methods of particle charge and energy measurement needed to obtain the yield per 100 eV, the G value, have been described[9]. By the use of methods and various solutes (unpublished work), measurements of oxygen yields have been used to obtain primary G values of HO_2, O_2, H_2O_2 and H_2 for γ rays, and some of these for several different kinds of radiation.

The principle of the method to measure HO_2 is to generate oxygen by the reaction of HO_2, with cupric ion[10,11]

$$HO_2 + Cu^{2+} \rightarrow Cu^+ + H^+ + O_2 \qquad (4)$$

in a deaerated solution of ferrous ammonium sulphate (10^{-3} M) and cupric sulphate (10^{-2} M) adjusted to $pH = 2$ with sulphuric acid. Other relevant reactions are

$$OH + Fe^{2+} \rightarrow Fe^{3+} + OH^- \qquad (5)$$
$$Cu^+ + Fe^{3+} \rightarrow Fe^{2+} + Cu^{2+} \qquad (6)$$
$$e_{aq}^- + H^+ \rightarrow H \qquad (7)$$
$$H + Cu^{2+} \rightarrow Cu^+ + H^+ \qquad (8)$$
$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH + OH^- \qquad (9)$$

Any primary oxygen yield will also be measured from this solution and so must be subtracted from the overall oxygen yield.

The yield of O_2 was obtained as the lowest limiting yield when the concentration of Fe^{2+} ions was increased in deaerated Fricke solutions (ferrous ammonium sulphate 10^{-3} M, sulphuric acid 0.4 M), and was usually obtained between 10^{-2} and 10^{-1} M Fe^{2+}. The relevant overall reactions[12,13] are (5), (7), (9), (10) and (11)

$$H^+ + Fe^{2+} + HO_2 \rightarrow Fe^{3+} + H_2O_2 \qquad (10)$$
$$H^+ + H + Fe^{+2} \rightarrow Fe^{3+} + H_2 \qquad (11)$$

Some results are shown in Table 1.

The mean instantaneous concentration of a track product c_o mol l^{-1} can be derived from the initial track G value G_0, the mean LET, L (eV nm^{-1}) and the mean track radius r_o (nm): $c_o = G_0L/60\pi r_o^2$). In the absence of further reaction c_o will change with time to give c_t dependent on time

$$c_t = G_0L/60\pi(r_o^2 + 4Dt)$$

where t is the time (s) and D ($nm^2\,s^{-1}$) is the diffusion constant. For typical α-particle values[14] of L and r_o, 10^2 and 1 respectively, c_o for oxygen would be 4.2 mM and after 10^{-8} s, c_t would be 51 μM (taking $D = 2.1 \times 10^9$ $nm^2\,s^{-1}$ (see ref. 15)) if G_0 were assumed to be the measured value. If, however, oxygen were generated in the track core, the diffusion theory suggests[16] that much of it would be converted to O_2^- and HO_2 by track reactions (12) and (13)

$$e_{aq}^- + O_2 \rightarrow O_2^- \qquad (12)$$
$$H + O_2 \rightarrow HO_2 \qquad (13)$$

possibly giving rise to the yield of HO_2 measured in acid solution. Initial track core concentrations of oxygen may therefore be higher than c_o given above, and this is being investigated.

The way in which oxygen increases radiation sensitivity may be by reaction with lesions in the biological material formed by direct (or indirect) action in the δ-ray sheath surrounding the track core. For α particles of 5 MeV (90 eV nm^{-1}) Alper and Bryant find an OER for survival of 1.5 for two biological systems, *Chlamydomonas* and *Shigella*[2], for which the OER for γ-ray survival is 2.5. Using a mechanism based on competition between repair and fixation derived from data for low LET radiation they estimate an effective stationary oxygen concentration in the irradiated track volume of 2.2 μM. By interpolation of the results in Table 1 for 29 MeV and 6 MeV α particles (which are based on the average LET for the whole track) it can be shown that the G value for oxygen is ~ 0.005. The concentration of 2.2 μM together with this G value implies an irradiated track volume with a radius of 33 nm, in which it can be shown[17] ~ 90% of the dose is initially deposited. This indicates that the small yield of oxygen is sufficient to produce the observed effect.

The above argument has been simplified in that variations of oxygen concentration with time, and therefore of its reaction rate, have been ignored. More detailed calculations[16], however, including diffusion, using the same parameters for initial track geometry and the repair fixation competition confirm the adequacy of the oxygen yield. In addition, the reaction times are within those required[18] for the oxygen effect. Work in the determination of oxygen and HO_2 yields at varying Cu^{2+} and Fe^{2+} concentrations, and on oxygen enhancement ratios for radiation types with similar LET but differing secondary electron spectra, is in progress to test conclusions.

We wish to thank Messrs P. E. J. Abbott, W. R. Marsh, Dr R. May and Miss R. Cochrane for experimental assistance and advice and Drs C. B. Amphlett, A. J. Tench and J. Vennart for encouragement.

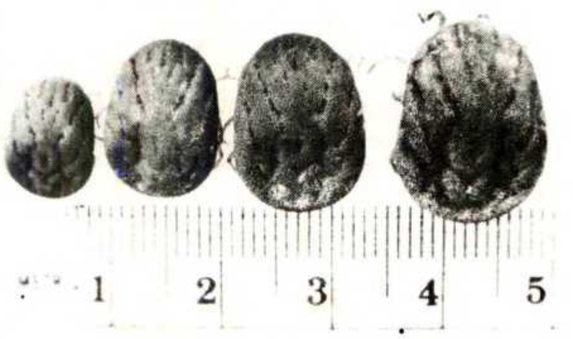
Ecdysone and the super tick

TICKS and insects develop and grow through intermittent replacement of their integument. This moulting does not occur beyond the adult stage, with the exception of primitive apterygote insects such as silverfish, which continue to moult and grow after they become sexually mature. Moulting ceases to occur in the pterygote adult insect because the glands secreting ecdysone, the hormone required to induce moulting, break down and disappear soon after the insect (and presumably also the tick) becomes adult[1]. The adult tissues of both hemimetabolous insects and those with complete metamorphosis continue to respond to ecdysone if exposed to it. There are, however, differences in the responsiveness of different segments of the insects and the resulting 'super-moulted' adult insects are usually defective[2–5]. We have found that ticks also retain the full potential to moult, grow and reproduce normally as adults if they receive ecdysone. Through successive adult moults 'super ticks' are obtained (Fig. 1) which consume very large volumes of blood and produce many more viable eggs than normal ticks.

Fig. 1 From the left, a normal fully engorged female compared with females super-moulted once, twice and three times.



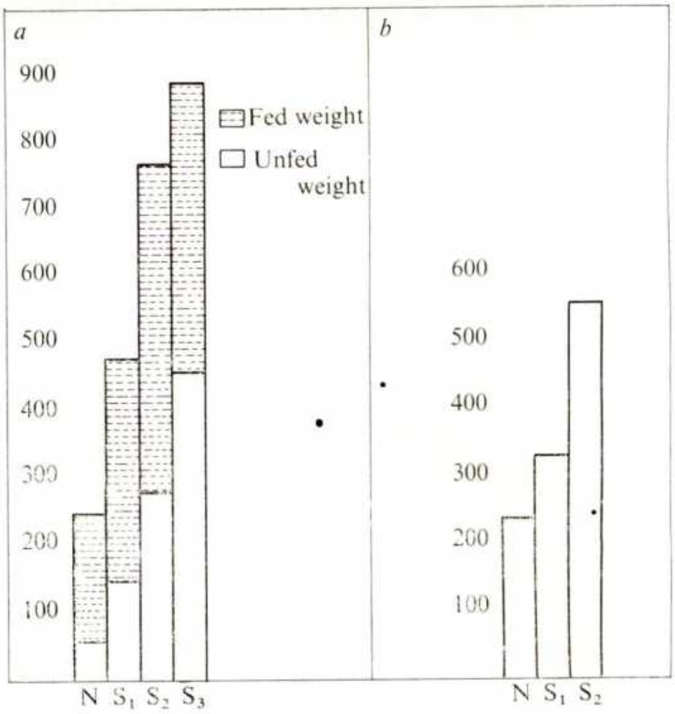


Fig. 2 The effects of ecdysone on body weight (*a*) and egg output (*b*) of female *Ornithodoros moubata* (w) super-moulted once (S_1), twice (S_2) and three times (S_3). Shaded areas, fed weight; unshaded areas, unfed weight (in mg).

We used the eyeless tampan, *Ornithodoros moubata* (Murray) (Argasidae), which is widely distributed throughout East Africa. We used adult ticks which were at least 1 month past their last moult. Females of this age are usually ready to take a blood meal and mate, and then lay about 250 eggs. Subsequent meals are necessary for additional batches of eggs. Ticks were divided into groups of 30 and fed on defibrinated pig blood through bat's membrane[6]. β-Ecdysone or the phytoecdysone ponasterone A were dissolved in 95% ethanol and added to the blood meal in concentrations of 1–5 μg ml^{-1}, the range which induces moulting in *O. moubata*[7]. After moulting, the ticks were offered a blood meal free of ecdysone, and then mated to assess their reproductive capacity. Another group was allowed to feed and moult as in the first group, and then fed again on blood containing ecdysone. The procedure was repeated again with the ticks that moulted on the second blood meal.

As Table 1 shows, if the blood contained ecdysone in a concentration greater than 2 μg ml^{-1}, most of the females moulted. With 4–5 μg ml^{-1} many of the moulted females underwent a second moult—without a further blood meal. Thus it seems that ingested ecdysone is not destroyed during digestion in ticks, and continues to stimulate moulting when the contents of the gut are being absorbed. This effect is dose dependent and seems to be rather rare at the lower concentrations.

Adult males seem more refractory than females to induction of moulting by ecdysone. Many of them, however, secreted new cuticle that was only loosely attached and could be peeled away easily. These males always died. Ponasterone A, which is more active than β-ecdysone when fed to insects[8], was more effective on ticks too, and at a dose of 5 μg ml^{-1} was highly toxic.

If females were mated and then fed on blood containing ecdysone, they moulted first, and if this process did not completely drain the food reserve, the remainder was utilised for egg production. Thus in one experiment 50 inseminated females were fed blood containing β-ecdysone

Table 1 Effect of β-ecdysone and ponasterone A on moulting of adult *Ornithodoros moubata*

Each group contains 30 ticks.
*Moulting twice without a second blood meal.

(5 µg ml^{-1}). Twelve died and 38 moulted. Six out of the 38 then laid some eggs.

When super-moulted females were mated and fed blood, they consumed a much larger meal and consequently laid many more eggs than the normal tick. Blood utilisation seemed to be similar in normal and super-moulted ticks whether they moulted once or twice: for each 1 mg of blood consumed one egg was deposited (Fig. 2).

After one moult ticks were fed again on blood containing ecdysone (3 µg ml^{-1}); 57 out of 95 moulted after that meal. These twice-moulted ticks were about twice as heavy as the once-moulted adults, and about five times heavier than normal adult females. They consumed about 500 mg of blood and laid about 500 viable eggs. The larvae that hatched from these eggs developed normally. Only about four out of 12 females moulted after a third blood meal containing ecdysone. At this stage the weight of the unfed tick was nine times that of the normal tick (Fig. 2).

Our results may have some practical consequences as the use of ecdysone and its analogues has been proposed as a means of controlling ticks[10]. Obviously 'super ticks', produced by the application of ecdysone or its analogues, would constitute a danger of increasing the damage done by this pest rather than controlling it.

Ponasterone A belongs to a group of ecdysones widespread in large concentrations in plants. Many of them act in lower concentrations than does insect ecdysone[8], and it is conceivable that host animals might feed on plants containing large amounts of these substances, thus maintaining in their blood sufficient concentrations to induce super-moults in ticks. We have collected mature adult ticks from warthog burrows in the Nairobi National Park that were much bigger than ticks from the same source bred in the laboratory on pig blood. The possibility that warthogs feed on plants containing these phytoecdysones merits investigation.

Transitory hemizygosity of paternally derived alleles in hybrid trout embryos

IT is generally assumed that in species with yolk-rich eggs early embryonic development is sustained by maternally transmitted storage substances in the egg cytoplasm[1,2], while embryonic genes become activated later in development. As a rule, the maternally and paternally derived alleles of a particular gene locus start to function simultaneously at a defined developmental stage. But preferential activation of the maternally derived allele has been observed[3-7]. This prompted the suggestion[2,4] that the information required to switch on embryonic structural gene loci is transcribed by the diploid nucleus of the mother during oogenesis. According to this hypothesis, regulatory substances from the egg cytoplasm bind to receptor sequences adjacent to the structural genes, and thus induce their initial derepression. When the parentally derived receptor sequences are identical, the two alleles at the respective structural gene locus become activated synchronously. But when the base sequence of the paternally derived receptor site is different from the maternally transmitted one, for example when the two haploid genomes stem from different species, the recognition of the paternally derived receptor sequence by the regulatory substance of the egg might become difficult or even impossible. This would lead to either transitory or permanent exclusive expression of the maternally transmitted structural gene. Using the first appearance of embryonically specified α-glycerophosphate dehydrogenase (α-GPDH) isozymes as markers during the ontogeny of interspecific hybrid trout, we have now observed preferential activation of the paternally derived alleles. This seems to contradict the model of gene activation outlined here.

Brown trout (*Salmo trutta*) and brook trout (*Salvelinus fontinalis*) are easily hybridised to produce viable but sterile

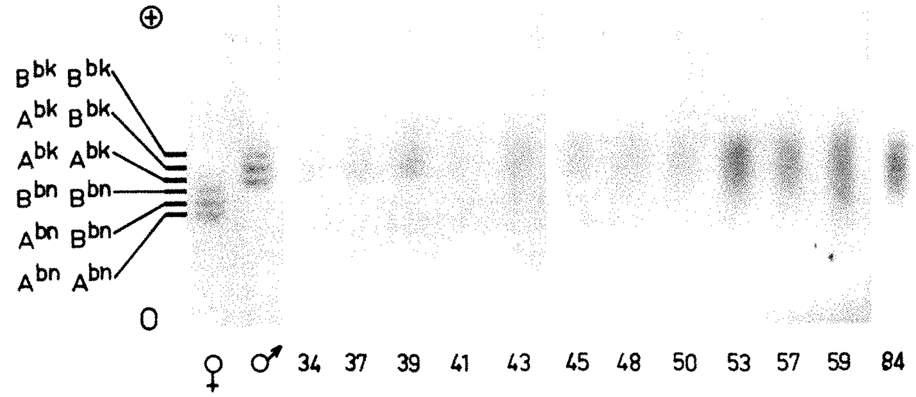

Fig. 1 Starch gel electrophoresis of α-GPDH isozymes from parental skeletal muscle tissue and single embryos at different developmental stages (age after fertilisation in days). Skeletal muscle (1:1 w/v) and embryos (about 1:0.25 w/v) were homogenised in 0.01 M phosphate buffer, *p*H 7.5, containing 10^{-4} M $MgCl_2$. The 20,000*g* (skeletal muscle) and 10,500*g* (embryos) supernatants were subjected to electrophoresis. Gels were made of 14% starch in 0.008 M Tris-0.003 M citrate buffer, *p*H 8.0; bridge: 0.223 M Tris-0.068 M citrate buffer, *p*H 8.0; run for 5 h at 12 V cm^{-1}. Gel slices were stained as described before[9].

hybrids. The time sequence of embryonic development in the offspring of intraspecific and interspecific matings is identical[8]. Both species have two ubiquitously expressed gene loci coding for a α-GPDH (EC 1.1.1.8), an enzyme of apparently dimeric structure[8,9]. The wild-type isozyme patterns in the two species consist of electrophoretically distinct triplets, of which the subunit designations are given in Fig. 1.

No α-GPDH staining activity was observed in unfertilised brown trout eggs. In the offspring of a mating between a female brown trout (phenotype $A^{bn}B^{bn}$) and a male brook trout (phenotype $A^{bk}B^{bk}$) staining activity was observed for the first time on day 34 after fertilisation (Witschi stage 20). The stain clearly was located in the position of the paternal type of isozymes, and the pattern remained unchanged until day 52. On day 53 (Witschi stage 23) enzyme activity in the position of the maternal species was visible for the first time. On day 84 (shortly before the resorption of the yolk sac) all of a sample of ten embryos showed the expected $A^{bn}B^{bn}$ $A^{bk}B^{bk}$ phenotype, exhibiting an electrophoretic pattern of seven bands (Fig. 1). Our study was extended also to the offspring of the reciprocal and the intraspecific matings. In these cases the maternally and paternally derived α-GPDH genes seemed to become activated simultaneously. (These findings will be reported elsewhere in detail.)

The preferential activation of paternally derived α-GPDH alleles seems incompatible with the model of gene activation in embryonic development outlined above. If, however, one assumes that a genetic polymorphism exists at a common receptor site adjacent to both of the two α-GPDH structural loci (preliminary results indicate close linkage of the two loci[8]) our finding becomes reconcilable with the model. The brown trout mother should have passed on to all of her offspring a variant receptor sequence, characterised by a lowered affinity to the regulatory substance compared with the paternally transmitted receptor sequence. Only when the cellular concentration of the regulatory substance has reached a threshold, possibly also by synthetic activity of the embryonic genome, can the maternally derived α-GPDH loci be switched on.

It is conceivable that mutational events could alter receptor sequences so that they will never be recognised by the regulatory substances. In fact, permanent repression of the maternal allele was observed in interspecific *Drosophila*[10] and sunfish[11,12] hybrids. Whitt *et al.*[12] suggested that permanent maternal allele inhibition is due to a repressor molecule produced by the paternal genome which, when associated with the paternal DNA, can react appropriately to specific gene-activating stimuli, but when associated with the maternal DNA, with a different nucleotide sequence, cannot respond. This model, based on observations with adult animals is obviously difficult to apply to early development, whereas genetic variability at receptor sequences might explain either set of findings.

If receptor sequences can occur in different allelic forms, preferential activation of paternally inherited genes should also occur in the offspring of intraspecific matings. We are testing this hypothesis. We thank Fischzuchtmeister H. Scheiffelen, Alpirsbach, Black Forest, for breeding the hybrids.

Increased frequency of heterozygotes for α_1 antitrypsin variants in individuals with either sex chromosome mosaicism or trisomy 21

THERE have been two reports[1,2] of an association of alpha-1 antitrypsin (α_1AT) variants and sex chromosome mosaicism. The data suggest that decreased α_1AT activity, as found in individuals heterozygous or homozygous for α_1AT variants, gives rise to abnormal chromosome segregation during mitosis. We report here further data which support those previous studies and suggest that decreased α_1AT activity is also an aetiological factor in trisomy 21.

α_1AT is produced by the liver and found in blood, semen, cervical mucus and other body fluids. It is a readily detectable, polymorphic, codominantly inherited inhibitor of cellular proteases. The structural gene for α_1AT is not on chromosome 21; however, its exact location is not known at present[3].

Using acid starch gel electrophoresis[4] and immunofixation electrophoresis at *p*H 8.6 (ref. 5), we found that three of nineteen individuals with mosaic sex chromosome abnormalities had a heterozygous α_1AT phenotype (Table 1). Of the three, two had the M_{LAMB} variant of α_1AT. M_{LAMB} is a newly discovered variant with approximately 20% less activity than the usual M form of α_1AT and, in one survey, was found in less than 1% of individuals typed[5]. Given an average frequency of heterozygotes for all α_1AT variants of approximately 10% (ref. 6), the observed number of α_1AT heterozygotes (12) in the three studies of individuals with mosaic sex chromosome abnormalities ($N = 47$) is significantly greater than expected: $\chi^2 = 12.6$, $P = <0.001$. (For this and subsequent calculations we have assumed the expected population frequency of heterozygotes for α_1AT to be exactly 10%.)

We have also performed α_1AT phenotyping on 60 institutionalised patients with karotype proven trisomy 21. Since advanced maternal age markedly affects the incidence of Down's syndrome, we collected samples from two groups of patients with trisomy 21. Group 1 consisted of 29 patients whose mothers were under 30 yr old at the time of the patient's birth (mean maternal age± s.e. = 25.0±0.51 yr). Group 2 consisted of 31 patients whose mothers were older than 35 yr at the time of the patient's birth (mean maternal age± s.e. = 40.0±0.38 yr). The mean ages of the patients in the two groups (29.7±1.9 and 26.4±1.8 yr, respectively) were not significantly different. α_1AT phenotyping was performed blind with respect to maternal age, and the age and sex of the patient. We found two α_1AT heterozygotes in group 1 and 14 in group 2 (Table 2). The frequency of α_1AT heterozygotes in the total of both groups is significantly greater than that of the general population ($P = <0.0001$). But the two groups are significantly different from each other ($P = <0.005$). Group 1 alone, compared with the general population, had no greater frequency of α_1AT heterozygotes; group 2 had a markedly greater frequency of α_1AT heterozygotes ($P = <0.0001$). Thus the significant association of trisomy 21 with variant α_1AT alleles seems to be confined to individuals born to mothers over 35.

These observations, if supported by more extensive studies, raise additional questions. How do advanced parental age and diminished α_1AT activity (associated with heterozygous variants of α_1AT) interact to produce chromosomally abnormal offspring? Does diminished α_1AT activity predispose to other types of chromosome aberrations? What role, if any, does α_1AT have in normal meiosis and mitosis? Answers to these questions will provide important insights into mechanisms which control chromosome segregation. One important practical benefit may be the identification by α_1AT phenotyping of individuals with a significantly increased risk of producing children with chromosome abnormalities.

Table 2 α_1AT phenotypes in patients with trisomy 21

Cytoplasmic factor responsible for germinal vesicle breakdown and meiotic maturation in starfish oocyte

IN starfish, the first maturation division of oocytes within an ovary is arrested at a late stage of prophase. It is resumed after stimulation by 1-methyladenine (1-MA) produced in the follicle cells under the influence of the gonad-stimulating hormonal peptide, released from the nervous tissues[1–3]. 1-MA induces breakdown of the germinal vesicle and maturation of oocytes isolated in seawater[2]. When it causes maturation, 1-MA first acts on the oocyte surface[4,5] to bring about cytoplasmic maturation, which is manifest in the acquisition of fertilisability[6]. The change in the cortical region of the oocyte under the influence of 1-MA is believed to produce a cytoplasmic factor which induces germinal vesicle breakdown (GVBD), leading to the completion of oocyte maturation. We now report microinjection experiments that provide evidence of such a cytoplasmic factor in the starfish *Asterina pectinifera*.

An earlier experiment had shown that 1-MA injected directly into an immature oocyte failed to induce germinal vesicle breakdown even in a concentration higher than that which is effective when applied externally[4]. We found, however, that cytoplasm from an oocyte which is maturing after treatment with 1-MA can induce GVBD when injected into an immature oocyte by Hiramoto's method[7] (Fig 1) The frequency with which GVBD was induced in recipient oocytes was proportional to the volume of cytoplasm injected. Almost 100% breakdown was observed when the volume injected was 220 pl (about 1/15–1/20 of the oocyte volume). Germinal vesicle was broken down 20–40 min after microinjection, and so was follicular envelope, but GVBD was never observed when the cytoplasm of immature oocytes was injected as a control.

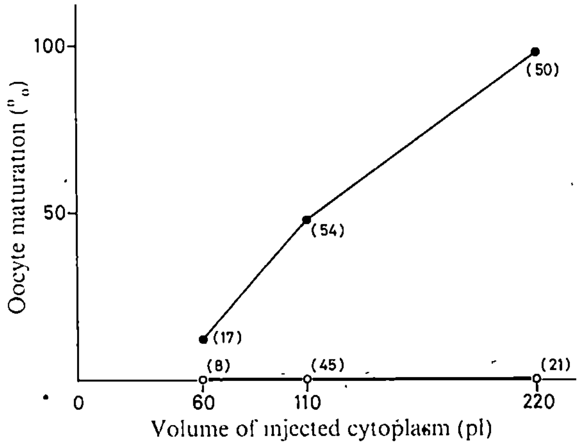
Cytological examination of oocytes which underwent

GVBD after microinjection of cytoplasm from 1-MA-treated oocytes showed that meiosis was completed normally. Recipient oocytes were fixed with ethanol–acetic acid (1 : 1) and stained with aceto-orcein. Each oocyte was crushed under a cover glass and the chromosomes were observed microscopically. Chromosome condensation was observed 35 min, metaphase about 45 min and anaphase about 55 min after injection. The first and second polar bodies were discharged 70 min and 100 min after injection, respectively. The egg pronucleus was observed 120 min after injection. The time course of meiosis of injected oocytes was the same as that of oocytes treated with 1-MA in 80% artificial seawater. Thus the maturing oocyte produces a cytoplasmic factor which induces GVBD, leading to the completion of meiotic maturation. Furthermore, on insemination, oocytes induced to mature by injection of maturing cytoplasm formed somewhat incomplete fertilisation membranes. They then cleaved and developed normally.

Next we investigated the changes in the maturation-inducing capacity of the cytoplasm of 1-MA-treated oocytes as they matured. Cytoplasm (about 220 pl) of 1-MA-treated oocytes, taken at 20-min intervals after treatment, was injected into immature oocytes with germinal vesicles. When oocytes were taken from the same ovary and treated with 1-MA in the same way as donor oocytes, the germinal vesicle broke down after 15–30 min, the first polar body was discharged after 60–70 min and the second polar body was discharged after 110–120 min. Injected cytoplasm was most effective in inducing GVBD 20–40 min after administration of 1-MA, and then its efficacy declined (Fig. 2). After 80 min, the cytoplasm had almost lost the capacity to induce germinal vesicle breakdown when injected into immature oocytes, although recipient oocytes matured normally when subsequently transferred to seawater containing 10^{-6} M 1-MA. Furthermore, maturation-inducing capacity was found in the cytoplasm of some oocytes 13 min after administration of 1-MA, when germinal vesicles remained intact. The activity thus does not seem to be the result of GVBD.

Cytoplasm of an oocyte undergoing maturation as a result of microinjection of maturing cytoplasm was injected successively into immature oocytes. In three replicates about 220 pl of cytoplasm taken just after GVBD, was injected into an oocyte with intact germinal vesicle. Since this volume of injected cytoplasm, 1/4 of which barely induced maturation (Fig 1), was about 1/15 of the oocyte volume, the cytoplasm of the original oocyte which matured in response to 10^{-5} M 1-MA was diluted 15^4 times after the fourth injection. In spite of such extensive dilution, the rates of maturation of the recipient oocyte were, respectively, 100% (18 of 18), 88% (15 of 17), 93% (14 of 15) and 92% (12 of 13) in the first, second, third and fourth injections. Thus the cytoplasmic factor able to induce maturation was amplified in recipient oocytes during maturation.

Fig. 1 GVBD induced by microinjection of cytoplasm taken from 1-MA-treated oocytes of *A. pectinifera* Donor oocytes were treated with artificial seawater (ASW) containing 10^{-5} M 1-MA for 10 min and washed with ASW. Cytoplasm was removed from donor oocytes 20–25 min after the commencement of treatment with 1-MA and injected into immature oocytes with intact germinal vesicle, which were then placed in 80% ASW. This concentration was more suitable than normal ASW for injecting a large quantity of cytoplasm ●, Cytoplasm from 1-MA-treated oocyte; ○, cytoplasm from intact immature oocyte. Number of injected oocytes is shown in parentheses.



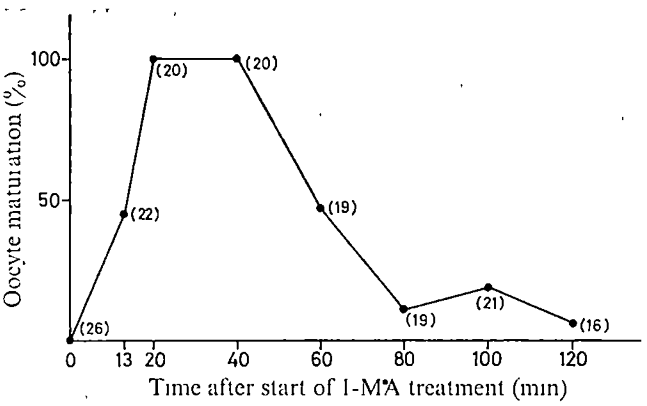


Fig. 2 Changes in the maturation-inducing capacity of the cytoplasm of 1-MA-treated oocytes during maturation in *A. pectinifera*. Donor oocytes were treated with ASW containing 10^{-5} M 1-MA for 10 min and washed with ASW. Number of injected oocytes is shown in parentheses.

These results are interesting when compared with data for oocyte maturation in frogs[8,9]. In *Rana pipiens*, pituitary gonadotropins seem to act on the follicular tissue to produce progesterone or a related substance which brings about oocyte maturation. Injection of progesterone into the oocyte fails to induce maturation, whereas external application to oocytes free of follicle cells is effective. But the cytoplasm of progesterone-treated frog oocytes can also induce maturation when injected into immature oocytes. Therefore, progesterone is considered to act externally on the oocyte surface to produce a cytoplasmic factor called "maturation-promoting factor", which causes the oocytes of frogs to mature In the starfish, gonad-stimulating hormonal peptide is secreted from the nervous system to produce 1-MA in the follicle cells. 1-MA acts on the oocyte surface to produce and release a new factor in the cytoplasm which is the true inducer of germinal vesicle breakdown and meiotic maturation. Further work should be directed towards the characterisation of this factor.

We thank Professor Y. Hiramoto for advice on microinjection and Professor J. C. Dan for reading the manuscript. This investigation was supported in part by grants-in-aid from the Japanese Ministry of Education and the Ford Foundation.

Association of lipid oxidation with seed ageing and death

SEEDS usually exhibit their maximum germination potential soon after harvest, and as storage time increases, they lose vigour and eventually die. The rate of physiological ageing generally increases with increased moisture content and temperature[1]. In addition, certain xerophytic storage fungi (primarily *Aspergillus* spp.) can attack seeds in storage when seed moisture content is in equilibrium with relative humidities greater than 65% (ref. 1), and cause changes that mimic physiological ageing Physiological changes accompanying physiological ageing[1–5] and attack by storage fungi[5] have been catalogued, but the basic biochemical events leading to these changes are not known. Harrington[1] and Pammenter *et al.*[6], however, have suggested that oxidation of unsaturated lipids may lead to free-radical formation. Free radicals may then damage cellular membranes and react destructively with macromolecules. Similar suggestions have been presented to explain ageing in several other systems[7], and the results of experiments reported here indicate that free-radical formation may be important in seed deterioration. Theories of mechanisms of lipid oxidation indicate that fatty acids with two or more unsaturated bonds should be more labile and prone to form free radicals than more highly saturated acids[8,9]. Thus, if fatty acid oxidation and free-radical formation are occurring, the highly unsaturated acids should decrease as seeds deteriorate, whereas the quantity of saturated fats should remain constant in the absence of beta oxidation

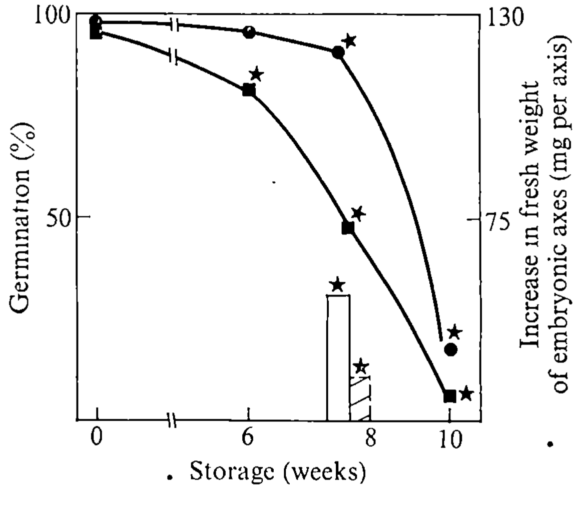
To determine whether these predicted changes occurred as a result of ageing and/or of infection by storage fungi, we used pea (*Pisum sativum* L. 'Alaska') seeds rendered microorganism-free or inoculated with *Aspergillus ruber* (Konig, Spieckermann, and Bremer) Thom and Church prepared as described elsewhere[5]. They were stored at 30 °C and 92% relative humidity. Periodically, seeds of different ages were removed from storage, and the percentage germination, the vigour, and the quantities of the major fatty acids in whole seeds and embryonic axes were determined. Seeds inoculated with *A ruber* were sampled only at 8 weeks, since visible infection (sporulation from the hila) does not commence until at least 6 weeks after inoculation. Only seeds with visible sporulation were used in these experiments. The percentage germination was determined by placing 30 seeds between sterile, wet paper towels, and counting the number of seeds germinating normally after 5 d incubation at 25 °C. A vigour rating was obtained by placing other seeds in the same conditions as for germination testing, and measuring the increase in fresh weight of the shoot–root axes after 3 d growth. This method measures the speed of germination and is correlated with several biochemical tests for vigour[5].

To determine the quantities of fatty acids, seeds were first lyophilised, and then ground to a fine powder in a Waring Blendor. Hydrolysis, methylation of fatty acids and extraction of the resulting esters was accomplished by a modification of the method of van Wijngaarden[10]. An aliquot (400 mg) of each subsample of ground pea seeds was placed in a 50-ml round bottomed flask, and 3 ml of 0.66 N methanolic KOH and 1 ml of heptadecanoic acid in methanol (1 mg ml^{-1} as an internal standard) were added to the flask The flask was then connected to a condenser, the mixture was brought to a slow boil for 5 min, 4 ml of BF_3 in methanol (14% w/v) was added through the condenser, and the mixture was boiled for a further 2 min Heptane was then added (1 ml), again through the condenser, the mixture boiled for an additional minute, and the condenser and flask then cooled rapidly in an ice bath. Sufficient saturated NaCl solution was added to the cooled mixture to bring it to the neck of the flask, and an aliquot of the heptane layer transferred to a vial containing a small amount of anhydrous Na_2SO_4. This heptane solution contained the fatty acid esters and was injected directly into the gas chromatograph. Separation was accomplished on a column (32 mm outside diameter and 1.8 m long) of Chromosorb WHP 100–120 mesh coated with 5% diethylene glycol succinate maintained at 150 °C. The carrier gas was N_2 at 10 ml min^{-1}. Detection was by a flame ionisation detector and quantitation was by integration of the area of each peak, corrected for the sensitivity of the detector relative to a heptadecanoic acid standard (determined earlier using known quantities of each of the fatty acid esters). The identities of the acid esters were verified by chromatography on 1% SE-30 (methyl), a non-polar gum rubber, using the same conditions as for the diethylene glycol succinate column. All experiments were conducted in triplicate.

The percentage germination of microorganism-free pea seeds decreased gradually from 0 to 8 weeks of storage, and then decreased markedly between 8 and 10 weeks (Fig. 1). Vigour, however, had decreased noticeably by 6 weeks of storage and declined more rapidly than germination during 8 weeks of storage. Between 8 and 10 weeks, vigour, like germination, decreased rapidly. The rapid decline of vigour compared with viability (germination) as a consequence of ageing has long been noted[12], but its cause is unknown. Seeds infected with *A. ruber* showed reduced vigour and germination compared with similar seeds stored in aseptic conditions.

The principal fatty acids of pea seeds were identified as palmitic, stearic, oleic, linoleic and linolenic acids. No treatment changed the concentrations of the saturated or monoenoic acids (palmitic, stearic, and oleic) in whole seeds or embryonic axes. The concentrations of these acids in whole seeds were 2.0, 0.50, and 5.1 mg per g dry weight, and those in axes were 1.8, 0.25, and 5.8 mg per g dry weight, respectively. The concentration of both the di- and trienoic acids (linoleic and linolenic), however, were affected by both storage and infection (Fig. 2). In whole seeds, the concentration of linoleic acid declined gradually with increased storage, and there was no additional decrease after infection. There was no significant change in linoleic acid concentration in the axes, larger changes were observed with linolenic acid: in whole seeds, only about 50% of linolenic acid remained after storage for 10 weeks with the most dramatic decrease of this acid occurring between

Fig. 1 Percentage germination of microorganism-free (●) and *Aspergillus ruber*-infected seeds (open column), and the increase in fresh weight of embryonic axes from microorganism-free (■) and *A. ruber*-infected seeds (hatched column) after 3 d germination Starred points (★) are significantly different (*K* = 100) from values obtained from unaged seeds according to the test of Waller and Duncan[14].



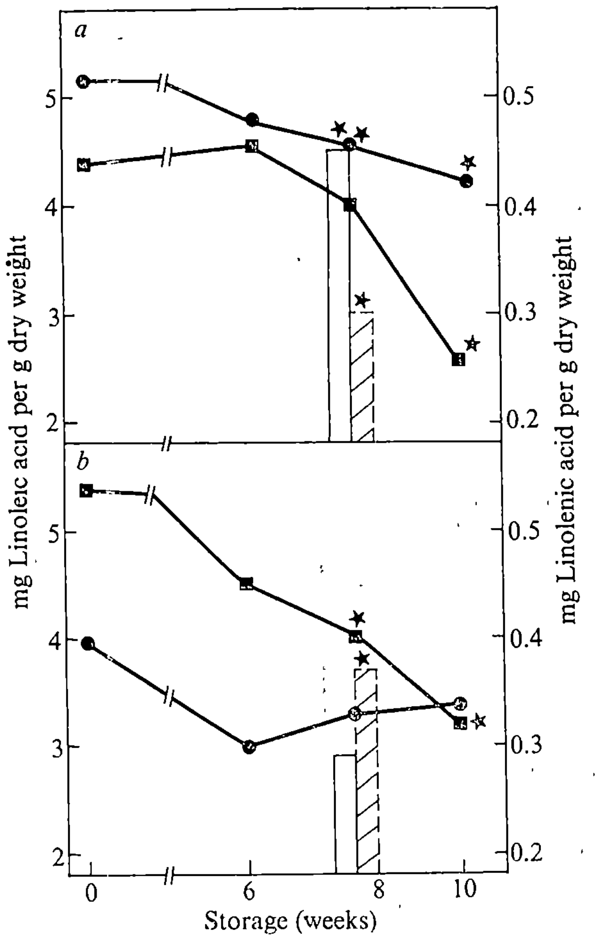


Fig. 2 Changes in the concentration of linoleic and linolenic acids in whole pea seeds (*a*) and in embryonic axes (*b*) after storage for various times The concentration of linoleic acid in microorganism-free (●) and in *Aspergillus ruber*-infected (open column), and the concentrations of linolenic acid in microorganism-free (■) and *A. ruber*-infected (hatched column) seeds are shown. Starred points (★) are significantly different ($K = 100$) from the levels obtained for unaged seeds according to the test of Waller and Duncan[14].

weeks 8 and 10. In embryonic axes, there was a rapid decrease in the quantity of linolenic acid with ageing, but no additional decrease as a result of infection by *A. ruber.*

These results suggest strongly that beta oxidation or other utilisation of fatty acids does not occur in stored seeds, since the saturated and monoenoic acids did not change in concentration. The rapid decrease in linolenic acid with ageing in axes roughly paralleled the loss of vigour of the seeds and suggests that free-radical formation may be a factor in loss of seed vigour and, subsequently, seed death. Changes occurring in the axes are probably of more consequence to the overall health of the seed than those occurring in the whole seeds (cotyledons, axes and seed coat), since only the axes are capable of growth. They should also be more sensitive to oxidation processes since they are rather small structures, comprising ~ 1% of the total seed weight, attached to the outer surface of the embryo Toxic materials formed in the cotyledons as a consequence of oxidation could, however, be transported to the axes and cause damage.

Changes in linoleic acid were less pronounced than changes in linolenic acid; this was expected since linoleic acid is less reactive than linolenic acid[9], and since it is present in an approximately tenfold higher concentration than linolenic, relatively small changes (less than ~ 0 5 mg g^{-1}) are difficult to detect.

A. ruber infection caused a statistically significant reduction in the quantity of linolenic acid in whole seeds, but not in axes (Fig. 2). Any explanation of this phenomenon must consider that *A. ruber* damages pea embryos by way of a diffusable substance, since the fungus is restricted to the seed coats and rarely invades living embryos[13]. The *A. ruber* toxin could somehow initiate oxidation without a pronounced effect on the subsequent oxidation rate. Thus, in axes where oxidation due to ageing occurred before infection was heavy, lipid oxidation would not be strongly affected by *A. ruber* infection, whereas in whole seeds (primarily cotyledons), the processes of initiation could still be occurring. More information on the mechanisms of oxidation as a consequence of ageing and infection is needed before any conclusions can be drawn on the relative effects of ageing or infection on the oxidation of fatty acids.

The correlations shown here, particularly between the disappearance of linolenic acid, loss of seed vigour and seed death, thus indicate that free radical formation may well be an important factor in seed deterioration

We thank Glenda Nash for technical assistance and John Barnard for statistical analyses.

Enrichment of antigen-specific helper and suppressor T cells

LYMPHOCYTES are known to differ on the basis of their antigen specificity, as postulated by Burnet[1], and experimentally confirmed by a variety of techniques[2–5]. Although there are many problems involved in purifying cells reactive to a given antigen there have been successful reports. These include the purification of rosette-forming cells[6], the separation of cells binding fluoresceinated antigen on a cell sorter[7], and the recovery of cells which have bound to an antigen matrix[8] or a cell surface[8–10]. The use of gelatin[8,11] substrates has proved to be successful in the purification of B lymphocytes, with enrichment of antigen-specific cells estimated in the order of 100-fold[11,12] Because antigen-binding T cells bind better at 37 °C than at 4 °C (refs 13 and 15), collagen gels were used in this study, as gelatin melts at 37 °C. A procedure for the enrichment of antigen-specific T cells should provide an essential step in the approach to many problems of understanding T cells and their function, such as the nature of T-cell receptors on subpopulations of T cells, the nature of mediators of T-cell function (especially antigen-specific mediators) and the mechanisms and control of T-cell activation. Here we describe a method for the selective enrichment of T cells reactive to protein or synthetic polypeptide antigens, and demonstrate the selectivity and specificity of the procedure by cross absorption experiments. The general applicability of the procedure was verified by using T cells immunised *in vivo* or *in vitro*, and by demonstrating 100-fold enrichment with different subpopulations of T cells, namely carrier-specific helper and carrier-specific suppressor cells involved in the *in vitro* antibody response.

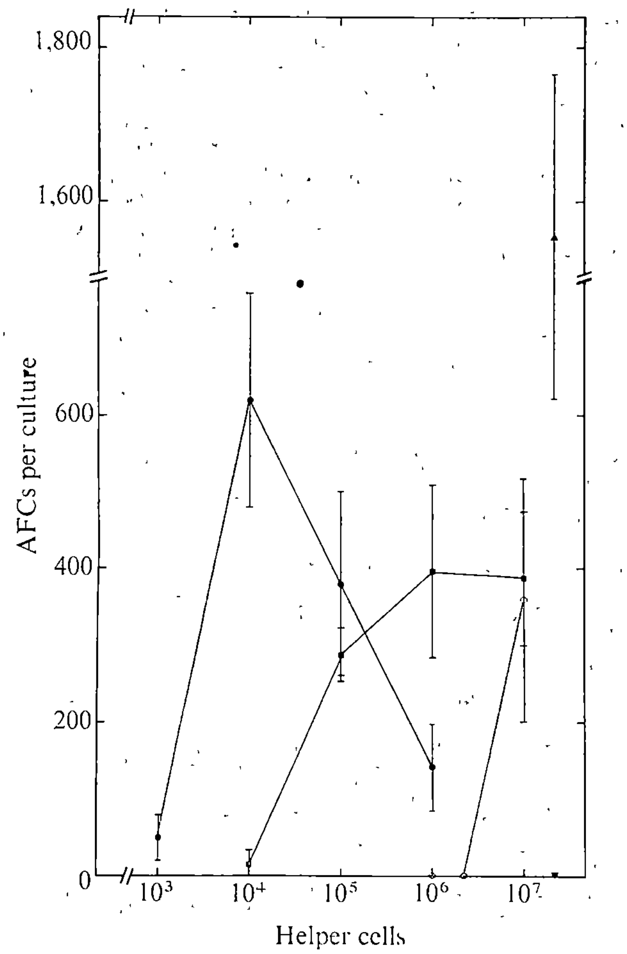

Fig. 1 Enrichment of helper cells from mice primed *in vivo*. ●, Adherent cells; ■, unfractionated cells; ○, non-adherent cells. Spleen T cells from mice primed 3 times with TNP–KLH adsorbed on bentonite[27] were passed through nylon wool[28]. The passed cells contained 4% cells stainable with fluoresceinated anti-Ig (B cells) and 95% cells stainable with anti θ. These cells were plated on keyhole limpet haemocyanin (KLH) derivatised collagen gels. Cell suspensions (20×10^6–35×10^6 cells per 2 ml) in HEPES (15 mM) buffered Eagle's (HEM) were incubated on a rocker for 60 min at 37 °C Non-adherent cells were removed by aspiration followed by 2 washes with HEM. Adherent cells were recovered from the gels by digestion with collagenase (Worthington Biochemicals Co), 180 μg per plate in 2 0 ml HEM for 90 min at 37 °C, followed by centrifugation and resuspension in a small volume of HEM containing 10% foetal calf serum. The specific binding of the populations used was 1–2% of the cells applied, and nonspecific binding, to collagen itself, or derivatised collagen (with another protein) was 0.5% The helper capacity of the 2 fractions was compared with that of the unfractionated T cell *in vitro*, using unprimed CBA spleen (sometimes anti-T treated spleen) as a source of B cells and 0.1 μg ml^{-1} trinitrophenylated KLH (TNP–KLH) as antigen. Cultures were performed in Marbrook–Diener flasks as described in detail elsewhere[25,29]. Antibody-forming cells to DNP or TNP were assayed after 4 d in culture[25,29] Gels used in this study were made from acid-soluble rat tail tendon collagen, 0.1% in 0.1 M acetic acid, layered in Petri dishes (usually Sterilin 50 mm), and the gels formed by exposure to ammonia Binding of antigen to the gels was performed following periodate oxidation of the gels with 0 1% sodium periodate (BDH) for 1 h at room temperature in the dark The gels were washed with phosphate-buffered saline (PBS) and the protein solution (usually 0 1–1.0 mg ml^{-1}) was added and left overnight The gels were then washed with PBS and HEM, and usually used immediately Occasionally they were stored in the cold for up to 4–5 d. Arithmetic mean ±s e m. of 3 cultures per group (for all groups). Analogous results were obtained in 7 experiments of this type with KLH and 5 with chicken gamma globulin.

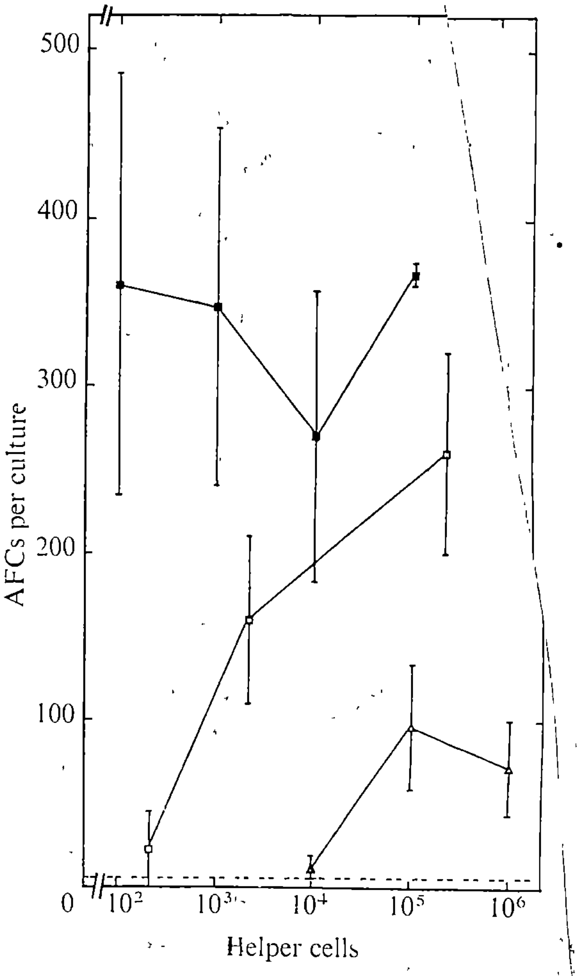

Fig. 2 Enrichment of *in vitro* primed helper cells to KLH ■, Adherent cells; □, unfractionated cells; △, non-adherent cells T-helper cells were induced by culture for 4 d in Marbrook flasks with low concentrations of antigen[16]. Surviving cells were plated on KLH gels and the adherent and non-adherent fractions were collected and compared for their helper capacity *in vitro*, as described in the legend to Fig. 1. As few as 100 adherent cells sufficed for an optimal helper response, compared with 10^5 of the unfractionated cells. 10^6 non-adherent cells were less efficient than 10^2 adherent, verifying that the technique both enriches and depletes for antigen-specific cells. Note that the depletion in this (and all other) experiment is not complete. Three experiments of this type have been performed with analogous results.

Nylon wool-purified T cells from mice primed to keyhole limpet haemocyanin (KLH) were incubated with KLH derivatised collagen (1 mg per 50-mm dish was found to be optimal) for 60 min on a rocker at 37 °C. The non-adherent cells were removed and the gels rinsed and digested with collagenase. In all experiments the viability of the adherent cells was about 90%.

The helper capacity of three fractions were compared: (1) the nylon-purified T cells, (2) the cells adherent to the KLH and (3) the non-adherent cells. Titrations were performed *in vitro*, comparing the numbers of *in vivo* primed T cells needed to generate anti-dinitrophenyl (anti-DNP) antibody responses, using normal spleen as a source of antibody-forming cell (AFC) precursors and triphenylated KLH (TNP–KLH) as antigen. As shown in Fig. 1, the adherent cells were about 30 times more efficient helper cells than the unfractionated T cells. The T cells which did not adhere to the KLH gels were depleted of helper cells by about 100-fold

Analogous experiments were also performed with helper cells obtained from tissue culture[16]. These helper cells, perhaps being more recently in contact with antigen, are effective in smaller numbers (optimum in range 10^3 to 5×10^5) than helper cells from primed mice. Such cells

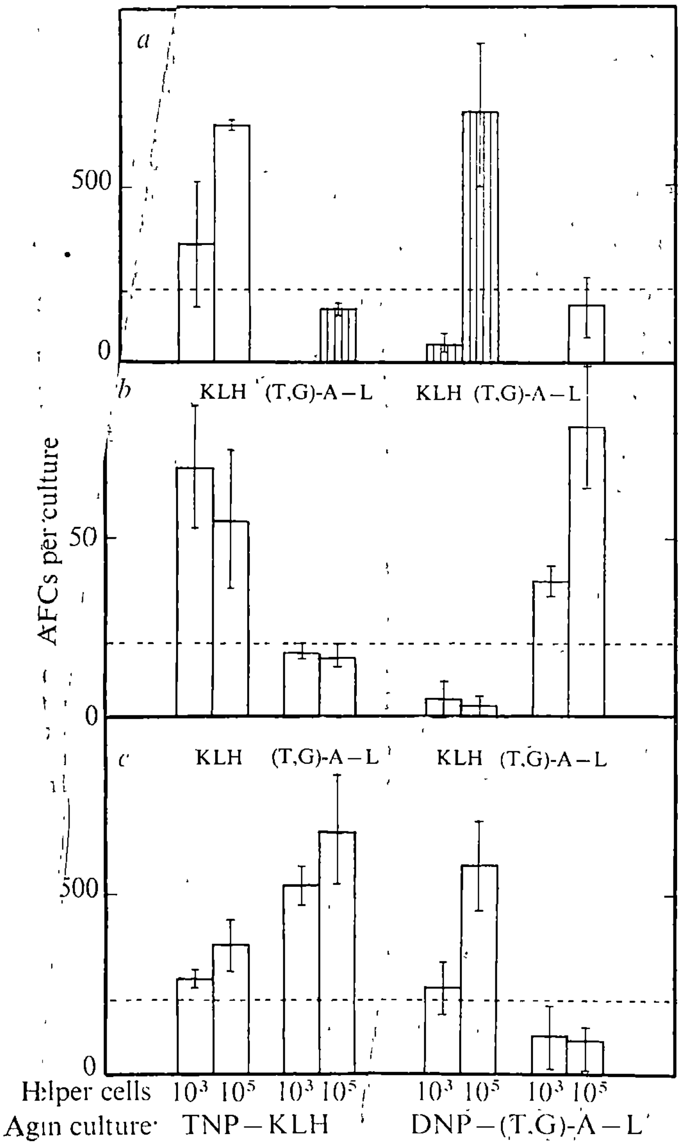

Fig. 3 Specificity of the enrichment of *in vitro* induced helper cells. Spleen cells were cultured with either KLH or (T,G)-A–L to induce helper cells. To determine the specificity of binding of helper cells to antigen-coated gels, KLH and (T,G)-A–L specific helper cells were mixed in equal numbers and applied to either KLH or (T,G)-A–L gels The adherent and non-adherent cells were tested for their helper capacity for both (T,G)-A–L and KLH by culture with spleen cells containing 1.0 μg ml^{-1} DNP–(T,G)-A–L and 0.1 μg ml^{-1} TNP–KLH respectively. Cells adherent (*b*) to KLH gels provided excellent help when challenged with TNP–KLH (for example, 700 AFC with 10^3) cells but did not help when challenged with DNP–(T,G)-A–L (180 with 10^3 cells) thus verifying the specificity of the absorption. In a reciprocal way, cells non-adherent (*c*) to KLH gels provided better help when stimulated with DNP–(T,G)-A–L than with TNP–KLH. *a*, Unfractionated cells, plated on KLH or (T,G)-A–L gels, and tested as shown Two cell doses were used (10^3 and 10^5). Two experiments of this type have yielded analogous results. Background (no helper cells added) is indicated by dotted lines.

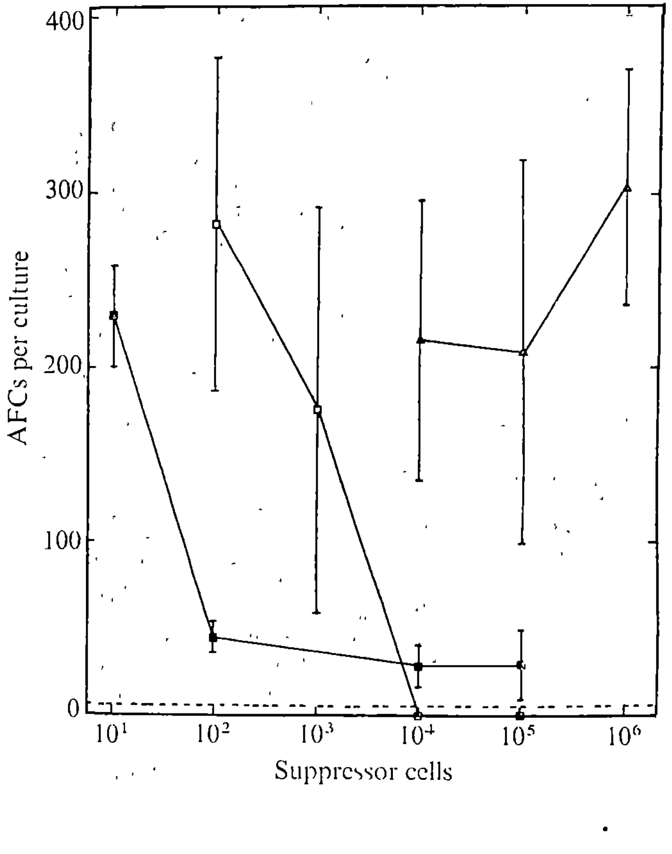
were incubated with KLH collagen, as described (see legend to Fig. 1) and divided into adherent and non-adherent populations The adherent cells were highly efficient helper cells, with 100 cells sufficing for an optimal response (Fig. 2). This represents an enrichment factor of ~ 10^3 Repeat experiments have yielded analogous results, with the enrichment varying from 100- to 1,000-fold. The depletion of helper cells is hard to assess precisely as it is not possible to add very large numbers of cultured helper cells to the test cultures, because of the suppressive effects of these cells if added in excess of 10^6. In Fig. 2 the depletion is 100-fold. In other experiments it has ranged from 10- to 100-fold. These experiments demonstrated the capacity of the technique to enrich for KLH reactive cells, or in other experiments, chicken gamma globulin or cells reactive to (T,G)-A–L (a random copolymer of L-tyrosine, glutamic acid, coupled to DL-alanine side chains, attached to poly L-lysine backbone) have been purified. Since there was appreciable nonspecific binding (~ 0.5%) it was of importance to establish that the cells binding nonspecifically do not belong to a given subpopulation of T cells. It could be argued, for example, that helper cells (of any antigenic specificity) are preferentially retained on collagen. To exclude this possibility, and to demonstrate further the specificity of cell selection, helper cells immunised to KLH and (T,G)-A–L *in vitro* were mixed, and the mixture plated on KLH or (T,G)-A–L gels. Adherent and non-adherent cells were recovered from each, and both fractions tested with both DNP–(T,G)-A–L (for (T,G)-A–L helper cells) and TNP–KLH, for KLH helper cells. The results (Fig. 3) show that there is no detectable cross contamination of enriched helper-cell populations. Since as many as 10^5 adherent cells to one antigen, KLH, did not stimulate responses to (T,G)-A–L whereas 10^3 were sufficient for optimal help to KLH, the degree of contamination was less than 1%. Results of this type indicate that the usual nonspecific binding (~ 0.5%) is not selective for helper cells in general, and that the enrichment for helper cells is through their antigen specificity.

Another major class of T cells involved in antibody responses are suppressor cells (reviewed in ref 17). These may be specific or nonspecific. It was of interest to ascertain

Fig. 4 Enrichment of KLH-specific suppressor cells induced *in vitro*. Suppressor cells were induced by incubation of CBA mouse spleen cell with 100 μg ml^{-1} KLH for 4 d *in vitro*[30]. These cells suppress the action of KLH helper cells *in vitro* in an antigen-specific manner, and are assayed by their capacity to suppress the cooperative response of (usually) 3×10^5 *in vitro* educated helper cells and 15×10^6 normal spleen cells stimulated with 0.1 μg ml^{-1} TNP–KLH. As shown 10^4–10^5 suppressors suffice to inhibit this response After adherence to KLH gels the efficiency of these cells was augmented 100-fold, likewise the non-adherent cells were depleted of suppressor cells by 100-fold. ■, Adherent cells; □, unfractionated cells; △, non-adherent cells. Four experiments of this type have been performed with analogous results.



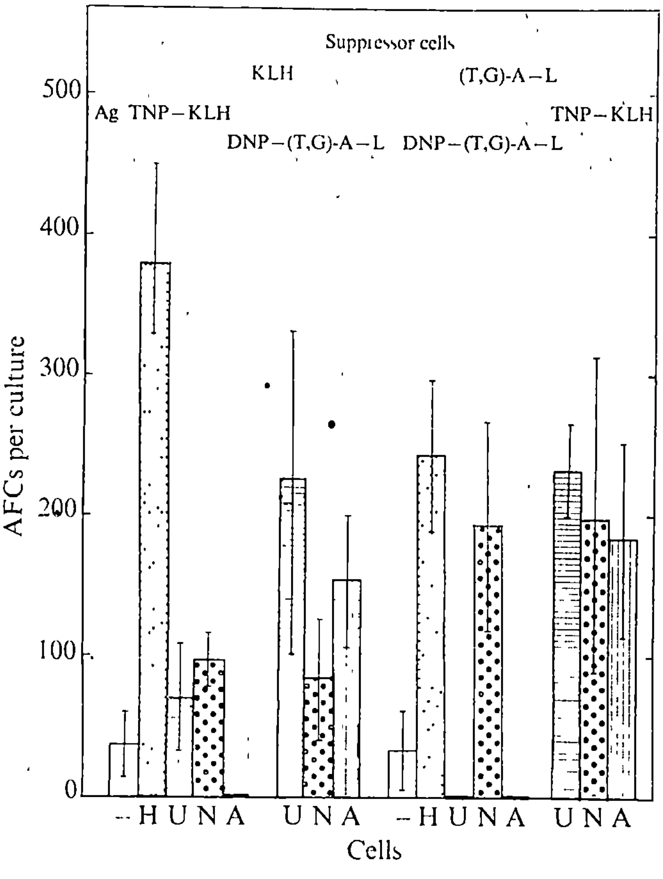


Fig. 5 Specificity of the enrichment of suppressor cells. Suppressor cells were induced *in vitro* to KLH and (T,G)-A–L. A mixture of suppressor cells were plated on KLH and (T,G)-A–L gels, and the adherent and non-adherent cells tested for their suppressor activity directed to KLH or (T,G)-A–L. As shown, KLH suppressors inhibited the response to TNP–KLH but not to DNP–(T,G)-A–L. Cells which adhered to KLH gels suppressed the response to KLH, but not to DNP–(T,G)-A–L, and vice versa. For simplicity, the results with 10^5 cells are shown. By dilution analysis the degree of specificity is > 100-fold. —, Background; H, helper cells, U, unfractionated, suppressor cells; N, non-adherent; A, adherent suppressor cells. Two experiments of this type have been performed with analogous results.

whether suppressor T cells could also be partly purified with antigen coated gels. Suppressor cells specific for KLH were obtained from cultures stimulated with a high concentration of KLH. These suppressor cells are assayed by their capacity to inhibit the response induced by KLH-specific helper cells. Figure 4 indicates that small numbers (10^5–10^4) of such suppressor cells suffice to abolish the response totally. After adherence and recovery from KLH gels, as few as 100 cells were sufficient to abolish the response, again yielding an enrichment factor of 100-fold. Repeat experiments yielded enrichments of 100–1,000-fold. The degree of depletion of suppressor cells, was, however much less satisfactory, probably because so few cells suffice for suppression. The results have varied, but a single passage on KLH gel resulted in 10–100-fold depletion, more usually nearer tenfold.

To test the specificity of the purification of suppressor cells, a mixture of KLH and (T,G)-A–L suppressor cells was purified on KLH or (T,G)-A–L gels, and the unfractionated, adherent and non-adherent (to both gels) cells were tested for suppression of the response to DNP–(T,G)-A–L or TNP–KLH. Figure 5 illustrates such an experiment, which indicates that only KLH suppressors bound to KLH, and (T,G)-A–L suppressors to (T,G)-A–L. By dilution analysis, the degree of contamination was less than 1% (full data not shown).

The results indicate that collagen is a useful substrate for the partial purification of antigen-specific T cells. It was successful with T cells primed *in vivo* or *in vitro*, with two different functional subclasses of T cells, helper cells and suppressor cells (which have recently been shown[18] to be phenotypically different).

The difficulty in demonstrating antigen-binding T cells[13,15], taken together with the increasing evidence that mouse cytotoxic T cells preferentially recognise H–2D or H–2K specificities (see for example ref. 19) and virus[20,22] or hapten modification[23], thereof, and since T cells cannot respond to antigen in the absence of macrophages[24,25], it has been suggested that, unlike B cells, T cells may only respond to antigen-modified self components, particularly transplantation antigens. Because we have succeeded in purifying helper T cells on antigen–collagen gels and this binding is blocked (by > 90%) by free antigen (to be published) it is clear that T-helper cells, at least, do have receptors for the antigen (for example KLH) *per se*. Similar considerations apply to antigen–collagen purified suppressor cells, and the results (Figs 4 and 5) together with analogous experiments performed with suppressor cell populations, in the absence of helper cells (which were killed by anti-Lyl antiserum[18]) indicate that suppressor cells can recognise antigen, and eliminate the possibility that suppressor cells can only recognise idiotypic determinants[26].

We thank Dr Edna Mozes for gifts of (T,G)-A–L, Dr Marvin Rittenberg for KLH, Dr P. Beverley for enumerating T and B cells and Mrs M. Dunkley for technical assistance. A.M. holds an EMBO long term fellowship. The authors wish to thank their colleagues for critically reading this manuscript.

Immunoglobulin-bearing cells in bone marrow of mice after prolonged treatment with anti-IgM antibodies

IN the chicken, differentiation of immunoglobulin (Ig)-bearing cells occurs in the bursa Fabricius[1,2]. Removal of the bursa at various times in the perinatal period[3-5] and/or administration of anti-μ chain antibodies have led to the postulate that IgM-bearing cells give rise in a sequential manner to cells with IgG and IgA on their surface[6]. Thus, administration of anti-μ to chicken embryos results in the elimination of cells bearing Ig of all classes, and in a depression in the synthesis of both IgM and IgG[7]. Administration of anti-μ to neonatal mice has also been shown to lead to a decrease in the serum level of all Ig classes, as well as a reduction of all Ig-bearing cells in the spleen, suggesting that the maturation sequence of Ig-bearing cells in birds and in mammals may be similar[8-10]. Recent work by one of us (D.G.O.) has shown that in mice the bone marrow is a site of production and differentiation of Ig-bearing lymphocytes, suggesting that the bone marrow may be a mammalian equivalent of the bursa of Fabricius[11-13]. The aim of the present investigation was to establish the distribution of lymphocytes bearing various Ig classes in the bone marrow of mice treated with anti-IgM, and compare it with that in normal bone marrow. The results indicate that anti-IgM injections prevent the development of lymphocytes bearing Ig of all classes in mouse bone marrow. In addition, most of the "null" small lymphocytes and many large lymphoid cells, hitherto found to be devoid of detectable surface Ig[11-14], are also eliminated.

The anti-IgM serum administered to mice was produced in rabbits by methods modified from those of Murgita *et al.*[8] and Crowle *et al*[15]. IgM was purified from the sera of BALB/c mice bearing myeloma 104E. Specific precipitates of the IgM with rabbit anti-IgM serum were injected into rabbits twice, 2 weeks apart, and were followed by a booster injection of 1 ml BALB/c serum. The animals were bled 5 d later. Serum, pooled from 64 rabbits, was twice precipitated with ammonium sulphate at 50% and 33% saturation respectively, absorbed with rat and mouse erythrocytes to remove natural red cell agglutinins, Millipore filtered, and stored in the frozen state. The final preparation had a protein concentration of 138 mg ml^{-1}; in gel diffusion in a dilution of 1 : 32 it reacted with a purified IgM preparation (Bionetics Laboratory Products), while against BALB/c serum it gave a single line of precipitation identified by immunoelectrophoresis as IgM.

The mice used in all the experiments were DBA/2 (Jackson Laboratories). One-day-old mice were injected intraperitoneally with 5 mg or 10 mg anti-IgM globulin, followed by maintenance injections of the same amount, three times weekly. A second group of experimental animals consisted of 9-week-old males, X irradiated (950 r.) and reconstituted with 2, 5 or 10×10^6 syngeneic bone marrow cells. They received 75 mg or 200 mg anti-IgM globulin 5 d later, followed by maintenance injections of 20 mg antibody globulin 3 times weekly. Controls consisted of untreated mice, or X-irradiated mice, repopulated with bone marrow, and injected with physiological saline.

Autoradiography of antiglobulin-binding cells was performed as described previously[14]. Antibody used to detect IgM-bearing cells in the first group of mice was purified by chromatography on DEAE–Sephadex from the rabbit anti-IgM pool used to inject the mice. The antisera used for the second group of animals were monospecific, anti-μ, anti-γ1, anti-γ2 and anti-α (Meloy Laboratories), precipitated with ammonium sulphate at 50% saturation. All preparations were iodinated with ^{125}I (specific activity 1.5×10^7 Ci mg^{-1}) according to the procedure of Hunter and Greenwood[16]. Femoral marrow and spleen cell suspensions were mixed at 0 °C for 30 min with the ^{125}I-antisera and washed twice through foetal calf serum gradients. The final concentration of antibody in the first preparation was 10 μg ml^{-1}; that in the commercial antisera was unknown. Smear preparations were dipped in melted Kodak NTB2 emulsion and exposed for 3 d.

Two mice injected with anti-IgM from birth were killed at 3 months of age. Autoradiographs of cells exposed to ^{125}I-anti IgM showed that 1% or less of the small lymphocytes in the spleen were IgM bearing (> 10 grains per cell) compared with 53.3% in control spleen (Table 1). In the bone marrow, IgM-bearing small lymphocytes totalled only 0.3% or less of all nucleated cells as a result of great reductions both in the total number of small lymphocytes and in the proportion showing ^{125}I-anti IgM labelling (Table 1). The small number of residual bone marrow small lymphocytes may represent mainly recirculating T lymphocytes[11-13]. The incidence in the bone marrow of large lymphoid (transitional) cells, which include the immediate precursors of small lymphocytes, was also reduced from 2.0% in the controls to 0.2% in anti-IgM-treated mice. In a separate experiment, bone marrow and spleen cells from two mice treated with anti-IgM serum for the first four weeks of life showed a similar depletion of IgM-bearing cells (mean: marrow, 0.7%; spleen, 1.1%) compared with two normal controls (mean: marrow, 39.6%; spleen, 66.4%). These results confirm the findings of a previous report, indicating depletion of Ig-bearing cells in the spleen of mice injected with anti-μ antibodies as newborn[9], and extend them to the bone marrow.

Three irradiated, marrow-reconstituted adult mice were injected with anti-IgM for 3 months and were 22 weeks of age when studied by autoradiography. The incidence of cells bearing Ig of various classes in the spleen and bone marrow of these animals and in two groups of controls is shown in Table 2.

The results in the two groups of controls are comparable, suggesting that repopulation is complete 3 months after X irradiation and bone-marrow reconstitution. The incidence of IgM-bearing cells in the spleen of these mice is rather high when compared with other reports[14,17], while the number of IgA-bearing cells is lower than reported previously[17]. These differences may be due to differences in the age and strain of mice used, or in the reagents employed. In the bone marrow, the large proportion of IgM-bearing cells agrees with previous findings[14]. The incidence of small lymphocytes bearing the other Ig heavy chains has not been reported previously in mouse bone marrow. The IgG$_2$-bearing cells in the bone marrow are clearly more numerous than could be due to immigrant cells[12,13], indicating that they are part of the indigenous population of small lymphocytes maturing in the bone marrow. This supports the view that murine bone marrow has bursa-like properties. It remains to be shown whether the smaller numbers of

‡ No labelled intact small lymphocytes were seen on extensive scan.

IgG_1 and IgA-bearing lymphocytes are also produced locally in the bone marrow, or are simply part of the recirculating lymphocyte pool.

Treatment of adult X-irradiated, bone marrow-reconstituted mice with anti-IgM resulted in the virtual elimination of all Ig-bearing small lymphocytes from the spleen and bone marrow (Table 2). As with newborn mice treated with anti-IgM, the few Ig-bearing small lymphocytes detected were pycnotic in appearance and their labelling was generally near threshold (approximately 12–15 grains, compared with heavy labelling, frequently exceeding 30 grains per cell, in controls). These experiments constitute the first successful application of anti-IgM to suppress the generation of Ig-bearing lymphocytes in adult animals. It has been reported that administration of anti-μ chain antibodies does not suppress IgM synthesis in normal adult[3], or 7-d-old mice[18]. Our results demonstrate that anti-IgM can be suppressive in the adult animal after X irradiation and bone marrow reconstitution. A full report describing the immune status of these mice will be published elsewhere (J Gordon, *et al.*, in preparation).

The mode of action of anti-IgM and the identity of the target cell are not entirely clear. Probably, anti-IgM acts primarily on early precursors of Ig-bearing cells. Supporting this view are the present observations in the bone marrow that anti-IgM treatment eliminates "null" (Ig−ve; Thy 1−ve) small lymphocytes, previously shown to be the youngest marrow small lymphocytes[11], and many large lymphocyte precursor cells. The question may be raised how anti-IgM can affect these cells on which sensitive autoradiographic techniques fail to reveal Ig[14]. The answer may be given by recent data of Melchers *et al.*[19], demonstrating a subpopulation of rapidly sedimenting marrow cells which synthesise 7–8S IgM with a considerably more rapid turnover than that of mature small lymphocytes. Conceivably, cells having such a rapid transport and release of endogenous IgM through their surface membrane may be sensitive to anti-IgM, yet apparently Ig-negative by conventional antiglobulin-binding techniques[19].

Not all types of Ig-bearing cells were eliminated by anti-IgM treatment in adult mice. In both the spleen and bone marrow, well marked antiglobulin binding was still shown by a small number of plasma cells bearing IgG_1, IgG_2 and IgA, as well as monocytoid cells, large macrophages, and damaged cells, bearing each heavy chain immunoglobulin class. Further work is required to determine the origin and significance of these cells.

The present results are consistent with the model according to which IgM-bearing cells give rise to lymphocytes carrying all other classes of immunoglobulins[6]. Murine bone marrow, like the avian bursa of Fabricius, seems to be the site of an IgM to IgG_2 sequence during lymphocyte maturation.

This work was supported by the MRC of Canada and the National Cancer Institute of Canada. We thank Miss Els Schotman and Mrs P. Young for technical assistance.

Soluble factors substitute for T–T-cell collaboration in generation of T-killer lymphocytes

IMMUNOLOGICAL responses to histoincompatible tissues and to tumour cells are mediated by thymus-derived (T) lymphocytes. The cells that effect these responses have been termed cytotoxic T-killer cells and are derived from T-precursor cells that have become programmed (committed) to recognise specific antigenic determinants. The generation of T-effector or killer cells involves the collaboration of two distinct subpopulations of T cells. Helper T cells interact with specific precursor T cells when stimulated by antigen and, during the resultant differentiation processes, the precursor clones mature into specific killer cells[1–3]. The nature or mechanisms of the collaboration between the precursor and helper T cells has been obscure until now. The data presented here demonstrate that soluble T-cell products can replace the requirement for helper T cells in the generation of T-killer cells. The active substances are produced on antigenic stimulation and are as effective as T-helper cells during the differentiation of precursor T cells into killer cells.

Antigens of the murine major histocompatibility complex, *H-2*, were used. H-2-associated antigens served both as the stimuli for the precursor and helper T cells and as targets for the immunologically activated cells. An antigen associated with the *H-2* complex also served as a cell-surface marker for a helper

* A total of 10^6 viable and washed cells were cultured with an equal number of stimulating cells for 98 h including an 18-h pulse with 0.5 μCi ^{3}H-thymidine per ml. Procedural details are outlined in Table 2.

† B10.A anti-B10.D2 serum plus rabbit serum as a source of complement.

‡ (AKR×RF)F_1 anti-C58 thymus cells

T-cell subpopulation. The precise *H–2* genetic region coding for the T-helper cell antigen is under investigation. The helper cell antigen is temporarily designated Ha.

The anti-helper cell serum (anti-Ha) was raised in B10.A mice against B10.D2 lymph node cells (LNCs). These congenic resistant partners differ at *H–2K* and portions of the I region of the *H–2* complex. Anti-Ha serum greatly depresses the T-cell responses of C57BL/10 LNCs to foreign H–2 antigens, *in vitro*[4] (Table 1). The effectiveness of the anti-Ha serum against the responding cell population is demonstrated by the elimination of a response to B10.A(2R)-stimulating cells (Table 1). B10.A (2R) cells are insensitive to lysis by the B10.A anti-B10.D2 serum and share *H–2K* and I-region specificities with the B10.A antibody producer[5]. Although a proportion of the cytotoxic activity to C57BL/10 cells is directed against an I-region antigen on B cells[6], depletion of non-T cells is not responsible for the depressed T-cell activity, as the mixed lymphocyte responses (MLRs) could not be restored by addition of syngeneic B cells (Table 1) in increasing numbers or of macrophages[4]. Cell-free factors produced by activated T cells could, however, reconstitute the ability to respond.

Table 2 Effect of supernatant factors on killer-cell development in cultures containing C57BL/10 cells pretreated with NMS, B10.A anti-B10.D2 (anti-Ha) serum or anti-θ serum plus complement and mixed with irradiated B10.D2 cells

Serum pretreatment of responding cells		Additions to sensitising cultures*			
		Medium	Supernatant	Medium	Supernatant
		% ^{51}Cr release†		Total killing activity‡	
Experiment *A*§	Anti-Ha+RC	17.1	52.8±2.5	11	169

* Either 1.0 ml of fresh medium or of diluted supernatant from activated C57BL/10 LNCs stimulated by B10.D2 cells was added to each culture on day 0. The final concentration of supernatant was 21% in experiment *A* and 17% in experiment *B*.

† Spontaneous ^{51}Cr release of P815-X2 target cells after 4 h was 7.7%±0.2 in experiment *A* and 10.7%±0.2 in experiment *B*. Data are presented as %±s.e.

‡ Total killing activity = % specific ^{51}Cr release × cell yield after 5 d in culture per 10^6 cells.

§ 1.0 ml of diluted serum (1:5) was added to a pellet of 15×10^6 C57BL/10 LNCs and incubated in a shaking water bath at 37 °C for 15 min. An equal volume of diluted RC (1:4) was added and the suspensions were incubated for a further 45 min Antiserum and RC were removed by centrifugation and the cells washed twice in fresh medium Equal numbers of remaining viable cells and irradiated B10.D2 cells (2×10^6 per 0.5 ml) were then cultured in RPMI 1640 medium supplemented to 0.01 M HEPES buffer, 8% human serum (heated at 56 °C for 30 min), 100 U penicillin G, 150 μg L-arginine, 2 mM L-glutamine and 75 μg kanamycin sulphate per ml.

¶ A sample of 1.0 ml of diluted serum (1:5) was added to a pellet of 4×10^7 C57BL 10 per LNCs and treated further as above before mixing with irradiated B10.D2 LNCs.

The soluble helper factor(s) was obtained through a two-step tissue culture procedure. C57BL/10 LNCs were first sensitised in culture for 4 or 5 d against irradiated B10.D2 strain LNC. The activated cells were then washed and mixed with an equal number of fresh stimulating strain LNCs. The cell mixtures (4 × 10^6 of each) were cultured in 1.0 ml of RPMI 1640 medium without serum, centrifuged at 200*g* for 5 min and incubated at 37 °C in a humidified atmosphere of 5% CO_2. Six hours later the cells were resuspended, pooled and centrifuged at 900*g* for 10 min. To ensure removal of all cells, the supernatant fluid was filtered through a 0.45-μm Millipore filter. The supernatants were either diluted and used immediately or frozen at −70 °C in the presence of 10% human serum.

The effects of the supernatant factor(s) on proliferative responses and the development of killer cells to allogeneic H–2 antigens were assessed with C57BL/10 LNCs that had been treated, before culturing, with either normal mouse serum (NMS), B10.A anti-B10.D2 serum (anti-Ha) or anti-θ serum (Thy-1.2) plus complement (RC). Rabbit serum extensively absorbed with mouse tissues served as the source of complement[7]. Anti-θ serum was raised in (AKR × RF)F_1 mice against C58 strain thymus cells. The effects of this anti-θ serum on the MLRs were reported previously[8].

The generation of cytotoxic killer T cells was greatly reduced in cultures of cells that remained after lysis with either anti-Ha serum or anti-θ serum plus RC (Table 2). The addition of the supernatant factor to the antibody-treated cells completely reversed the depressive effect of the anti-Ha serum but had no effect on killer cell development in cultures with anti-θ treated cells (Table 2).

Table 3 Effect of supernatant factors on the proliferative responses of C57BL/10 cells pretreated with either NMS, B10.A anti-B10.D2 serum (anti-Ha) or anti-θ serum plus RC

Serum pretreatment of responding cells	Supernatant concentration		
	0%	25%	6.25%
	Average c p.m. of ^{3}H-thymidine incorporation±s e.*		
Anti-Ha+RC†	1,889±636	11,495±304	10,108±53
NMS+RC†	42,353±5,859	46,494±1,594	41,069±735
Anti-θ+RC†	6,022±773	8,367±982	8,530±371

* The cultures were collected after 87 h which included a pulse of 0.5 μCi ^{3}H-thymidine per ml during the final 19 h

† The background c.p.m. of the serum treated cells were as follows: NMS+RC, 7,696; anti-Ha serum+RC, 146, and anti-θ serum+RC, 445.

C57BL/10 LNCs were treated with antiserum plus complement as outlined in Table 2. Equal numbers of viable serum-treated cells and irradiated B10.D2 cells (1.5×10^6 per 0.5 ml) were mixed 1.0 ml of either fresh medium or of diluted supernatants from C57BL/10 activated cells was then added to triplicate cultures of each combination.

Table 4 Effect of supernatant factors on the proliferative responses of non-stimulated and MLR-stimulated cell cultures

Cells cultured	Supernatant concentration*				
	0%	50%	25%	12.5%	6.25%
	(average c.p.m. of ^{3}H-thymidine incorporation±s.e.)†				
C57BL/10	2,253±33	3,240±571	2,585±187	3,473±446	2,325±123
C57BL/10+B10.D2 (1,000 rad)	11,852±1,852	15,581±549	18,749±1,092	15,341±1,415	10,065±1,059
B10.D2+C57BL/10 (1,000 rad)	8,875±1,883	18,148±3,610	13,897±1,069	16,015±1,069	5,814±1,264

* The supernatant used in these cultures was produced by C57BL/10 cells after activation with B10 D2 irradiated cells for 5 d.
† The cultures were collected after 66 h which included a pulse of 0.5 μCi ^{3}H-thymidine per ml during the final 18 h of culture.

Three conclusions can be drawn from these data. First, the C57BL/10 precursor T cells that respond to H–2 antigens are not lysed by the anti-Ha serum plus RC. We have also demonstrated that the depressive effect of this antiserum on MLR cannot be reversed by the addition of various numbers of cells remaining after lysis with anti-θ serum plus RC[4] (Table 1). Therefore, the depleted H–2 responsive cell must reside in the θ-antigen-bearing T-cell population but not, as demonstrated in Table 2, in the precursor subpopulation. The most likely target of the B10.A anti-B10.D2 serum, then, is the helper T cell.

Second, the supernatant factor(s) can serve functionally as an adequate substitute for the antibody-depleted cells in the generation of killer T cells. Although much information has been accumulated about T-cell replacement factors in B-cell-mediated responses[9–18], this is the first evidence that a stable soluble helper product mediates T–T-cell collaboration.

Third, one of the functions of the helper factor(s) is to increase the numbers of killer cells generated. The total yield of killer cell activity obtained from C57BL/10 cells treated with the anti-Ha serum and subsequently cultured with stimulating cells in the presence of the supernatant factor(s) was equivalent to that obtained with NMS-treated cells (Table 2). This increase in killing activity was probably accomplished through the enhancement of clonal proliferation of the precursor cells. Clearly, the helper factor provided a signal that was necessary for DNA synthesis (Table 3). The helper factor was active even at quite dilute concentrations, in the enhancement of the MLRs obtained with cells remaining after lysis with anti-Ha serum (Table 3). The helper factor(s) had only slight effects on the proliferative responses of cultures that either contained both (NMS + RC) or lacked both (anti-θ + RC) the precursor and helper T-cell subpopulations (Table 3). Similar results were obtained with C57BL/10 LNCs cultured without irradiated stimulating cells (Table 4). Enhanced proliferation of unsensitised cells was never greater than 2.5-fold over background in three separate experiments. The helper factor did enhance MLR-induced proliferation within a wide range of concentrations and apparently was not specific for the stimulating H–2 antigens (Table 4).

The difference between the levels of thymidine incorporated and the total yield of cytotoxicity generated in supernatant-supplemented cultures of cells remaining after lysis by anti-Ha serum is revealing. In the normal MLR, helper cells as well as precursors proliferate, thus both subpopulations contribute to the observed responses. The proliferative contribution of helper cells is lost, however, in cultures pretreated with anti-Ha serum. At the levels of supernatant tested, maximum ^{3}H-thymidine incorporation by the antiserum-resistant precursor cells is reached even at the lower concentrations (Table 3). The total yield of killer-cell activity in the supernatant-supplemented cultures of anti-Ha-treated cells is equivalent to that obtained with unfractionated T–T-cells (Table 2). Thus the sequence of events in the generation of T-effector cells seems to be: the release of soluble factors and proliferation of helper cells on contract with antigen and the subsequent stimulation of proliferation and potentiation of specific precursor cells by the helper factor and antigen.

The relationship between the helper factor described here and the T-cell replacement factors that function in mediating B-cell responses is being investigated. Many of the factors that help in antibody production have been obtained from allogeneic cell cultures. The nonspecific allogeneic effect factor[17] and the specific T-cell factor of Munro and Taussig[18] which mediate B-cell responses are of particular interest as each can be removed with anti-H–2 serum-conjugated immunoabsorbants. It is possible that the H–2-associated marker detected on the helper T cells is similar or identical to a determinant on the soluble helper substance probably produced by these cells. This helper cell marker is expressed by a small proportion of T-effector cells and the end-stage or mature killer cells may no longer express the antigen[4]. This supports the notion that the H–2-associated helper cell marker is also expressed by the soluble helper product and that it functions in the differentiation of the precursor T cells to effector T cells.

I thank B. Allitto, B. Malynn and C. Pinto for technical assistance and Dr D. B. Amos for critical evaluation of the manuscript. This work was supported by a grant from the National Cancer Institute.

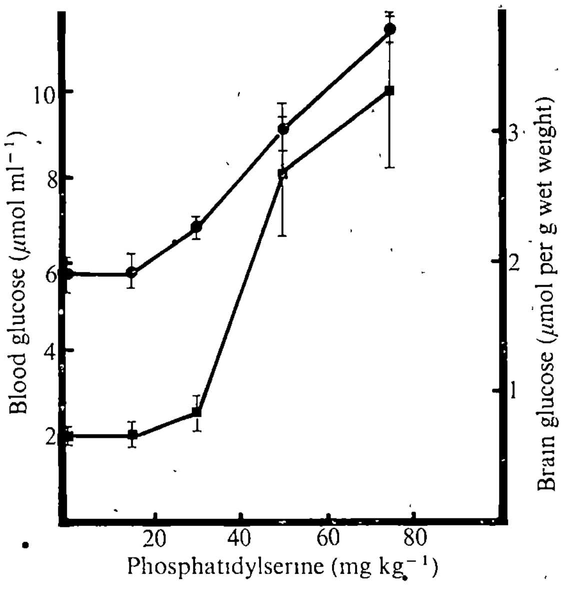
Pharmacological effects of phosphatidylserine liposomes

PHARMACOLOGICAL studies on diacylphospholipids develop along two lines of investigation. In the first, preparations of liposomes are used as carriers of drugs either bound to the bilayer or entrapped inside the vesicles. Sonicated liposomes have been shown to be able to transport inhibitors or drugs to target sites *in vitro*[1] and *in vivo*[2]. In the second, liposome preparations are administered and pharmacological effects are recorded. In this context significant effects have been observed on cholesterol distribution[5]. The molecular mechanism underlying the possibility of pharmacological effects *in vivo* by long chain diacylphospholipids is indicated by a series of investigations[4–7] showing the capacity of phospholipid vesicles to fuse with cellular membrane *in vitro*. As a consequence of changed composition of membrane lipids, alteration in the permeability properties, transport systems and other functions of biological membranes are expected to occur. It has been shown[8] that sonicated dispersion of bovine brain phospholipids can induce in mice modification of glucose distribution Purification of lipid mixtures indicated that phosphatidylserine was one of the active components. Phosphatidylserine liposomes have shown great capability to interact *in vitro* with biologically active compounds (histamine[9] or calcium[10]), with phospholipid-dependent enzymatic systems (Na$^+$–K$^+$-stimulated ATPase[11] or tyrosine hydroxylase[12]), or with intact cells (enhancement of histamine release during antigen–antibody interaction[13]; promotion of cell fusion[4]). In this investigation data on phosphatidylserine-induced effects *in vivo* are presented.

Fed male albino mice were used throughout. The purity of phosphatidylserine extracted from bovine brain[14] was checked by thin-layer chromatography using Silica gel G and a solvent of chloroform–methanol–water (65 : 35 : 4, by volume). Dispersion of phosphatidylserine was obtained by 8-min sonication (MSE apparatus) at 0 °C in 50 mM Tris-HCl, *p*H 7.4. Liposomes in 0.1–0.2 ml buffer were injected intravenously in the tail vein within a few hours of their preparation, and the animals killed 30 min later by decapitation so as to collect the blood and allow the head to fall into liquid nitrogen. Brain hemispheres were removed, powdered under liquid nitrogen together with frozen 0.5 ml 0.3 N perchloric acid and allowed to warm at 0–4 °C. Glucose was estimated by the hexokinase method on perchloric acid extract[15].

Figure 1 shows the effect of phosphatidylserine liposomes on free glucose content of blood and brain tissue. The level of glucose was increased in both compartments; 15–30 mg kg^{-1} were required to trigger the effects (0.35–0.70 mg per mouse, equal to about 0.5–1.0 µmol phosphatidylserine) This low amount, which can be calculated to be composed of about 2×10^{14} vesicles[4], is not expected to produce gross changes in the body circulation. Accordingly, variations in brain glycogen or lactate were not recorded. Parallel experiments showed that neither uncharged liposomes of phosphatidylcholine nor charged, small liposomes of bovine brain phosphatidylinositol produced effects on glucose distribution. Among phosphatidylserines, liposomes made by purified soya bean phosphatidylserines were only slightly or not active, suggesting a role of both acyl chain and structure of polar head. As it was observed with the mixture of bovine brain phospholipids[8], the effect of phosphatidylserine liposomes was more manifest after intravenous injection and dispersion by sonication at neutral *p*H (Table 1) The enhancement of brain–blood glucose ratio revealed the tendency for glucose accumulation in the brain tissue. The need for small liposome formation in order to produce the pharmacological effect is difficult to explain in terms of possibility to cross membrane barriers. The average diameter of phosphatidylserine liposomes prepared by sonication[16] is estimated to be about 200 Å, not compatible with free transfer across cellular membranes, the blood–brain

Fig. 1 Effect of increasing amounts of phosphatidylserine on glucose distribution in mice. Sonicated dispersion of liposomes in 50 mM Tris-HCl (*p*H 7.4) were injected intravenously to fed mice which were killed 30 min later. Other conditions described in text. Values are mean ± s.e. of four animals. ●, Blood; ■, brain.



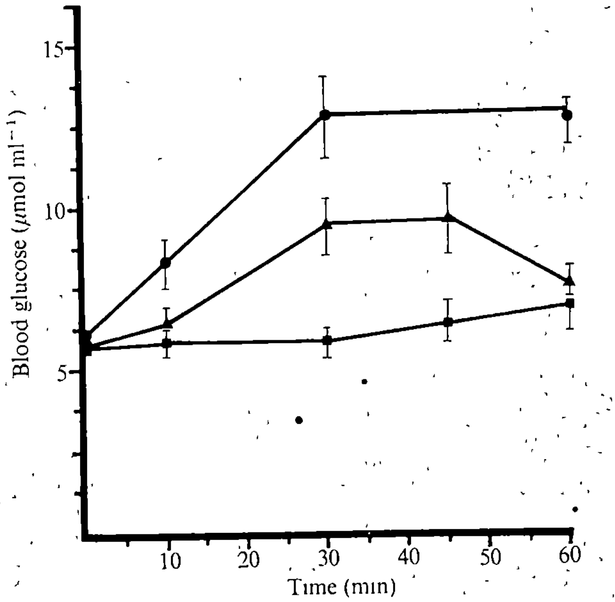


Fig. 2 Antagonism by Hydergine (dihydroergotoxine): sonicated liposomes (75 mg kg^{-1}) containing phosphatidylserine were given intravenously to mice treated (▲) or not (●) with hydergine (2 mg kg^{-1}) 30 min before phospholipid injection. Mean ± s.e. of four animals. ■, Hydergine alone.

Fig. 3 Decrease in adrenal catecholamine content. Mice were injected intravenously with sonicated liposomes of phosphatidylserine (150 mg kg^{-1}). At the time indicated the animals were killed and the adrenals homogenised in 0.4 N perchloric acid containing 0.1% sodium metabisulphite. Total catecholamines determined[18] on about 2 mg tissue. Values are mean ± s.e. of separate determinations whose number is given in parentheses.

*$P < 0.001$.

Liposomes were injected into fed mice at 75 mg phosphatidylserine per kg. Dry phospholipid was resuspended in 50 mM Tris-HCl buffer and dispersed by simple homogenisation or sonication (see text). Number of animals given in parentheses. Values are mean ± s.e. Significance levels (P) were assessed using Student's t test.

barrier or even the capillary wall of many organs. The effect of sonication is better understood in terms of facilitation of lipid–lipid, lipid–protein interaction or binding of blood cations. Penetration of liposomes into parenchymal cells is also enhanced after reduction of their size by sonication[17]. This would enable liposomes to produce a direct influence on cell carbohydrate metabolism in some organs (for example, liver). In spite of its high activity, the phosphatidylserine content does not completely account for the effect of bovine-brain phospholipid mixture observed earlier[8]. It is possible that other active components are present or that the optimal ratio between phosphatidylserine and other phospholipids increased the effect A mixture of phosphatidylcholine, lysophosphatidylcholine and phosphatidylserine was more active than phosphatidylserine alone in inducing cell fusion[4].

The involvement of catecholamine release in the hyperglycaemic effect is indicated in the experiments of Fig. 2 in which it is shown that previous administration of the adrenolytic agent Hydergine (dihydroergotoxine) strongly reduced the phosphatidylserine-induced increase of blood glucose level In separate experiments it was found that in the Hydergine-treated mice the normal values of glycaemia did not prevent the effect of liposomes on brain glucose, in agreement with the observations on lipid mixtures[8]. Attempts were made to demonstrate a decreased level of catecholamine content in the adrenal glands after phosphatidylserine injection. Figure 3 shows that a reproducible reduction of about 30% was found 30 min after administration of phospholipid vesicles (150 mg kg^{-1}). The increased cerebral content of glucose, the lack of lactate accumulation and the ineffectiveness of phosphatidylcholine and phosphatidylinositol excluded the possibility that nonspecific damage of blood circulation followed by cerebral hypoxia was responsible for catecholamine release.

The accumulation of free glucose in brain tissue and the release of catecholamines are phosphatidylserine-induced pharmacological effects which can be differentiated by the use of an adrenolytic agent. In spite of this distinction, a correlation between the two effects seems likely and it is indicated by the observation of a dopamine-induced high level of brain glucose[19]. The same pattern of activity (ineffectiveness of phosphatidylcholine and phosphatidylinositol, high activity of phosphatidylserine) was found on histamine release *in vitro*[20], an effect which required calcium. Calcium bridges between the negatively charged cell surface and liposomes may be required for the attachment of vesicles, as was suggested for phosphatidylserine-induced fusion of cultured cells[4]. This indicates a general capacity of phosphatidylserine vesicles to promote *in vivo* and *in vitro* the calcium-dependent release of cellular materials stored in specialised structure. Extending these observations it was found that injection of sonicated liposomes of bovine brain phospholipids increased catecholamine metabolism in mouse brain[21] and produced release of acetylcholine from rat brain cortex[22]. Phosphatidylserine was the active component in both cases. Further investigations are required to establish whether these effects taking place in the central nervous system reflect liposome penetration into the brain fluids.

Bacterial membrane transport of β-exotoxin, an anti-metabolite of RNA synthesis

β-Exotoxin is produced extracellularly by certain strains of *Bacillus thuringiensis* during the stationary growth phase, apparently resulting from nucleic acid metabolism[1]. It is a monophosphorylated adenine nucleoside derivative[2,3] and can modify RNA polymerase activity of mammalian and bacterial origin *in vitro* through substrate competitive inhibition[4,5]. RNA polymerase in nuclei from rat liver[6] and insect larval fat bodies[7] is sensitive to exotoxin, and inhibition seems to be subject to reversal by ATP. Other functional enzymes that catalyse reactions involving ribonucleoside triphosphates are similarly inhibited by exotoxin, such as adenylate cyclase[8]. Exotoxin is more toxic in mammalian and other eukaryotic systems than in cell-free prokaryotic extracts, and it can cross cell and nuclear membranes in mammalian systems[5,8,9]. But I know of no report of any effect of exotoxin on intact, physiologically normal bacterial cells. Therefore I have investigated the intracellular effect of exotoxin on RNA synthesis in actively metabolising bacterial cultures. This report describes the intracellular inhibition of RNA synthesis by exotoxin in cultures of *Escherichia coli* and *Bacillus subtilis* treated to increase their permeability. Further data revealed that exotoxin is totally excluded by the bacterial membrane, even in those treated cells.

Both organisms were impermeable to exotoxin in normal conditions. Extracellular exotoxin concentrations up to 1 mg ml^{-1} caused only slight inhibition (5% or less) of RNA synthesis in exponential cultures of *B. subtilis* and *E. coli*. Initially, no methods designed to increase membrane permeability of exponentially growing cells[10-13] increased exotoxin inhibition of cellular RNA synthesis. An adaptation of one method, however, involving EDTA–Tris treatment followed by resuspension of the washed cell pellet in complete minimal medium at *p*H 5.2, gave greater sensitivity to exotoxin. The rate of RNA synthesis was near normal in these cultures, although a lag of 2–3 h occurred before replication resumed.

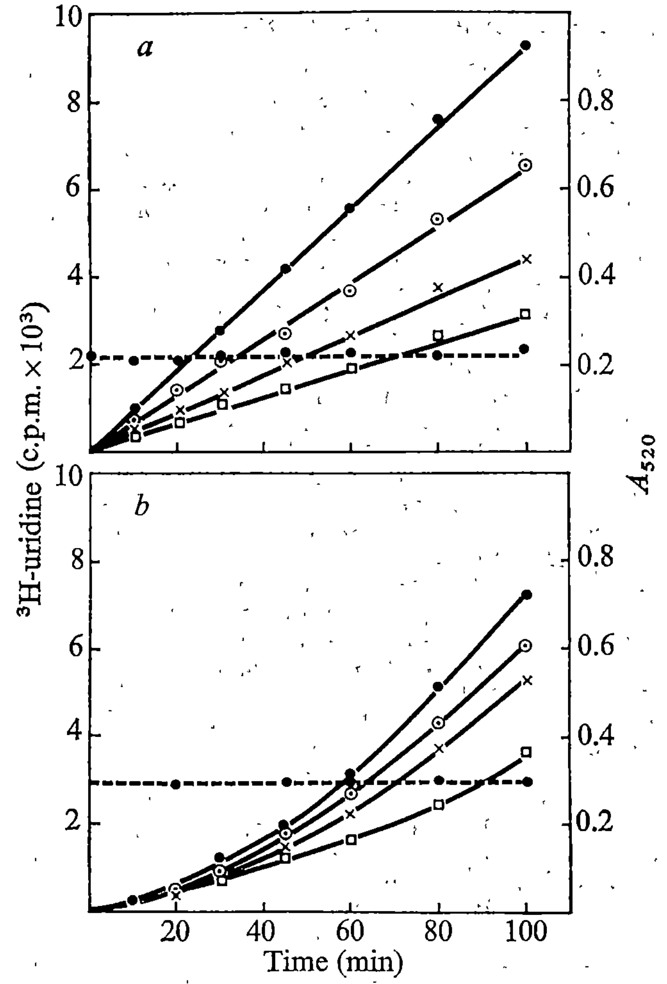

Fig. 1 *In vivo* inhibition of RNA synthesis by exotoxin. *a*, *E. coli*; *b*, *B. subtilis*. Cultures were pretreated by the EDTA–*p*H shift method. Extracellular exotoxin concentration: ●, 0 μg ml^{-1}; ○, 50 μg ml^{-1}; ×, 100 μg ml^{-1}; and □, 500 μg ml^{-1}. The absorbance of an uninhibited control culture (without exotoxin) is also shown (- - - -). Cultures of *E. coli* and *B. subtilis* were grown on a minimal salts medium at *p*H 6.8 supplemented with 0.2% glucose; filter-sterilised tryptophan (40 μg ml^{-1}) was added for growth of the *Bacillus* culture. Mid-exponential phase cultures were treated to increase their permeability by Leive's method[10]. Treatment was for 2 min (25 °C) with 0.25 M EDTA, after which the culture was diluted with 0.125 M Tris-HCl, centrifuged, washed again with Tris-HCl, recentrifuged, and the pellet resuspended in complete minimal medium at *p*H 5.2. Measurement of isotope incorporation in these permeabilised cells was determined by incubation on a water bath shaker (30 °C) in the presence of ^{3}H-uridine (specific activity, 3.7 μCi μmol^{-1}) and various concentrations of exotoxin by withdrawing 1-ml samples at intervals and by precipitating the RNA with cold 10% TCA. The samples were filtered on Whatman GF/A glass-fibre filters, washed with TCA (containing 0.4 mM carrier uridine) and cold ethanol, dried, and counted by liquid scintillation.

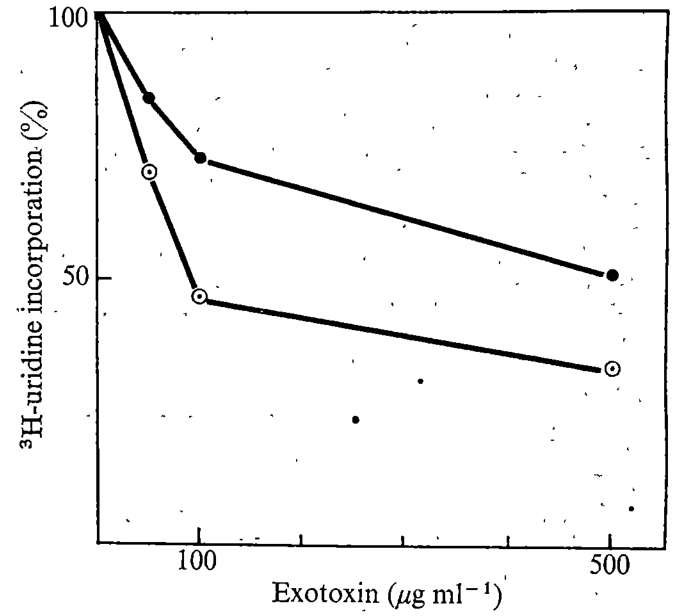

Fig. 2 Percentage inhibition of ^{3}H-uridine incorporation by exotoxin. ○, *E. coli*; ●, *B. subtilis*. Values are percentage incorporation compared with an uninhibited control after 100 min incubation, and reflect the final data points from Fig. 1 for both organisms.

Incorporation of ^{3}H-uridine into trichloroacetic acid (TCA)-precipitable RNA in the presence and absence of exotoxin is shown in Fig. 1. Total RNA synthesis after 100 min in *E. coli* cells treated with EDTA–Tris was inhibited 29.9, 53.2 and 66.1%, respectively, by the addition of exotoxin at 50, 100 and 500 μg ml^{-1}. Corresponding data were obtained from *B. subtilis* cells pretreated similarly; inhibition of total RNA synthesis after 100 min was 16.3, 23.1 and 49.2%, respectively, in the presence of the same concentrations of exotoxin. No cell division occurred with either EDTA–Tris-treated culture during the measured interval of uridine incorporation.

The degree of inhibition at each concentration of exotoxin fluctuated little throughout the experiment with both organisms. The inhibitory response, however, was not linear with respect to increased exotoxin concentration, but became less sensitive above 100 μg ml^{-1}, or 1.25×10^{-4} M (Fig. 2). These results corroborate data for *in vitro* exotoxin inhibition for purified *E. coli* RNA polymerase[14].

Attempts to measure exotoxin transport into EDTA–Tris-treated cells (not *p*H shifted) of either organism failed. The uptake of ^{3}H-uridine and ^{3}H-exotoxin was measured in the presence of rifampin so that only membrane transport would be measured and incorporation could be excluded. The effect of unlabelled exotoxin on ^{3}H-uridine uptake was followed. Exotoxin did not penetrate the membrane of EDTA–Tris-treated cells of either *E. coli* (Fig. 3) or *B. subtilis*. Uridine transport was most rapid during the first 5–10 min in both organisms, and then it diminished to a plateau when an inhibitor of RNA synthesis was present. Unlabelled exotoxin had little effect on uridine transport of *B. subtilis*, but slightly reduced uridine transport in *E. coli*. Growth was resumed in EDTA–Tris-treated cultures approximately 20 min after treatment.

Historically, bacterial membranes have been known to be poorly permeable to hydrophilic compounds. Nucleotides and hexose phosphates are classic examples. EDTA treatment disrupts the outer membrane of Gram-negative bacteria and provides improved access for some compounds, yet the inner membrane remains intact and presents still another barrier for certain external molecules[15]. Whereas deoxyribonucleoside triphosphates gain rapid entrance inside permeabilised cells of *E. coli*, the corresponding monophosphates are almost totally excluded[16]. The exotoxin produced by *B. thuringiensis* is structurally similar to deoxyribonucleoside monophosphates, and its inhibitory activity toward RNA polymerase is based on substrate analogue competition in cell-free extracts. My results, however, suggest that whatever the effect of exotoxin on cellular RNA synthesis in bacteria, it occurs externally. Figure 3 indicates that exotoxin may depress uridine uptake in *E. coli*, which could interfere with normal internal ribonucleotide precursor pools. Comparable experiments with cells of *B. subtilis* were inconclusive.

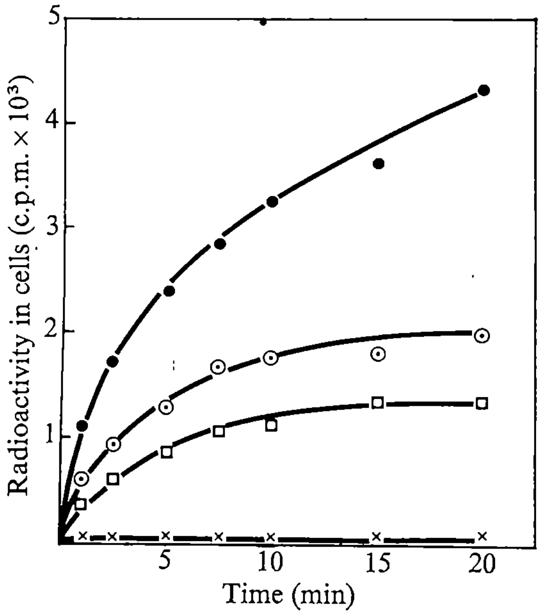

Fig. 3 Uptake of ^{3}H-uridine and ^{3}H-exotoxin in cells of *E. coli* treated with EDTA-Tris. ^{3}H-uridine uptake: ●, without rifampin; ○, with rifampin (50 μg ml^{-1}); □, with rifampin and unlabelled exotoxin (100 μg ml^{-1}). ×, ^{3}H-exotoxin uptake. Transport was measured with EDTA-Tris-treated cells, which were resuspended in complete minimal medium at *p*H 6.8 and held on ice until used. Either tritium-labelled uridine (Fig. 1) or exotoxin (specific activity about 0.27 μCi μmol^{-1}) was added to samples of permeabilised cells and placed in a reciprocating water bath shaker at 18 °C. Rifampin was added (50 μg ml^{-1}) to prevent *in vivo* ^{3}H-uridine incorporation into RNA Samples (1 ml) containing whole cells were withdrawn at intervals and immediately filtered on GF/A filters, washed with cold buffer (10 mM Tris-HCl, 50 mM KCl, *p*H 7.9), dried, and counted by liquid scintillation. Both labelled and unlabelled exotoxin were provided by T. R. Shieh (International Minerals and Chemical Corporation).

B. thuringiensis exotoxin has little or no effect on RNA synthesis in untreated cultures of *E. coli* and *B. subtilis*. Even in specially treated cultures with increased permeability, exotoxin seems to be totally excluded by the bacterial membrane. But RNA synthesis in similarly treated cultures of these organisms is inhibited by exotoxin in a concentration-dependent order. Thus inhibition of RNA synthesis by exotoxin in intact bacteria seems to be linked to membrane transport and not to competitive inhibition of RNA polymerase.

Role of mitochondria in control of calcium content of liver slices

INTRACELLULAR Ca^{2+} is thought to be important in the control of metabolic activity[1,2]. In liver cells, three energy-dependent transport activities capable of modifying the cellular distribution of this ion have been described—its accumulation by mitochondria[3,4] and endoplasmic reticulum[5] and its extrusion from the cell[6,7]. Mutual interactions, however, between these activities and their relative importance in determining total cell Ca^{2+} have so far been little studied in intact cells. One reason for this has been the difficulty of avoiding redistribution of Ca^{2+} between organelles when the cells are broken for isolation procedures, although Chen *et al*[8] used ruthenium red, added to the homogenisation medium, to prevent such redistribution in crab hepatopancreas. We now show that redistribution of Ca^{2+} into the mitochondria of rat liver can also be largely prevented by adding La^{3+} (another inhibitor of mitochondrial Ca^{2+} transport; ref. 9) to the homogenisation medium. We have also studied the contribution of mitochondria to the Ca^{2+} content of rat liver slices incubated in conditions in which total cell Ca^{2+} varies greatly.

Slices of rat liver were prepared and incubated as described previously[7]. Mitochondria were isolated from fresh liver and from incubated slices[10] using medium containing: mannitol 250 mM, sucrose 75 mM, EDTA 0.1 mM and Tris-HCl (*p*H 7.4) 2.5 mM. The swollen mitochondria of the 'fluffy layer' occurred in greater quantities in incubated slices than in fresh liver[11]; as we wished to determine the total mitochondrial contribution to the tissue Ca^{2+}, we usually analysed the mitochondrial pellet and 'fluffy layer' together Mitochondria from all preparations showed coupled, oligomycin-sensitive respiration[11]. For analysis, samples of slices and tissue fractions were dried and ions (including ^{45}Ca) extracted from the dry tissue[7]. Total Ca^{2+} was determined by atomic absorption spectrophotometry[7] and ^{45}Ca by standard techniques of scintillation counting. Protein was determined by a Biuret method[12]

To study the effectiveness of adding La^{3+} to the homogenisation medium as a means for preventing the redistribution of Ca^{2+}, we measured the entry of ^{45}Ca into mitochondria isolated from liver slices that had been incubated for 90 min at 1 °C. In these conditions the slices show the highest total Ca^{2+} content (see below). To half of the slices, ^{45}Ca was added in the homogeniser tube only 5 s before their disruption, so that the isotope could be considered totally 'exogenous'. In this case, the ^{45}Ca and La^{3+} present in the homogenisation medium would have reached the mitochondria simultaneously and a maximal possible inhibition of ^{45}Ca entry would be expected. Table 1 shows that about 50% of the added ^{45}Ca was taken up by the control mitochondria (homogenised without La^{3+}), and that the presence of 1 mM La^{3+} inhibited this uptake by 90%. Thus, La^{3+} can be used effectively to block redistribution of tissue Ca^{2+} into the mitochondria on

Table 1 Effect of presence of La^{3+} during homogenisation on entry of ^{45}Ca into mitochondria isolated from liver slices

^{45}Ca added	Slice group	La^{3+} added to homogeniser (mM)	^{45}Ca in mitochondria (10^{-6} × d.p.m. per g protein)	Total Ca^{2+} in mitochondria (mmol per kg protein)
To homogeniser	*a*	0	35.8±4.0*	—
	b	1	3.9±0.5	—
To incubating slices	*c*	0	1.49±0.08†	63.2±2.1
	d	1	0.68±0.05	47.3±1.7

* 51.2±3.5% of radioactivity in whole homogenate.
† 60.9±3.8% of radioactivity in whole homogenate.

Slices were incubated for 90 min at 1 °C in a Ringer solution containing, 146 mM Na$^+$, 5 mM K$^+$, 1.3 mM Ca^{2+}, 1.0 mM Mg^{2+}, 161 mM Cl$^-$, 1.0 mM SO$_4{}^{2-}$ and 10 mM Tris (*p*H 7.4). After incubation the slices were separated from the medium by suction and washed once with the mitochondrial isolation medium to remove superficial ions. The slices were then rapidly transferred to the isolation medium. The slices were divided into four groups which were treated as follows: *a*, ^{45}Ca was added to the isolation medium in the homogeniser, to give 0.5 μCi ml^{-1} (0.5 μCi per μmol Ca^{2+}), 5 s before homogenisation of the slices. *b*, As for group *a*, but with 1 mM La^{3+} present in the homogenisation medium. *c*, ^{45}Ca was added to the Ringer solution containing the slices after incubation at 1 °C for 89 min, giving 0.5 μCi ml^{-1} (0.38 μCi per μmol Ca^{2+}). *d*, As for group *c*, but with 1 mM La^{3+} present in the homogenisation medium. The medium used for rehomogenisation of the 600*g* pellets (ref. 9) of groups *b* and *d* contained 0.5 mM La^{3+}; further steps in the isolation procedure were carried out in medium free of La^{3+}. The counting rate for ^{45}Ca was corrected for background, and for quenching by the channels-ratio method; counting efficiency was approximately 55%. The results reported are mean ± s.e. of the mean from four experiments, each analysed in triplicate.

homogenisation. In the remaining slices we determined the effect of La^{3+} present during homogenisation on the distribution of ^{45}Ca added 1 min before the end of incubation at 1 °C (and approximately 1.5 min before homogenisation). The slices were rinsed free of the superficial, labelled Ringer solution before homogenisation so that all the remaining ^{45}Ca in the slices could be considered 'endogenous'. Mitochondria isolated from these slices without added La^{3+} again contained much of the total ^{45}Ca in the homogenate, but the presence of 1 mM La^{3+} reduced the recovery of isotope in the mitochondria by about 55%. We conclude that this inhibition largely represents the prevention of Ca^{2+} entry into the mitochondria on disruption of the tissue, and that the 45% of the ^{45}Ca still found in the mitochondria had entered by exchange before homogenisation.

It follows that the extent to which cell Ca^{2+} undergoes redistribution into the mitochondria on homogenisation should be indicated by a smaller Ca^{2+} content of organelles isolated in the presence of La^{3+}. Table 1 shows that slices homogenised with 1 mM La^{3+} yielded mitochondria containing 25% less Ca^{2+} than those homogenised in its absence. In a further series of experiments, La^{3+} at concentrations of 0.1, 0.5 and 2.0 mM reduced the mitochondrial Ca^{2+} from a control value of 47±5 mmol per kg protein to 42±3, 42±2 and 38±2 mmol per kg protein, respectively—that is, a fall of 20% at 2 mM La^{3+}. We concluded that the maximal effect of La^{3+} was at 1 mM, and that 20–25% of the Ca^{2+} of mitochondria isolated in the absence of La^{3+} was derived from extramitochondrial sources on homogenisation. La can precipitate tissue proteins[13] and when the ratio of La^{3+} to slice tissue in the homogeniser was 24 μmol per g wet weight we found a reduction of 50% in the recovery of mitochondrial protein. The protein yield, however, was not reduced when the ratio was 8–12 μmol La^{3+} per g wet weight, and this range was used in all the experiments we describe here.

The contribution of mitochondria to the total Ca^{2+} content of liver slices incubated in a Tris-buffered Ringer solution containing 1.3 mM Ca^{2+} was next determined in various conditions, subsequent homogenisation being carried out in the presence of 1 mM La^{3+}. The slices underwent a threefold increase in Ca^{2+} content at 1 °C, and much of the extra Ca^{2+} was extruded during subsequent incubation at 38 °C (Table 2). The mitochondrial Ca^{2+} changed in parallel with the total tissue content, showing a sixfold increase at 1 °C and a subsequent recovery towards low Ca^{2+} levels at 38 °C, which was even more complete than that of the whole slice. Whereas the mitochondria were calculated to contribute 35% of the total Ca^{2+} of the slices at 1 °C, they only contributed 17% after recovery (Table 2). Preliminary experiments in which La^{3+} had not been used during homogenisation, showed qualitatively similar results whether slices were incubated in Tris-buffered or phosphate-buffered Ringer solutions[14]. In a few experiments the 'fluffy layer' was isolated and analysed separately; it was found to undergo qualitatively similar changes but with a Ca^{2+} content which was about 30% less, per unit protein, than the mitochondrial pellet proper. In contrast to the parallel changes of whole-slice and mitochondrial Ca^{2+} just described, the partial (35%) inhibition by cyanide of Ca^{2+} extrusion from the slices was not reflected in any inhibition of the loss of Ca^{2+} from the mitochondria (Table 2).

Mitochondrial K$^+$ participated in the overall loss of this

Table 2 Ca^{2+} and K$^+$ contents of liver slices and of mitochondria isolated from them after incubation in varying conditions

	Fresh tissue	90 min at 1 °C	90 min at 1 °C followed by 30 min at 38 °C Control	Cyanide (2 mM)
Ca^{2+}				
Intact slices (mmol per kg slice dry weight)	4.4±0.8	12.8±1.5	8.4±0.8	10.0±1.7
Mitochondria (mmol per kg protein)	7.3±0.6	44.1±3.7	11.9±0.9	11.8±2.5
(mmol per kg slice dry weight)	1.1	4.5	1.4	1.4
K$^+$				
Intact slices (mmol per kg slice dry weight)	317±20	103±6	173±11	88±5
Mitochondria (mmol per kg protein)	147±3	91±2	84±4	37±3
(mmol per kg slice dry weight)	21	9	10	4

Slices were incubated in Tris-buffered Ringer solution (see Table 1) as indicated, the vessels being gassed with O$_2$ before incubation at 38 °C. Samples of the slices were taken for analysis after incubation; the remainder were homogenised in the presence of 1 mM La^{3+} and their mitochondria isolated together with the 'fluffy layer'. The quantities of intramitochondrial ions are expressed per kg mitochondrial protein and per kg tissue dry weight, the latter being calculated from the recovery of mitochondrial protein per unit of slice dry weight. The results shown are mean ± s.e. of the mean from three experiments, each carried out in triplicate.

ion from slices incubated at 1 °C and the further loss at 38 °C in the presence of cyanide (Table 2). Active aerobic metabolism at 38 °C, however, did not lead to restoration of mitochondrial K$^+$ levels, although supporting reaccumulation of total slice K$^+$. Mitochondria accounted for rather less than 10% of the total K$^+$ content of the slices.

We have shown that addition of La^{3+} to the homogenisation medium inhibits the accumulation of both endogenous and exogenous Ca^{2+} by liver mitochondria to an extent sufficient to permit determination of the quantities of intra- and extramitochondrial Ca^{2+} that existed in the intact cell. The results of Table 2 provide direct experimental evidence that the Ca^{2+}-accumulating system of mitochondria functions in the intact liver cell and that the accumulation is reversible, thus complementing the findings of Rose and Loewenstein[15] who used intracellular aequorin as an indicator of cytosolic Ca^{2+} in intact cells of a salivary gland. Accessibility of Ca^{2+} to, and its retention by, the mitochondria seems to be controlled to a large extent by an opposing energy-dependent mechanism which maintains a low total cellular Ca^{2+}. This calcium-extruding system may be situated either in the plasma membrane[7] or in a region of the endoplasmic reticulum communicating with the extracellular fluids[5]. Inhibition of the extruding system at 1 °C permits entry of Ca^{2+} into the cytosol from the exterior, and from there to be accumulated by the mitochondrial system which remains active at 0 °C (ref. 4). Restoration of aerobic metabolism at 38 °C leads to withdrawal of Ca^{2+} from the mitochondria due, presumably, to a greater affinity of the extruding system at the cell surface The fall of mitochondrial Ca^{2+} at 38 °C in the presence of cyanide, in spite of partial inhibition of extrusion from the cell, is probably due to a more complete inhibition of the mitochondrial system (which is totally dependent on respiration) than of the system at the cell membrane, since the latter would be able to utilise ATP derived from the continuing glycolysis. These considerations suggest that mitochondria may be able to regulate Ca^{2+}-dependent aspects of cell metabolism as postulated by a number of workers (for example, refs 1, 2, 16 and 17), but that this regulatory effect would itself be modulated by the activity of the calcium-extruding system at the cell boundaries.

Increasing intracellular sodium triggers calcium release from bound pools

An increase in the free ionised cytosolic Ca^{2+} concentration is generally regarded as the critical event necessary for the induction of exocytotic release of neurotransmitters and hormones from excitable cells. Stimulation of such cells is thought to result in an alteration of the membrane permeability to Ca^{2+} with a subsequent flow of Ca^{2+} ions down their gradient into the cytosol from the extracellular space[1]. In addition, release of Ca^{2+} from intracellular compartments —notably the mitochondria—mediated by a rise in intracellular cyclic AMP may also, in some systems, result in an increase in the cytosolic Ca^{2+} concentration and thus to exocytotic release[2]. Recent evidence suggests that small increases in Na$^+$ concentration may release Ca^{2+} from mitochondria isolated from cardiac muscle cells[3]. Conversely, the uptake of Ca^{2+} into mitochondria of squid axoplasm is reduced by elevated sodium[4]. Since increases in the internal Na$^+$ concentration occur during stimulation of many excitable cells, it is feasible that Na$^+$ could act as a physiological releaser of Ca^{2+} from intracellular stores. We have obtained evidence for this possibility from studies designed to examine the role of Na$^+$ in the calcium-dependent exocytotic release of insulin from the pancreatic β cell.

Pancreatic islets of Langerhans were isolated from 8-week-old male albino rats (200–250 g) and placed in a perifusion system which permitted the temporal monitoring of insulin release from their β cells[5]. Using this system, the effects of veratridine, an alkaloid well known for its ability to increase Na$^+$ permeability in nerve cells[6], were examined to test the possible role of Na$^+$ in Ca^{2+}-dependent insulin release. Our studies show that veratridine leads to a large release of insulin which is totally blocked by tetrodotoxin (TTX), a specific inhibitor of sodium channels in excitable membranes.

A typical experiment is presented in Fig. 1. Veratridine also stimulates release of neurotransmitters from synaptosomes[7] and noradrenaline from the hypogastric nerve[8],

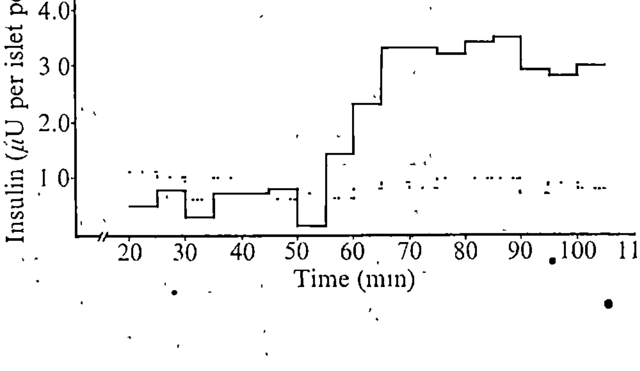

Fig. 1 Islets of Langerhans were isolated by the collagenase technique[13]. An exact number of islets (80–100) were placed in each of two perifusion chambers and perifused with Krebs-Ringer-bicarbonate (KRB) of the following ionic composition: Na$^+$ 139 mM; K$^+$ 5 mM; Ca^{2+} 2.5 mM; Mg^{2+} 1 mM; Cl$^-$ 127 mM; HCO$_3$$^-$ 24 mM. This was supplemented with bovine serum albumin (5 g l^{-1}) and 5.6 mM D-glucose, and maintained at 37 °C and *p*H 7.40 by bubbling constantly with 95% O$_2$ and 5% CO$_2$. Islets in both chambers were exposed to this solution for 45 min, after which one chamber was perfused with KRB containing 100 μM veratridine (*a*) and the other with KRB containing 100 μM veratridine and 3 μM TTX (*b*). The perifusate was collected at timed intervals and the insulin content determined by radioimmunoassay[14] Veratridine caused a fourfold increase in insulin release that was completely inhibited by TTX.

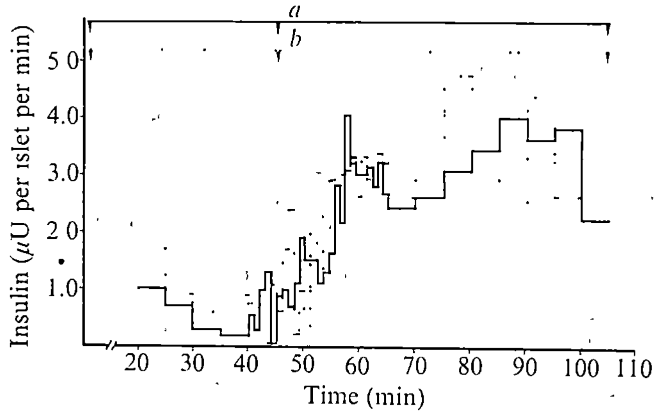

Fig. 2 Same procedure as in Fig. 1. After being perifused for 45 min with KRB alone, islets in one chamber were perifused with KRB containing 100 μM veratridine (*a*) and the others with Ca^{2+}-free KRB supplemented with 100 μM veratridine and 1 mM EGTA to chelate any remaining extracellular Ca^{2+} (*b*). Veratridine caused a fourfold increase in insulin release that was independent of extracellular Ca^{2+}.

release in both systems being blocked with TTX. Our original interpretation was that veratridine increased the intracellular Na^+ concentration by the maintained opening of Na^+ channels in the β-cell membrane, thus depolarising the membrane and opening voltage-sensitive Ca^{2+} channels Ca^{2+} may, in addition, have entered the cell by inward transport in exchange for outwardly transported Na^+, by counter-ion transport mechanisms similar to those identified in the squid axon[8].

Repetition of our experiments, however, in Ca^{2+}-free buffer, containing 1 mM EGTA to chelate any remaining extracellular Ca^{2+}, resulted in the same amount of veratridine-stimulated insulin release as when Ca^{2+} was present (Fig. 2). Since insulin release is always thought of as being strictly Ca^{2+} dependent[10], we suggest that increasing intracellular Na^+ concentration causes release of Ca^{2+} from intracellular compartments. Another method of increasing the intracellular Na^+ concentration is to poison the Na^+ pump with ouabain[11]. We have demonstrated that ouabain also causes insulin release in the absence of extracellular Ca^{2+}. Ouabain-induced release of acetylcholine from neuromuscular endplates also occurs in the absence of Ca^{2+} (ref. 12). Thus insulin release in the absence of Ca^{2+} is not a phenomenon specific to veratridine, but one related to the elevation of intracellular Na^+. In the light of these findings consideration must be given to the possibility that Na^+, by releasing Ca^{2+} from intracellular pools, is acting as a 'second messenger' in exocytotic release processes.

Interganglionic variation in cell body location of snail neurones does not affect synaptic connections or central axonal projections

RECENT accounts of invertebrate nervous systems have emphasised constancy in the occurrence and electrical properties of large identifiable neurones[1–5]. That constancy, however, has limits, and some giant neurones show variation in peripheral axonal projections[1] and dendritic morphology[6–8]. Smaller neurones increase in number during post-embryonic growth in several groups of invertebrates[9]. During electrophysiological mapping experiments on the brain of the pulmonate pond snail, *Lymnaea stagnalis* (L.), we have found two giant neurones whose positions varied considerably between ganglia, although the variation in cell body position was not associated with any variations in the synaptic connections of the neurones with each other or in identifiable synaptic inputs from other neurones, or with variations in the final projection areas of the principal axons within the brain. Some variation in the detail of axon branching was found to be correlated with cell body location for one peripheral projection.

Intracellular recordings were made from the cell bodies of neurones in the isolated brain maintained in snail blood, using standard electrophysiological techniques. Glass microelectrodes were filled with 2 M K_2SO_4 or 6% Procion Yellow M-4RS. Procion dye was injected intracellularly by iontophoresis[10] to determine axonal morphology of one or two cells in a particular brain Brains were processed histologically in the conventional way. Axonal morphology was reconstructed from superimposed camera lucida drawings of serial sections. No detailed analysis of dendritic morphology was made.

The two neurones which show interganglionic variation in cell body location were called LP2 and LP3 and could not be separated from one another on the basis of their electrical and morphological characteristics. Their bright orange cell bodies were 100–150 μm in diameter depending on snail weight, and the combination of size, positions, electrical properties and morphology of LP2 and LP3 made them uniquely identifiable in the brain of *Lymnaea.*

The somata of LP2, LP3 occurred as a pair in the visceral ganglion (49 snails) or left parietal ganglion (38 snails) or one in each of these ganglia (23 snails). Less frequently they occurred as a pair in the left pleural ganglion (3 snails) or one in the left pleural ganglion and one in the left parietal ganglion (2 snails) or one in the left pleural ganglion and one in the visceral ganglion (1 snail). The location of cell bodies within these three ganglia was limited to small areas of the ventral surface with typical positions shown in Fig 2.

The alternative positions of LP2, LP3 cell bodies did not affect the connections between the two cells or connections with other interneurones. Resting membrane potentials were within the range −45 to −60 mV, and the cells were invariably connected by an electrotonic synapse, even when the cell bodies were in different ganglia (Fig 1*a* and *b*). The junction between the cells was non-rectifying, and the coupling ratio for square pulses was in the range 0.05–0.15.

Spontaneous chemically mediated inhibitory postsynaptic potentials (i.p.s.p.s) were recorded in LP2 and LP3 originating from unidentified interneurones within the brain (Fig. 1, *c–e*). i.p.s p.s were found to be remarkably synchronous and often of similar amplitude in pairs of LP2 and LP3 (Fig. 1 *c–e*). This shared input was seen wherever the cell somata were located. In many preparations two identifiable unitary i p s.p.s were seen (Fig. 1 *c–e*, i.p.s.p.s 1 and 2).

Procion dye injections of LP2 and LP3 showed that they were monopolar cells with two principal axonal routes through the brain. The largest axon projected from the cell body anteriorly and then ventrally to the left pedal ganglion ("pedal axon", Figs 1*f* and 2) while a second finer branch, originating from the larger close to the cell body, projected posteriorly to the visceral ganglion ("visceral axon", Figs 1*f* and 2). When both neurones occurred in the same ganglion their axonal pathways through the central neuropile were extremely similar (Fig. 1*f*), although there were sometimes differences in the peripheral nerves into which they projected. When the cell bodies were in different ganglia their proximal axons met in the brain neuropile and then shared common pathways to the same final ganglion. To reach the same destination irrespective of cell body location required different lengths of pedal and visceral axons (Fig. 2).

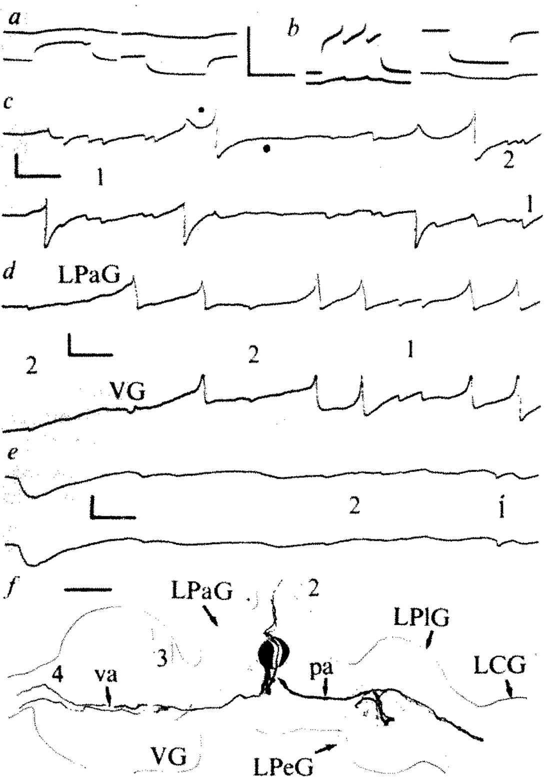

Fig. 1 Electrical properties and morphology of identified *Lymnaea* neurones, LP2 and LP3. *a*, Non-rectifying electrotonic synapse between a pair of neurones whose cell bodies were in the visceral ganglion. Two electrodes were placed in one cell body (bottom traces), one used for recording and the other for current injection, and a third electrode in the second cell body to record the postsynaptic response (top traces). 1-s square current pulse, 2×10^{-9} A, both polarities. Coupling ratio is 0.12 for depolarising (left-hand trace) and hyperpolarising currents (right-hand trace). *b*, Same but for neurones with cell bodies in the visceral ganglion (top traces) and left parietal ganglion (bottom traces). 1×10^{-9} A square current pulse, 1-s duration injected into the visceral neurone by the recording electrode. Coupling ratio for left and right traces, 0.07. Scale bars refer to *a* and *b*. *a*, horizontal, 0.5 s; vertical, 20 mV (top traces), 40 mV (bottom traces). *b*, Horizontal, 0.5 s; vertical, 80 mV (top traces), 40 mV (bottom traces). *c–e*, Spontaneous i.p.s.p.s recorded in paired recordings when the cell bodies were located both in the visceral ganglion (*c*) one in the left parietal ganglion (LPaG) one in the visceral ganglion (VG) (*d*) and both in the left parietal ganglion (*e*). Synaptic inputs to pairs of cells are synchronous and of apapproximately equal amplitude. Identified unitary i.p.s.p.s are marked 1 and 2 in records (*c–e*). In *d* continuous small i.p.s.p.s of a third type are present throughout the records and they probably form the principal component of the compound i.p.s.p.s seen at the beginning of the trace in (*e*). *f*, Reconstruction of a pair of Procion-injected neurones with cell bodies on the ventral surface of left parietal ganglion (LPaG). In the animal the left cerebral ganglion (LCG, the most anterior ganglion in the snail) is in the same horizontal plane as the left pleural ganglion (LPlG) the left parietal ganglion and the visceral ganglion (VG) whereas the left pedal ganglion (LPeG) is ventral to the others (dashed outline). Note the similar axonal geometry of the two cells. The visceral axon (va) projects to the anal nerve (4) but not to the cutaneous pallial nerve (3) in both cells. The pedal axons (pa) could not be traced to the pedal nerves although they penetrate the pedal ganglion neuropile. The left parietal nerve branch (2) arises from the visceral axon in one neurone (shaded) and the pedal axon in the other (unshaded). Scale bar, 200 μm.

One peripheral nerve axon branch of LP2, LP3 could originate from either principal axon depending on the ganglion in which the cell body was located. This was the constantly occurring left perietal nerve branch which emerged from the principal axon at a point where it passed close to the left perietal nerve root (in 37 out of 38 injected neurones). When the cell body was in the left pleural ganglion (3 cells injected) the branch originated from the visceral axon (Fig. 2*a*) but when the cell body was in the visceral ganglion (11 cells injected) it branched from the pedal axon (Fig. 2*c*). In cell bodies located in the left parietal ganglion it mostly branched from the pedal axon (in 21 injected cells) but occasionally from the visceral axon (in 3 injected cells) (Figs 1*f* and 2*b*). Thus the axon branch to the left perietal nerve is formed during development from whichever principal axon passes through the central neuropile of the left parietal ganglion.

Some axon branches to peripheral nerves were variable

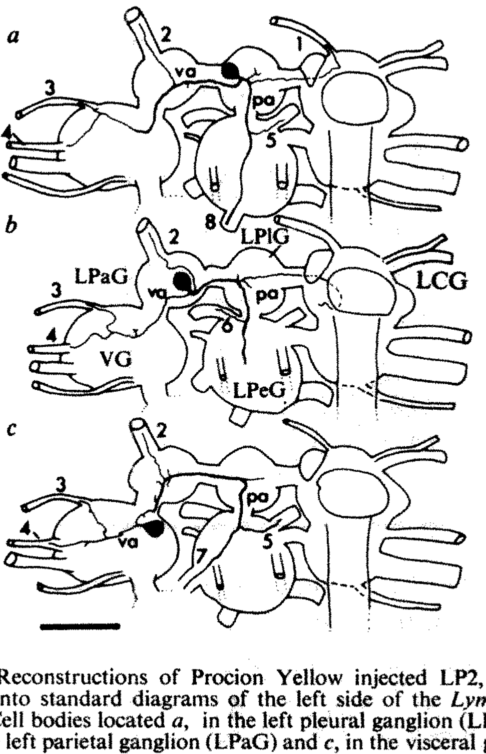

Fig. 2 Reconstructions of Procion Yellow injected LP2, LP3 drawn into standard diagrams of the left side of the *Lymnaea* brain. Cell bodies located *a*, in the left pleural ganglion (LPlG); *b*, in the left parietal ganglion (LPaG) and *c*, in the visceral ganglion (VG) on the ventral surfaces are shown for comparison. For simplicity only one of the LP2, LP3 neurones is included in each diagram. If the second cell occurred in the same ganglion as the one shown in *a–c* then its cell body was located next to the first (see Fig. 1*f*) and its central axonal projections were similar. The left cerebral ganglion (LCG) is most anterior in the brain and the left pedal ganglion (LPeG) most ventral. The cell body location determines the lengths of the visceral axon (va) and the pedal axon (pa). In the sequence *a–c* the visceral axon gets shorter and the pedal axon longer. The left parietal nerve branch (2) originates from the visceral axon in (*a*) and the pedal axon in (*b*) and (*c*). All three cells possess a peripheral axonal branch to the anal nerve (3) and the cutaneous pallial nerve (4). The axon branches to the pedal nerves are variable (see text for discussion). Only in the case of the cell located in the left pleural ganglion (*a*) was it possible to trace the cerebral ganglion axon branch to the nuchal nerve (1). Labelling of pedal ganglion nerve roots; 5, superior cervical nerve; 6, inferior cervical nerve; 7, inferior pedal nerve; 8, medial pedal nerve. Scale bar, 500 μm.

in occurrence. The apparent variability of pedal nerve projections seen in Fig. 2 may partly be due to problems of tracing distal nerve processes which have little dye in them, but in the visceral ganglion (Figs 1*f* and 2) axon branches were easy to map and some variation in branching pattern is certain. This was not obviously related to the location of the cell body. Thus in some snails the visceral axon projected to the anal nerve (this occurred in four cell bodies located in the visceral ganglion, and four cell bodies located in the left parietal ganglion), in others it projected to the cutaneous pallial nerve (in three cell bodies located in the visceral ganglion, one cell body located in the left parietal ganglion and one cell body located in the left pleural ganglion) or it projected to both these nerves (in three cell bodies located in the visceral ganglion and in three cell bodies located in the left parietal ganglion).

The constant presence of certain synaptic connections which LP2 and LP3 make shows that the position of cell bodies need not be constant for normal neural connections to be made. It seems more important to specify axonal projections rather than cell body position and this is suggested by the present study as well as that of Selverston and Mulloney[11] where cells from the lobster stomatogastric ganglia varied considerably in cell body location but had constant neuropile axon structure.

I thank Carole Slade for help with the anatomical part of the work, Professor G. A. Kerkut, Drs M. Burrows, T. S. Collett, D. A. Dorsett, M. F. Land, R. M. Pitman, N. V. Swindale and W. Winlow for their comments on drafts of this manuscript and the MRC for financial support.

Absence of a plateau in length–tension relationship of rabbit papillary muscle when internal shortening is prevented

IN the length–tension relationship of the isolated papillary muscle there is a region in which increased muscle length is associated with an increased force of contraction. Several problems make it difficult to determine the physiological basis for this relationship. Thick and thin filament lengths and sarcomere lengths have not been determined with the same accuracy in heart muscle as in skeletal, though there is evidence that these lengths are nearly the same in both muscles[1–3]. Papillary muscle cannot normally be tetanised or made to contract at low temperatures, and there is reason to believe that it is not fully activated by a single stimulus in the usual bathing medium[4,5]. In at least some papillary muscles there is considerable internal shortening during a twitch contraction[6,7]. Such length changes during contraction could change the amount of force developed by affecting the amount of thick and thin filament overlap and by producing shortening deactivation[8,9]. We have developed a photoelectronic servo apparatus similar to that developed by Gordon *et al.* (see refs 10 and 11 for details of operation) for use with papillary muscles to hold constant the length of a segment of preparation during contraction.

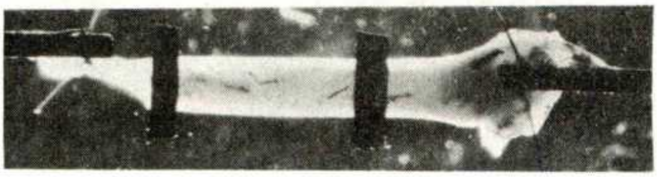

Fig. 1 A low power view of a typical rabbit papillary muscle preparation. The tapered tendon end and cut end are knotted to stainless steel wires with 10-0 nylon monofilament sutures. As a reference length, the diameter of the wires was 200 μm. The muscle was stretched to L_m. Its diameter in the uniform central region was about 500 μm, while its total length (knot-to-knot) was about 3.7 mm. The markers were about 1 mm long by 0.25 mm wide and were made from gold foil (2.5 μm thick), folded over along each long side, so that total marker thickness was 5 μm. Markers were glued to the surface of the papillary muscle with an epoxy adhesive able to cure underwater. The length between the markers (edge-to-edge) was about 1.7 mm. The dark streaks and spots visible in the muscle are collections of opaque 15-μm diameter microspheres; their presence does not influence muscle function.

Small diameter papillary muscles were obtained from the right ventricles of anaesthetised rabbits (about 0.5 kg). When these muscles were stretched to near L_m, the length at which peak developed tension is maximum, the diameter measured in the mid-region was about 500 μm, and striation patterns could be observed and recorded as described before[6]. The bathing medium was a modified Krebs–Ringer solution bubbled with a 95% O_2–5% CO_2 mixture. The solution contained (mM): NaCl, 117; $NaHCO_3$, 1.4; KCl, 4.2; $CaCl_2.2H_2O$, 2.5; $MgSO_4.7H_2O$, 1.2; NaH_2PO_4, 1.2; HEPES buffer, 7.4, and glucose, 5.6.

When a suitable muscle was obtained, it was tied to wires[6] (Fig. 1), which were connected to a servo motor and force transducer. The muscle was stretched slowly to just beyond L_m while being stimulated repeatedly. The experimental chamber was then drained of solution and gold markers (Fig. 1) were rapidly attached (within several minutes) to a central, uniform segment of the papillary muscle. The chamber was then refilled with solution and stimulation resumed. Comparison of length–tension relationships before and after marker attachment revealed no significant differences, and the muscles contracted vigorously for several hours after marker application. Microspheres which had been injected into the beating heart and subsequently lodged in the papillary muscle capillary network, were examined microscopically during fixed-end contractions to ensure that the markers moved synchronously with other elements distributed throughout the muscle cross section. Such synchrony was taken to indicate that during servo control, internal length does not change when the separation between the markers located on the muscle surface is kept constant.

The fixed-end length–tension relationship obtained from a papillary muscle after markers had been attached, but without servo control, is shown in Fig. 2. Peak twitch force declines to nearly zero when total muscle length is decreased by about 25% of L_m, and there is only a very narrow (about 1% of L_m) plateau present over which peak developed force remains near maximal. The steeply rising resting tension made it impossible to stretch the muscle more than a small amount beyond L_m. Servo control was used at each of the lengths indicated by arrows in Fig. 2 to prevent changes in marker separation. In each case, control was increased progressively to the point where only a small change in marker separation occurred during a twitch. Further increases in servo gain were avoided, since at higher gains the servo system became marginally stable. Only the record obtained at the longest indicated length is shown in Fig. 3, the others being similar in form. As the change in marker separation is progressively reduced, there are significant increases in the rate of rise of force and twitch peak amplitude. There is also an increase in the half time for twitch tension decay and a tendency for the twitch peak to occur slightly earlier.

Data obtained from each of the five records of the kind just described are plotted in Fig. 3, where it can be seen that the relative length error decreases monotonically as servo gain is increased. At maximum gain, the relative length error is less than 1%, and is even smaller at the two longest lengths, where large resting tensions were present. The extrapolated values give the best estimates of the force which would be present if marker separation had been held absolutely constant during a twitch contraction. The extrapolated values for the forces do not differ much from the values observed with minimum relative length error. These results provide a reasonable basis for belief that the small residual length error present did not significantly affect the force responses, so that the active tension developed indicates unambiguously force generation by the contractile component.

It is now possible to plot peak developed force against the length between the markers at maximal servo system gain (Fig. 4). The largest relative marker separation corresponds to a muscle length very near to L_m. The average sarcomere length corresponding to the greatest length between the markers was found by photographing the striation pattern[6] in the resting muscle. A mean value of 2.3 μm was obtained for the average sarcomere length at a marker separation corresponding to L_m in three muscles. In Fig. 4 the sarcomere length corresponding to a 15% decrease in marker separation 2.0 μm, was calculated by assuming a linear decrease of resting sarcomere length with marker separation, a good approximation in the sarcomere length range under consideration[6]. Figure 4 shows that there is a marked variation of twitch force within a range of average sarcomere lengths from about 2.0 to 2.3 μm, which contrasts with the results for frog skeletal muscle fibres in which isometric tetanic tension is essentially constant within this range[11].

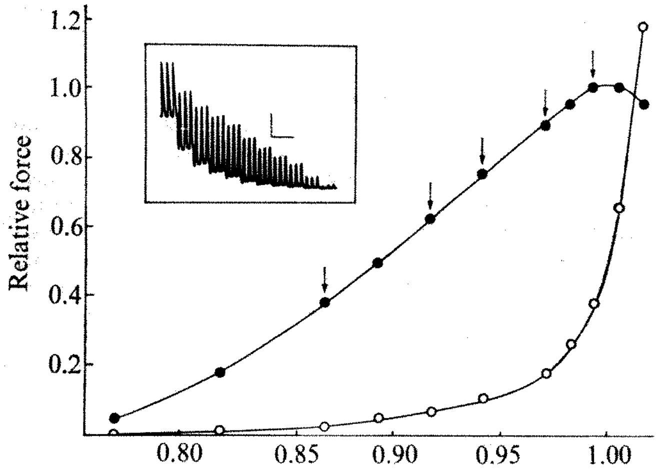

Fig. 2 A plot of peak developed (●) and resting (○) tension against muscle length for a rabbit papillary muscle. Data were obtained from the experimental record shown in the inset. Forces are expressed relative to the amplitude of the maximal peak developed twitches. Total muscle length (knot-to-knot) is expressed relative to L_m. Inset: length–tension relationship of a rabbit right ventricular papillary muscle. Markers had previously been attached as shown on a different muscle in Fig. 1. The muscle was first stretched slowly (not shown) until peak developed twitch tension passed a maximum and then declined slightly. After this, muscle length was decreased progressively allowing three twitches at each length. At the shortest length, resting tension was nearly zero. The amplitude of the twitches after the first and second decreases in length was nearly equal. Total muscle length (knot-to-knot) was 4.1 mm at the greatest length and 3.1 at the shortest length. The size of the length decreases in order were (μm): 50, 50, 50, 50, 100, 100, 100, 100, 200 and 200. Rate of stimulation was 17 per min, temperature was 22 °C. Calibration lines indicate 182 mg (vertical) and 14.4 s (horizontal). At the length corresponding to that after the second length decrease, muscle cross-sectional area was about 0.09 mm^2, based on microscopic determination of diameter in the central region between the markers. Maximal peak developed twitch tension was about 5 g mm^{-2}.

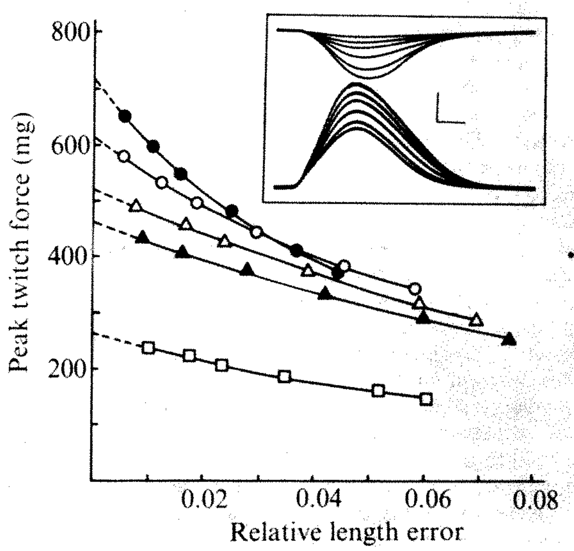

Fig. 3 Peak twitch force plotted against relative length error. Data were obtained at each of the positions indicated by arrows in Fig. 2 from records of the kind shown in the inset. In each case, as servo gain increased progressively, the maximum decrease in length produced by each twitch was obtained with the corresponding twitch amplitude. Decreases in length were expressed relative to the initial, resting length between the markers, so that a relative length error was obtained. Each set of data appears in sequence from top to bottom in correspondence with the arrows in Fig. 2. As servo gain was increased, the amount of relative length error decreased, that is, a nearly perfect isometric clamp was attained. In each case, the points are well fitted by a smooth curve. The extrapolations of these curves (dashed line segments) on to the force axis give good estimates of the true isometric forces obtainable if marker separation were held constant during a twitch. In sequence from top to bottom, the initial, resting marker separations were (mm): 1.60, 1.56, 1.52, 1.48 and 1.37. Inset: a sequence of length and force records showing the effects of increasing amounts of servo control applied to the papillary muscle from which the record shown in Fig. 2 was obtained. The upper series of traces are length signals from the photoelectronic spot follower. These indicate changes in marker separation, where length decreases are indicated by a downward deflection. A corresponding series of twitches is shown below. The smallest twitch is associated with the largest deflection in the length signal records. Between each twitch, the gain of the servo system was increased. This caused the end of the muscle attached to the servo motor to be driven so as to diminish progressively the amount of change in marker separation during a twitch. Finally, servo gain was increased to the point at which, during a twitch, there was a just perceptible deflection in the length signal trace. These records were obtained at the resting total muscle length indicated by the arrow in Fig. 2 closest to the active force peak. Similar sequences were obtained at the other four positions indicated by arrows in Fig. 2, but they are not shown here. At maximum gain, an error of 1 μm in the length between the markers causes an opposing force of about 73 mg at the end of the muscle attached to the servo motor. The vertical calibrating line indicates 44 μm or 182 mg, and the horizontal calibrating line indicates 200 ms. The largest twitch amplitude corresponds to a tension of about 8 g mm^{-2}.

The results presented here indicate that most of the ascending limb of the length–tension relationship of rabbit

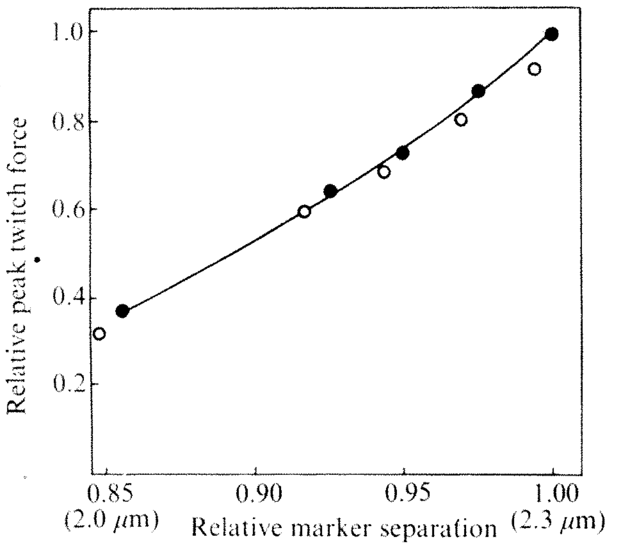

Fig. 4 Peak twitch force as a function of marker separation. Data were obtained from the graph shown in Fig. 3. All forces are expressed relative to the largest obtained by extrapolation, and all marker separations are expressed relative to the longest initial, resting value, 1.60 mm. ●, Plot of extrapolated force values against marker separation for the case of zero relative length error, that is the best estimates for perfectly isometric conditions. ○, Actual final values for forces and marker separations under maximum servo gain conditions. Note that a decrease in marker separation of only about 15% leads to a decrease in force of more than 60%. Average sarcomere lengths are given in parentheses. The value 2.3 μm was obtained by microscopic examination of the resting muscle at marker separation 1.60 mm. The value 2.0 μm was obtained by assuming a linear decrease of resting sarcomere length with marker separation.

papillary muscle cannot simply be explained on the basis of variation in the amount of thick and thin filament overlap, and, therefore, numbers of cross bridges available for interaction, or by changes in the amount of filament overlap and deactivation caused by internal shortening during contraction. Results obtained from skeletal muscle suggest that a variation in level of activation with muscle or sarcomere length is a significant factor[12-14]. This is, of course, not a new proposal[15-18]. Recent experiments with skinned muscle cells obtained from rat ventricles are interesting in this regard[17]. If these cells, which have had their sarcolemmae removed mechanically, are activated directly by high concentrations of calcium ion in the presence of a large Ca^{2+}-buffering capacity, the resulting sarcomere length–tension relationship resembles that obtained from living frog skeletal fibres[11]. Steady tension varies by only about 10% in the range of sarcomere lengths from about 1.7 to 2.3 μm, and it varies even less within the range 2.0 to 2.3 μm. But when the skinned cells were made to contract phasically by inducing a Ca^{2+}-triggered transient release of Ca^{2+} from the sarcoplasmic reticulum (SR), tension decreased substantially as sarcomere length was reduced below 2.3 μm. In the work with living papillary muscles reported here, tension decreased even more rapidly as sarcomere length was reduced below 2.3 μm than in the phasic contractions of skinned heart cells[17]. This suggests that in the living muscle the mechanism responsible for regulating the amount of activating calcium released in a twitch is not necessarily the same as that which governs the calcium-triggered release of calcium from the SR of skinned cells.

Electrophysiological measurements of spectral sensitivity of central visual cells in eye of blowfly

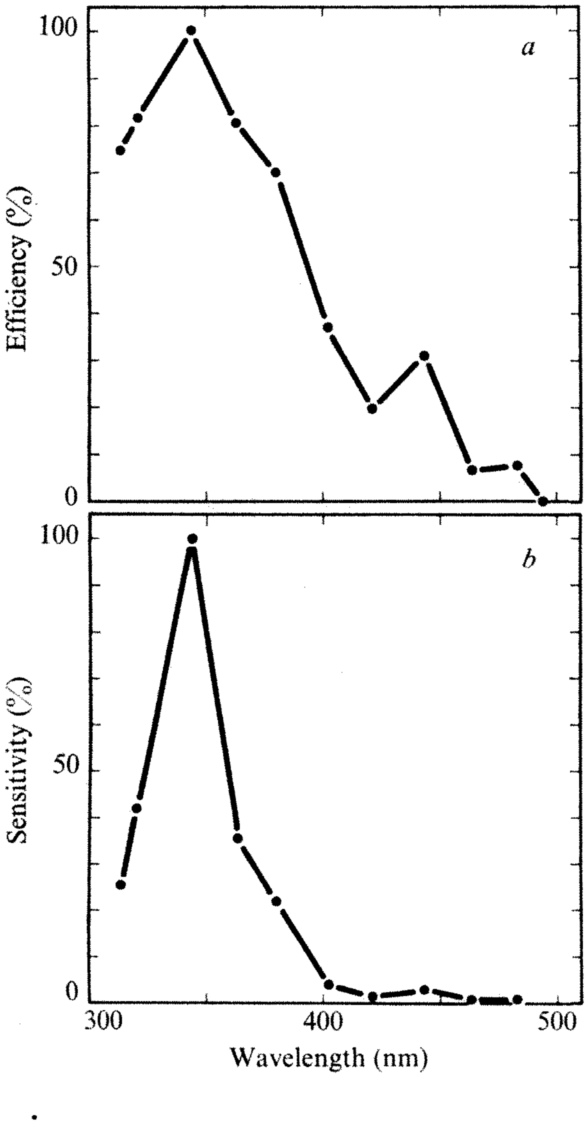
IN 1913 von Frisch was able to show that bees can discriminate between different colours. He thus refuted the then prevailing opinion that only certain vertebrates have colour vision. Since then insect colour vision has become a significant subject of research, the more so in view of the fact that using insect visual cells the transformation of light into neural excitation can be readily examined. In recent years numerous electrophysiological, microspectrometric and behavioural experiments have been carried out to determine the spectral sensitivity of visual cells not only of the bee but also of the fly. In the case of the blowfly *Calliphora erythrocephala*, each compound eye is made up of approximately 3,000 ommatidia. Under the lens of each ommatidium there are eight visual cells, and these can be divided into two groups according to their shape. Six of them (numbered R$_{1-6}$) have short axons which end in the first optic ganglion (lamina ganglionaris). The remaining two visual cells (R$_{7+8}$, also called 'central visual cells' because of the position they occupy in the ommatidium) are characterised by their long axons, which stretch from the retina through the lamina ganglionaris down to the second optic ganglion (medulla).

Measurements by electrophysiological methods have given rise to double-peaked sensitivity curves[1-3], all having in common a maximum in the ultraviolet range at 350 nm. The other peaks occurred at different wavelengths in the visible range of the spectrum. According to the positions of these maxima Burkhardt[1] was able to divide the sensitivity curves into three categories which he ascribed to three colour receptors (blue receptor: λ_{max} = 475 nm, green receptor: λ_{max} = 493 nm, yellow-green receptor: λ_{max} = 515 nm). The frequency of occurrence found for the sensitivity curves in each category led him to ascribe the green receptor to visual cells R$_{1-6}$; and the blue and yellow-green receptor to central visual cells R$_{7+8}$. Microspectrometric measurements[4] confirmed this assumption in the case of visual cells R$_{1-6}$. For the visual cells R$_{7+8}$ together (these are positioned in line with one another and share one rhabdomere) absorption spectra were found which, in addition to an ultraviolet maximum, had a maximum at 475 nm. Electrophysiological measurements with simultaneous histological localisation of the cells in question showed that the spectral sensitivity with a maximum at 490 nm did in fact come from the visual cells R_{1-6}. Such a definite proof has not been possible for visual cells R_{7+8} taken separately.

To determine the spectral sensitivity of the central visual cells R_{7+8}, intracellular potentials were recorded from the first optic chiasma. Since the axons of the visual cells R_{1-6} already terminate in the lamina we could be sure that whenever depolarising potentials with shapes typical for generator potentials from a retinula cell occurred, the recordings from the chiasma came either from the seventh or eighth visual cell. The measurements were carried out on the dark-adapted eye of male blowflies *Calliphora erythrocephala* Meig. with normal eye pigmentation. Many attempts were made but only in two cases were the recordings from the central visual cells stable enough to enable complete measurement of the intensity–response curve and of the spectral efficiency. Using intracellular injection of the fluorescent dye Procion Yellow and subsequent histological examination, the exact recording site in the chiasma could be located. In one case only a part of a central visual cell became stained and therefore it was not possible to distinguish exactly between R_7 and R_8.

Figure 1 shows the spectral efficiency curve of a central visual cell (response elicited by light stimuli with the same quantum level at all wavelengths) and its spectral sensitivity curve (reciprocal of quantum level eliciting the same response at all wavelengths). The spectral efficiency (Fig. 1*a*) of this cell has its maximum in the ultraviolet range at 344 nm, and drops sharply as the wavelength increases. At 443 nm it shows a small subsidiary shoulder and at 500 nm the spectral efficiency is almost zero. The spectral sensitivity curve (Fig. 1*b*) shows very clearly a single-peaked ultraviolet receptor. Here, the subsidiary shoulder in the blue range has declined to a level 10% below maximum sensitivity. Figure 2 shows the spectral efficiency and sensitivity curve of another central visual cell, differing in shape from that in Fig. 1. The efficiency curve (Fig. 2*a*) also shows a maximum in the ultraviolet range at 344 nm; but in this case the other maximum at 443 nm in the blue range was much more evident than in Fig. 1. At 500 nm the efficiency of this receptor is considerable and is still evident above 550 nm. The sensitivity curve (Fig. 2*a*) also shows two maxima the positions of which correspond with those in Fig. 1. The height of the blue maximum, however, is different. The axon of the cell mentioned in Fig. 2 was stained in the region between medulla and basement membrane. Faint staining could also be seen in the proximal region of the retina. Here, it was impossible to ascertain whether a seventh or eighth visual cell had been stained.

Fig. 1 Spectral efficiency (*a*) and spectral sensitivity (*b*) of a central visual cell from eye of *Calliphora*. Single-peaked ultraviolet receptors of this kind were previously unknown in the blowfly eye.



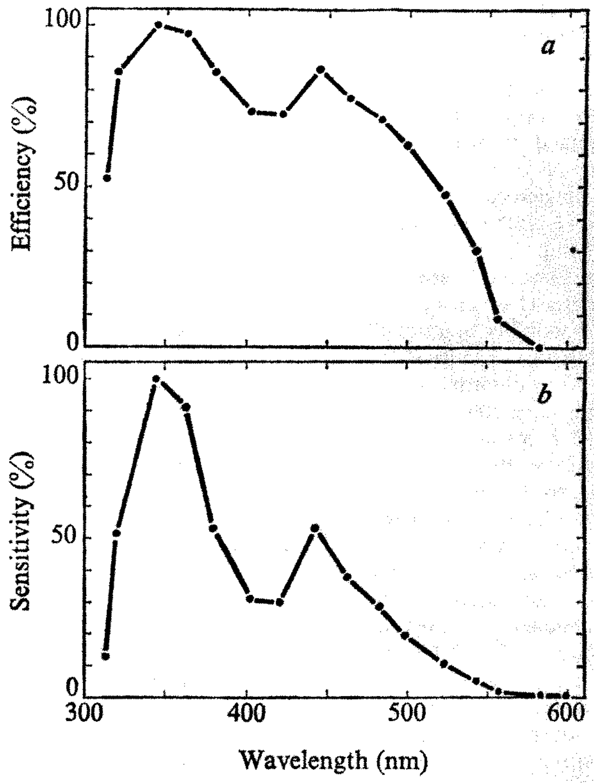


Fig. 2 Spectral efficiency (*a*) and spectral sensitivity (*b*) of another central visual cell which in addition to the ultraviolet maximum also shows a marked maximum at 443 nm in the blue range.

In electrophysiological experiments on the spectral sensitivity of visual cells in the eye of *Calliphora*, only double-peaked sensitivity curves have so far been found. Thus the occurrence of a single-peaked ultraviolet receptor is at first surprising[5]. The spectral sensitivity curve (Fig. 1*b*) suggests the existence of a special ultraviolet pigment in the rhabdomere of the seventh or eighth visual cell, such as has been isolated in *Ascalaphus*[6]. Ultraviolet receptors have also been found in other dipteran compound eyes[7-9]: thus they seem to be a characteristic of a number of dipterans. Also, the double-peaked sensitivity curves of the visual cells R_{1-6} in *Calliphora* can be ascribed to two separate pigments[3]. It is thus evident that the curves shown in Fig. 2 result from two visual pigments with maxima at 344 nm (ultraviolet pigment) and at 443 nm (blue pigment). The occurrence of such a blue pigment does not contradict earlier microspectrometric measurements on the rhabdomere of visual cells

R_{7+8}, for it is now well known that a stable metarhodopsin forms during these measurements, which shifts the maximum of the absorption curve towards longer wavelengths (H. Langer, personal communication).

We could not be certain which spectral sensitivity curve belonged to which visual cell; R_7 or R_8. Experiments on *Drosophila*[8] have shown, however, that the seventh visual cell is a single-peaked ultraviolet receptor whereas the eighth visual cell is a double-peaked ultraviolet–blue receptor. If one assumes that this also holds good for *Calliphora* the ultraviolet receptor (Fig. 1) would be the seventh visual cell and the ultraviolet–blue receptor (Fig. 2) the eighth visual cell. There remains, however, the possibility that not all the seventh visual cells and not all the eighth visual cells show uniform spectral sensitivities. Thus, the two different spectral sensitivity curves which we obtained might have come from two cells of the same type. If the ultraviolet pigment–blue pigment ratio varies from cell to cell this would be one explanation for the different maxima observed. This, for example, was the explanation suggested for the variation in height of maxima of spectral sensitivity curves with two or more peaks in *Eristalis*[9]. Microspectrometric measurements carried out on visual cells R_{7+8} of several dipterans do in fact show that neither of the rhabdomeres 7 and 8 constitutes an homogeneous population of receptors (K. Kirschfeld, personal communication). The question of which curve belongs to which cell type still remains to be answered, but our measurements show that, in addition to receptors with sensitivities found previously, there exist receptors with single-peaked ultraviolet sensitivities and with double-peaked ultraviolet–blue sensitivities. If one leaves out the possible shifting of the position of the blue maximum due to light-guide characteristics of the central rhabdomeres, one can conclude that the vision of the fly is based on at least three photopigments with maxima in the ultraviolet range (about 344 nm), blue range (about 443 nm) and green range (about 490 nm).

Membrane noise in *Paramecium*

THE ciliated protozoan *Paramecium* provides an opportunity to study the electrophysiological properties of an excitable membrane in relation with simple locomotor behaviour. The *Paramecium* surface membrane controls the locomotor activity, in particular ciliary reversal (resulting in backward swimming), by ionic conductance mechanisms like those in other excitable cells[1,2]. Depolarising stimuli (electrical, chemical or mechanical) cause a graded receptor potential due to a regenerative transient increase in calcium conductance and a delayed increase of potassium conductance. The resulting Ca^{2+} influx causes an increase in the intracellular Ca^{2+} concentration which initiates the reversal of the ciliary beating direction. Normal beating is resumed when the excess internal Ca^{2+} has been removed by metabolism-dependent processes.

The correlation between depolarisation and the orientation of the cilia was first observed in relation with spontaneous fluctuations of the resting membrane potential[3,4]. Spontaneous ciliary reversals seemed to coincide with voltage fluctuations in depolarising direction.

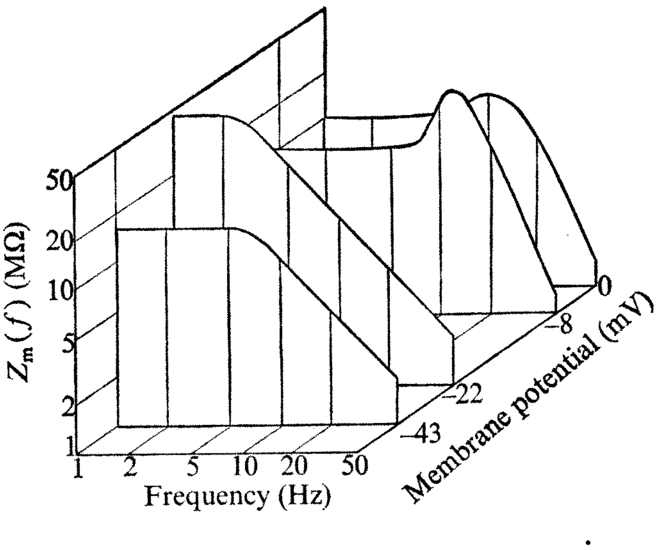
This report deals with the search for the physical origin of these fluctuations ("membrane noise") and with their relationship to spontaneous reversals. Membrane noise voltage (at constant current), although more easily measurable and less contaminated with electronic noise, may give less information about the underlying processes than noise current (at constant voltage), since the noise voltage is filtered by the frequency-dependent membrane impedance. The noise voltage is, however, expected to induce spontaneous ciliary reversals. We therefore measured both noise voltage and noise current and the impedance. We show that the membrane noise belongs to the so called $1/f$ type and that its intensity is related to the magnitude of the passive K^+ flux across the membrane. The noise voltage seems to be filtered by a resonance-like membrane impedance and, finally, we present evidence that $1/f$ noise can occasionally lead to spontaneous ciliary reversals.

Current clamp methods (using two intracellular microelectrodes) similar to those of Naitoh and Eckert[5] were used to record noise voltage from specimens of *Paramecium caudatum*. The noise voltage was perfectly correlated in both electrodes and independent of electrode positions, as expected from the isopotential nature of the *Paramecium* membrane[6]. Noise current was measured with standard voltage clamp techniques. The noise was tested for constancy and processed on an HP 3721 A correlator and Fourier transformed to obtain the spectral density function. The membrane impedance was obtained by cross correlation of injected white-noise current and membrane noise voltage response. In the "standard" bathing solution (4 mM KCl, 1 mM $CaCl_2$, 1 mM Tris, *p*H 7.2) the membrane noise was stationary and no spontaneous reversals were observed.

Figure 1 shows the membrane impedance modulus $|Z_m(f)|$ at different mean membrane potentials, measured from a specimen in the standard solution at 19 °C. At the resting potential (−22 mV) and on hyperpolarisation the membrane behaves as a simple RC circuit. On depolarisation, however, a resonance peak shows up at about 12 Hz. This resonance, which tends to diminish on stronger depolarisation, is reminiscent of the squid axon membrane impedance[7] and accounts for the oscillatory character of the voltage response on a steady depolarising current stimulus[5].

Figure 2*a* shows typical noise voltage spectra, $S_V(f)$, in which

Fig. 1 *Paramecium* membrane impedance modulus $|Z_m(f)|$ at various membrane potentials determined as (cross)power spectra of membrane voltage response to white noise current stimulus. R.m.s. value of injected noise was 5×10^{-11} A. In the standard bathing solution resting potential $V_r = -22$ mV and K^+-equilibrium potential $E_K = -38$ mV at 19 °C.



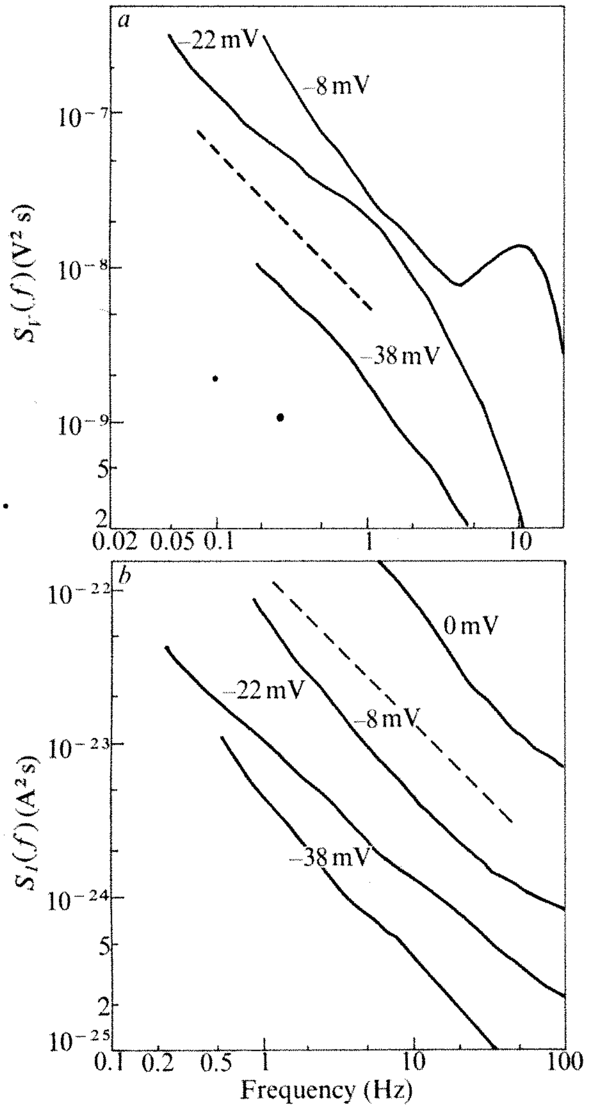


Fig. 2 Power spectra of stationary membrane noise at various membrane potentials. Standard solution at 19 °C. *a*, Noise voltage spectra, $S_V(f)$, measured under current clamp. Electronic noise negligible (10^{-11} V² s at 1 Hz). *b*, Noise current spectra $S_I(f)$, measured under voltage clamp. Electronic noise negligible up to about 50 Hz (10^{-25} A² s), but exceeding membrane noise above 100 Hz. Note the difference in frequency scale. Dashed lines represent slope −1. Spectra are related according to $S_V(f) = S_I(f)|Z_m(f)|^2$.

the impedance filtering effect is clearly reflected. No significant changes in membrane noise spectra nor in other electrical parameters were observed when ciliary beat was inhibited by adding 1 mM $NiCl_2$ to the standard solution. This is consistent with the known independence of ciliary beat on electrical events[2].

Noise current spectra, $S_I(f)$, are shown in Fig. 2*b*. The experimental data satisfy the theoretical conversion formula[8]

$$S_V(f) = S_I(f)\ |Z_m(f)|^2$$

Noise current spectral densities decrease with increasing frequencies. On a log–log plot their shapes suggest a power law fit of the form

$$S_I(f) = Nf^{-\alpha}$$

where N is voltage dependent. α has a value close to 1.0 at rest and tends to increase on depolarisation. Values exceeding 1.5 were not found. This result places the membrane fluctuations of *Paramecium* in the $1/f$-noise category.

This type of noise is also present in nerve fibres[9] and in cultured neuroblastoma cells (W. H. Moolenaar, unpublished), but unfortunately the physical basis of $1/f$ noise is not yet clear[10]. An empirical understanding of *Paramecium* membrane noise can, however, be obtained. Figure 3 shows the dependence of the noise intensity, N, on membrane potential V_m. A minimum value of N was found for V_m between −35 mV and −45 mV, that is the vicinity of the K⁺ equilibrium potential E_K ($E_K = -38$ mV in the standard solution[11]).

Replacement of the standard solution by a high-potassium solution (18 mM KCl, 1 mM $CaCl_2$, 1 mM Tris, *p*H 7.2) roughly eliminates the potassium concentration gradient across the membrane, thereby reducing both E_K and V_m to about 0 mV. In this case membrane noise was no longer measurable since it vanished in electronic background noise, but hyper- or depolarisation raised the membrane noise intensity substantially once again. Although quantitative data on the *I–V* relationship for the separate ionic currents in *Paramecium* have not been reported as yet, the presented data strongly suggest a proportionality between membrane noise intensity and the magnitude of the passive K⁺ flux. We attribute the remaining noise at zero K⁺ flux in the standard solution (at $V_m = E_K$ in Fig. 3) to calcium and nonspecific leakage currents. Metabolism-dependent processes most likely do not contribute to the membrane noise since cooling the specimen to 4 °C did not significantly alter noise spectra.

To relate membrane noise to spontaneous ciliary reversal a low-potassium bathing solution was chosen (1 mM KCl, 1 mM $CaCl_2$, 1 mM Tris, *p*H 7.2). In this solution the noise intensity at resting membrane potential (−25 to −29 mV) was substantially increased, as has to be expected from the mentioned relationship between noise intensity and K⁺ flux, since in this case the steady K⁺ flux is larger. Spontaneous transient ciliary reversals did occur, coinciding with depolarisations ranging from about 3–8 mV in amplitude and about 0.1–1 s in duration. These random depolarisations caused the noise to be non-stationary, which implies that the usual noise processing techniques do not give meaningful results. Under voltage clamp, on the other hand, spontaneous reversals were not observed. In this case noise current was stationary and exhibited a $1/f$ spectrum (intensity $N = 5 \times 10^{-23}$ A² at resting membrane potential).

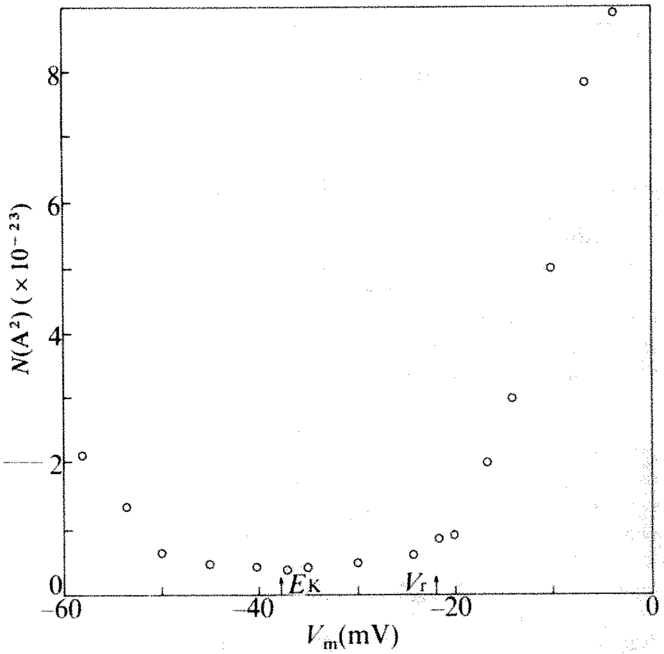

Fig. 3 Intensity N of $1/f$ noise plotted against membrane potential V_m. N was determined as the value of $S_I(f)$ at 1 Hz. Resting potential $V_r = -22$ mV, K⁺-equilibrium potential $E_K = -38$ mV in the standard solution.

We conclude therefore that membrane $1/f$-noise voltage, generated mainly by the steady passive K^+ flux, can activate Ca^{2+} conductance occasionally and thus underlies spontaneous reversals in *Paramecium*.

To our knowledge this is the first report which provides experimental evidence for a connection between membrane $1/f$ noise and simple behavioural effects in a living organism.

Antagonistic effects of GABA and benzodiazepines on vestibular and cerebellar neurones

ALTHOUGH benzodiazepines are widely used psychotropic drugs their mode of action within the central nervous system (CNS) is controversial[1–4]. Based on biochemical and pharmacological investigations of various central and peripheral neural substrates, Costa *et al.*[5] and Haefely *et al.*[6] suggested that they act, at least in part, through a facilitation of γ-aminobutyric acid (GABA)-ergic transmission. We have tested this hypothesis electrophysiologically at the single unit level in areas of the CNS in which GABA has been unequivocally shown to be an inhibitory transmitter. Single unit recordings were made in neurones of the lateral vestibular nucleus (Deiters) and in Purkinje cells of the cerebellum.

Deiters neurones receive a monosynaptic GABA-ergic inhibitory input through Purkinje cell axons originating in the cerebellar cortex. There is conclusive evidence for the synaptic release of GABA at the inhibitory afferences of Deiters neurones[7–9]. Furthermore, GABA is released at the level of the inhibitory synapses between the so-called basket cells and the Purkinje cells[10]. Purkinje cells were identified on the basis of the spontaneous "inactivation response"[11] recorded at the appropriate levels of electrode penetration.

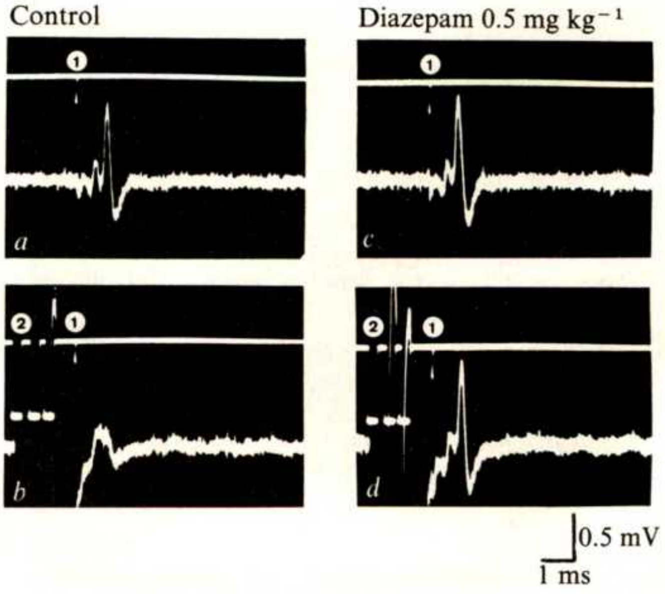
Experiments with Deiters neurones involved three cats anaesthetised with N_2O and artificially ventilated. Deiters neurones were activated by antidromic stimulation of the vestibulo-spinal tract (Fig. 1*a*). The antidromic response was inhibited by the preceding stimulation of Purkinje cell axons (Fig. 1*b*). Intravenous diazepam had no effect on the antidromically evoked action potential (Fig. 1*c*), but readily and reproducibly suppressed monosynaptic inhibition of Deiters neurones evoked by stimulation of the cerebellum (Fig. 1*b*). The inhibitory effect of the stimulation of Purkinje fibres (Fig. 1*b*) could be duplicated by the iontophoretic application of the inhibitory neurotransmitter GABA on to Deiters neurones; antidromically evoked action potentials were reduced by GABA in a dose-dependent manner. Likewise, the intravenous injection of diazepam suppressed this inhibition of the antidromically evoked potential by GABA.

The inhibitory effect of Purkinje cell fibres on Deiters neurones, which was abolished by diazepam (Fig. 1*d*) could be restored either by increasing the intensity of stimulation of Purkinje fibres, or by increasing the amount of microiontophoretically delivered GABA. The effect of increased cerebellar stimulation was in turn antagonised by locally applied bicuculline (compare ref. 12).

The experiments on Purkinje cells were carried out on five Füllinsdorf albino rats (200–300 g body weights) anaesthetised with urethane (1.2 g kg^{-1}, intraperitoneally). In all cases, the spontaneous firing of Purkinje cells could be inhibited completely and instantaneously by small amounts of iontophoretically applied GABA (of the order of 2–5 nA). This inhibition was strikingly affected by a preceding injection of the benzodiazepine derivative bromazepam: a large amount of GABA (10 nA) now required several seconds to suppress spontaneous activity (Fig. 2*a*). The same amount of locally applied GABA could be made even less effective in suppressing neuronal activity by increasing the dose of injected bromazepam (Fig. 2*b*). This indicated again a dose-dependent relationship between the effects of GABA and the benzodiazepine derivative.

These electrophysiological findings on vestibular and cerebellar neurones demonstrate for the first time a functional antagonism between benzodiazepine derivatives and the inhibitory neurotransmitter GABA. In both systems, inhibitory GABA influences are suppressed in a dose-dependent manner by these psychotropic drugs, but their effect can be overcome by increasing local GABA concentrations, either through stimulation of the appropriate axons or by microiontophoretic delivery of GABA. By contrast, the effect of the specific GABA antagonist, bicuculline, does not seem to be impaired by benzodiazepine. To ascertain that the benzodiazepine derivative diazepam

Fig. 1 Modification of antidromic (1) potentials recorded from a single neurone in the Deiters nucleus of the cat. *a*, Potential obtained of the antidromic stimulation of the vestibulo-spinal tract with single pulses of 0.5 mA, 0.05 ms duration (five responses superimposed). *b*, Abolition of the antidromic potential by preceding orthodromic stimulation (2) (train of three pulses, 0.8 mA, 0.1 ms, 250 per s) of Purkinje fibres. *c*, Antidromic response obtained 6 min after intravenous injection of diazepam (0.5 mg kg^{-1}) is unchanged. *d*, Suppression of the inhibitory effect of the orthodromic stimulation (compare *b*) after injection of diazepam (5 min).



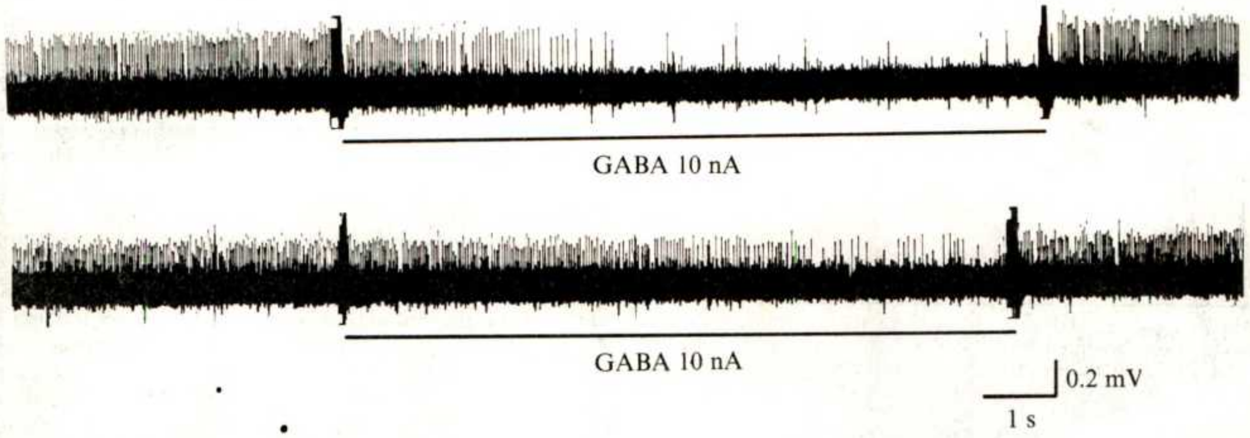


Fig. 2 Single unit activity of a rat Purkinje cell recorded through the central barrel of a five-barrelled micropipette[13]; GABA was delivered from a lateral barrel as a 0.5–1 M solution at *p*H 3.0–3.5. *a*, Delayed inhibitory effect of GABA (10 nA) 47 min after intravenous injection of bromazepam (2 mg kg^{-1}). Action potentials persisting during the second two-thirds of GABA iontophoresis represent the non-suppressible climbing fibre responses[14]. *b*, Further attenuation of the GABA effect (10 nA) 2 min after a second intravenous injection (4 mg kg^{-1}).

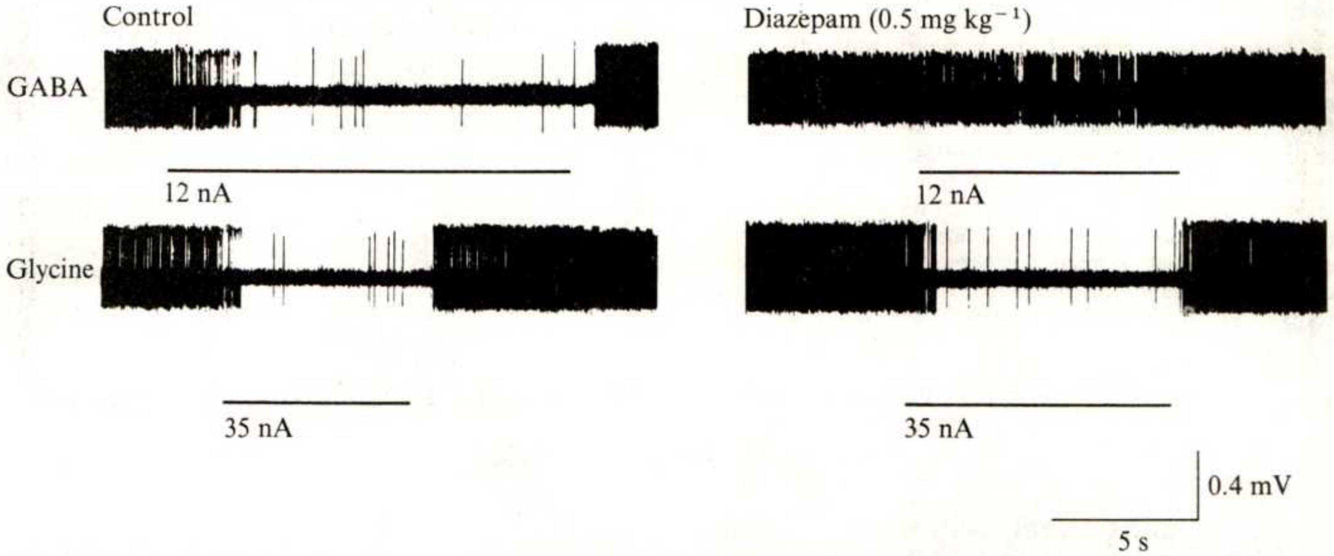

Fig. 3 Single unit activity of a cat Purkinje cell. GABA and glycerine were delivered alternately by iontophoresis (12 nA and 35 nA respectively, indicated by horizontal bars) at *p*H 3.0 from 0.5 M solutions. After intravenous injection of diazepam (0.5 mg kg^{-1}) the GABA depression of cell activity (control) was nearly abolished. In contrast, the glycine-induced depression was not reduced after injection of drug.

specifically counteracts GABA-ergic transmission its effect on glycine-induced inhibition[3] was tested in cat Purkinje cells (Fig. 3). These neurones were less sensitive to glycine and intravenously administered diazepam had no antagonistic influence in the inhibitory effect seen after the iontophoretic delivery of glycine. Thus, this study on Purkinje cells suggests differential effects of benzodiazepines on the two inhibitory amino acids, GABA and glycine. In further experiments, the soluble benzodiazepine derivatives, chlordiazepoxide HCl, was applied iontophoretically to Purkinje cells in rats and cats (unpublished results). Again, the GABA-mediated inhibition of Purkinje cells by basket cells, as well as the direct inhibitory effects of GABA were attenuated or abolished.

In summary, these results fail to support the idea that the action of benzodiazepine could be explained by a facilitation of the GABA-ergic transmission[5,6]. On the contrary, the GABA-mediated inhibition on Deiters neurones and Purkinje cells was clearly antagonised by these drugs.

Differentiation of L-aspartate and L-glutamate high-affinity binding sites in a protein fraction isolated from rat cerebral cortex

THE possibility that L-glutamate and L-aspartate are excitatory transmitters in the CNS is supported by neurochemical and neurophysiological evidence[1]. The problems of identifying particular synapses that are excited by one or the other of these dicarboxylic amino acids, and distinguishing

Table 1 Inhibition of the binding of L-^{14}C-glutamate and L-^{14}C-aspartate to the hydrophobic protein from rat cerebral cortex by L-glutamate inhibitors

	Bound L-^{14}C-glutamate (nmol per mg protein)	Bound L-^{14}C-aspartate (nmol per mg protein)
Control	0.56 ± 0.03	1.98 ± 0.28
DL-α-methyl glutamate	0.29 ± 0.04	1.54 ± 0.19
Diethylester of L-glutamate	0.19 ± 0.06	1.46 ± 0.10
L-Nuciferine	0.26 ± 0.09	1.62 ± 0.07

The binding was carried out in aliquots of 100 μg of protein from the first fraction separated by Sephadex LH20 chromatography of the rat cerebral cortex. In the control experiments the binding was carried out with 2×10^{-7} M L-^{14}C-glutamate or 4×10^{-7} M L-^{14}C-aspartate. After incubation for 15 min the samples were rechromatographed on small Sephadex LH20 columns (15 × 0.8 cm) and the bound radioactivity and protein, eluted in chloroform, were measured. For the competition experiments the fractions were preincubated for 30 min with 4×10^{-5} M of the various drugs. The results are the mean of three experiments ± s.d. L-(U)^{14}C-aspartate (231 mCi nmol^{-1}) and L-(U)^{14}C-glutamate (270 mCi mmol^{-1}) were from Amersham.

between the two receptors are, however, more difficult. At the recent International Meeting of Neurochemistry (September 1975) Graham summarised some of the evidence favouring distinct functions for the two amino acids, concentrating on the possible transmitter role of L-aspartate. For example, a higher content of this amino acid is found in the ventral than in the dorsal grey matter of the spinal cord[2], aortic occlusion leads to loss of aspartate content and degeneration of small neurones[3], reduction in aspartate content is seen in the spinal cord after section of dorsal roots[4] and in the olfactory cortex after olfactory bulbectomy[5], which also decreases glutamate. Renshaw cells are slightly more sensitive to the ionotophoretic administration of L-aspartate while the reverse is true of interneurones of the dorsal spinal horn[6]. It is possible that L-glutamate and L-aspartate, being flexible molecules, fold or unfold and could interact with either receptor and McCulloch *et al.*[7] accordingly used kainate, a conformational restricted analogue of glutamic acid, which would be unlikely to fold to occupy the aspartate receptor, and *N*-methyl-D-aspartate, which would be too small to interact with the glutamate receptor (Fig. 1). The difference in sensitivity between the two groups of neurones to these agonists was much greater: the Renshaw cells were much more sensitive to *N*-methyl-D-aspartate and the dorsal interneurones to kainate[7].

The L-glutamate binding proteins of insect[8] and crustacean muscle[9,10] are hydrophobic proteins (that is, proteolipids) extractable with organic solvents. Such proteins did not bind L-aspartate and, in the case of the crustacean muscle, can be separated from another protein binding γ-aminobutyric acid (GABA)[9,11]. Recently we have separated a hydrophobic protein fraction from synaptic membranes of the rat cerebral cortex that binds, with high affinity, L-glutamate and GABA[12]. The same protein fraction also binds L-aspartate and this poses the problem of differentiating between the various binding sites. We shall present here some evidence that this fraction contains a protein binding L-aspartate and which may be its receptor.

Amounts of 200–300 mg of lyophilised cerebral cortex of adult rats were extracted with chloroform–methanol (2 : 1)[13] and the extract, containing 3–4 mg of hydrophobic protein (that is, proteolipid) per g fresh tissue, was chromatographed on a Sephadex LH20 column equilibrated with chloroform. Elution was carried out with chloroform and a series of mixtures of chloroform–methanol of increasing polarity[14]. The first protein fraction, eluted in chloroform in the void volume of the column, is the one that binds L-^{14}C-aspartate and L-^{14}C-glutamate. The binding sites were differentiated by the following experiments. (1) Aliquots of the first protein fraction, containing 100 μg of protein, were preincubated with 4×10^{-5} M of L-glutamate or with 2×10^{-5} M L-aspartate; then they were submitted to binding with 4×10^{-7} M ^{14}C-aspartate or 2×10^{-7} M L-^{14}C-glutamate following an experimental procedure similar to that indicated in Table 1. It was found that L-aspartate did not inhibit the binding of L-^{14}C-glutamate (0.41 nmol per mg protein in the control and 0.43 ± 0.02 in the experimental) and, vice versa, L-glutamate only slightly inhibited the binding of L-^{14}C-aspartate (3.07 nmol per mg protein in the control and 2.62 ± 0.07 in the experimental).

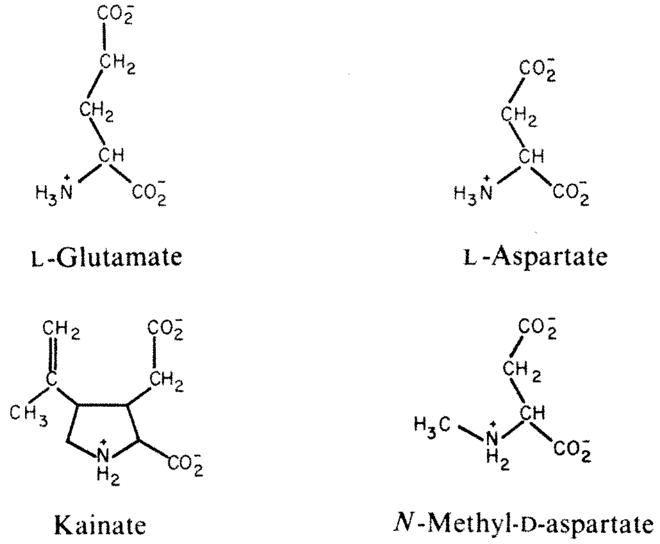

Fig. 1 Structural formulae of L-glutamate and L-aspartate and their respective analogues: kainate and *N*-methyl-D-aspartate.

(2) Experiments were carried out with the physiological competitors of L-glutamate. DL-α-methyl glutamate[15], the diethylester of L-glutamate[15] and L-nuciferine[16] were much more potent in blocking the binding of L-^{14}C-glutamate than in blocking that of L-^{14}C-aspartate (Table 1). The three drugs inhibited, respectively, by 65, 48 and 54% the binding of L-^{14}C-glutamate and only by 26, 22 and 18% that of L-^{14}C-aspartate.

(3) The most striking results were, however, those obtained with the two agonists kainate and *N*-methyl-D-aspartate, which according to McCulloch *et al.*[7], bind preferentially glutamate and aspartate receptors respectively (Fig. 1). Kainate inhibits the binding of L-^{14}C-glutamate by 54% but it does not interfere with the binding L-^{14}C-aspartate (Table 2). On the other hand, *N*-methyl-D-aspartate does not change the binding of L-^{14}C-glutamate but inhibits that of L-aspartate by 45%. These results are in

Table 2 Inhibition of the binding L-^{14}C-glutamate and L-^{14}C-aspartate to the hydrophobic protein from rat cerebral cortex by their analogues kainate and *N*-methyl-D-aspartate

	Control	Kainate (2.5×10^{-5} M)		*N*-Methyl-D-aspartate (4×10^{-5} M)	
Labelled amino acid	(nmol per mg protein)	(nmol per mg protein)	Inhibition %	(nmol per mg protein)	Inhibition %
L-^{14}C-Glutamate (2×10^{-7} M)	0.56 ± 0.03	0.26 ± 0.02	54	0.57 ± 0.11	0
L-^{14}C-Aspartate (4×10^{-7} M)	1.98 ± 0.28	1.99 ± 0.19	0	1.09 ± 0.07	45

The binding was carried out as described in Table 1. The results are the mean of three experiments ± s.d. Kainate and *N*-methyl-D-aspartate were generous gifts from Professor D. R. Curtis.

agreement with the physiological observations of McCulloch *et al.*[7], and support their interpretation[17].

Our findings suggest that the hydrophobic protein fraction isolated from the cerebral cortex, in the void volume of the Sephadex LH20 column, contains different binding sites for L-aspartate and L-glutamate. We have previously shown that it also contains different binding sites for GABA[12]. It remains to be seen whether these binding sites reside in a single or, more probably, in different proteins and whether they represent the true receptors or belong to the active transport system for these amino acids[18,19]. In favour of their possible receptor function is the fact that, in our experiments, the binding is carried out in the absence of Na ions, which are essential for the transport mechanism to operate. Furthermore, several of the drugs used, such as *N*-methyl-D-aspartate, kainate and diethyl ester of L-glutamic acid are not substrates for the transport system[19].

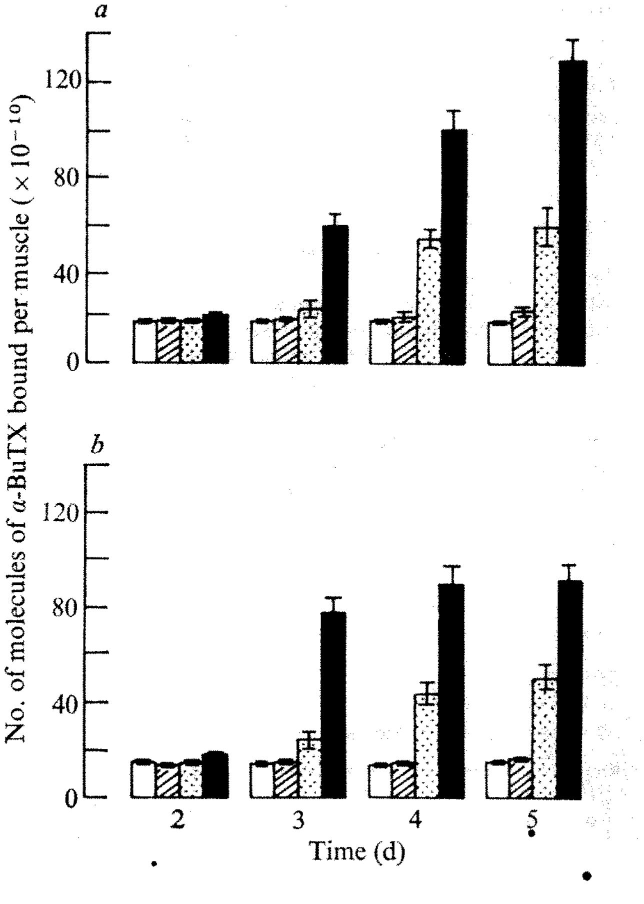
Comparison of α-bungarotoxin binding to skeletal muscles after inactivity or denervation

DENERVATION of skeletal muscles causes a spread of acetylcholine (ACh) sensitivity along muscle fibres, but it is not yet clear whether this results from muscle inactivity or from a loss of trophic influence of the nerve on the muscle[1]. It has been suggested that inactivity is responsible for the phenomenon because the application of a cuff containing a local anaesthetic to a nerve blocked the conduction of the nerve impulses and caused the development of widespread sensitivity to ACh (ref. 2, but see ref. 3). The local anaesthetics used in that study, however, have since been shown to block axoplasmic transport *in vitro*[4,5] and *in vivo*[6], as well as to induce neuronal degeneration[7]. Axoplasmic transport seems to be involved in the trophic influence of the nerve on muscle because blocking this transport induces spreading of ACh sensitivity in muscle fibres[8,9]. We have used tetrodotoxin (TTX), incorporated into silicone cuffs placed around motor nerves, to test whether the resultant inactivity induced a spread of ACh sensitivity in skeletal muscle, as inferred from the binding of α-bungarotoxin (α-BuTX). TTX was chosen because it does not block axoplasmic transport *in vitro*[5].

Female Sprague–Dawley rats (225–250 g) were anaesthetised with ether, the left sciatic nerve was exposed, and a hollow cylindrical cuff made from Silastic 382 (Dow Corning) was placed around the nerve. The control cuffs contained 20% NaCl (w/w) mixed in the Silastic, and the TTX cuffs contained in addition 0.02% TTX (Sigma); each TTX cuff contained approximately 5 μg of TTX. Paralysis was evaluated three times a day by inspecting the toe-spreading reflex when the animals were lifted by the tail[7]; paralysis was present when the animals that received a TTX cuff recovered from anaesthesia and lasted 3–5 d, but the animals that received a control cuff showed no paralysis. The muscles of the contralateral side served as unoperated controls in the animals that received a control cuff, while those contralateral to a TTX cuff were denervated by removing a 5-mm segment of the sciatic nerve in the mid-thigh region.

At various times thereafter, the extensor digitorum longus (EDL) and soleus (SL) muscles from both sides were removed under ether anaesthesia and exposed to ^{125}I-α-BuTX[10]. The muscles were incubated for 1 h (22 °C) in a Krebs solution containing labelled α-BuTX (1 μg ml^{-1}), and then washed for 16–20 h with Krebs solution (4 °C). The total radioactivity retained by the muscles was measured (Nuclear Chicago gamma spectrometer), and the change in α-BuTX binding induced by control cuffs, TTX cuffs and surgical denervation was compared (Fig. 1). The muscle inactivity produced by the TTX cuffs resulted in only a slight increase in α-BuTX binding after 3 d, but α-BuTX binding increased fivefold in the SL and threefold in the EDL muscles denervated for the same time; the difference of α-BuTX binding to the TTX-inactivated

Fig. 1 Effect of TTX cuffs, control cuffs, and surgical denervation on the binding of α-BuTX to the EDL (*a*) or SL (*b*) muscle of the rat. Each column represents the mean ± s.e. of 7–11 muscles. Binding is expressed as molecules of α-BuTX bound, which was calculated from the specific activity of the ^{125}I-α-BuTX used. Columns: open, unoperated; hatched, control cuff; spotted, TTX cuff; black, denervated.



muscles and the denervated muscles was significant ($P<0.001$). But muscles that had been paralysed for 4 and 5 d by TTX cuffs showed a clear increase in α-BuTX-binding ($P<0.001$), although the magnitude of this increase was again less ($P<0.001$) than that produced by denervation. Some of the animals that had been exposed to TXX cuffs for 4 and 5 d showed some recovery of function and it is possible that this short (< 12 h) recovery reversed some of the induced increase of ACh receptors; however, its effect was probably small because α-BuTX binding was still increased (240±30% of control) in the muscles of animals 3-4 d after recovery from 4–5 d of TTX-induced inactivity.

The increased α-BuTX binding observed with the TTX cuffs was not due to nerve degeneration. Rats that had received cuffs 3 d earlier were anaesthetised with pentobarbital (intraperitoneal, 50 mg kg^{-1}), the sciatic nerve was exposed and stimulated electrically (supramaximal voltage, 0.3 ms, 0.4 Hz), and the isometric contractions of the EDL muscle were recorded; the muscle was also stimulated directly. In nine animals in which impulse conduction was completely blocked by a TTX cuff, nerve stimulation distal to the cuff induced a muscle contraction (11.4±0.7 g tension per 100 mg muscle wet weight; mean ±s.e.) similar to that produced by direct muscle stimulation (11.9±0.7 g): thus, TTX, unlike lidocaine[7], does not induce nerve degeneration. In 10 animals that received a control cuff, nerve stimulation proximal or distal to the cuff, and direct muscle stimulation all induced similar muscle contractions (10.8±0.6, 11.6±0.5, 11.5±0.4 g tension, respectively), showing that the cuff itself did not damage the nerve.

Other results demonstrated that the TTX cuffs did not block axoplasmic transport *in vivo*. For these experiments a ligature (Ethicon 4-0 thread) was tied around the sciatic nerve 3–4 mm distal to the cuffs and the accumulation of cholinesterase (ChE) activity at these ligatures after 20 h (ref. 11) was measured. Nerve segments (2 mm) were weighed, homogenised in ice-cold sucrose (0.32 M; 20 mg tissue per ml) and the ChE activity in 50 μl of the homogenate was assayed (22 °C) by the method of Ellman *et al.*[12], using acetylthiocholine (200 μM) as the substrate. There was no significant difference ($P>0.20$) between the accumulation of ChE activity at a ligature distal to a TTX cuff and the accumulation in ligatured control nerves (289±22% of penultimate segment; mean±s.e.), whether the ligature was tied 1 h (306±22%) or 24 h (271±27%) after placing the TTX cuff.

Thus, our results show that local application of TTX to the sciatic nerve of rats will produce muscle inactivity without causing nerve degeneration or blocking axonal transport. This inactivity increases the amount of α-BuTX bound by the SL and EDL muscles, but this change seems to be less than and to have a different time course from that induced by denervation. This difference might reflect a role for factors other than activity in the control of ACh sensitivity in skeletal muscles.

We thank the Medical Research Council of Canada for financial support and Dr W. E. Dennis of Dow Corning Ltd for Silastic 382.

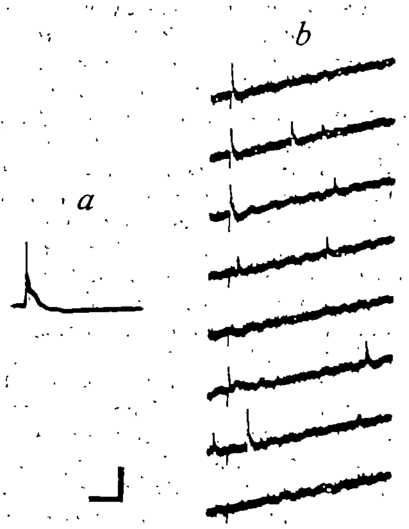
Suppression of transmission at foreign synapses in adult newt muscle involves reduction in quantal content

IN the search for the principles underlying the orderly development of the nervous system, it is interesting to know whether vertebrate neurones or muscle fibres can distinguish synaptic contacts of the axons which normally innervate them from the input of incorrect (or foreign) nerves. This possibility has been considered by asking whether foreign synapses induced on a denervated muscle fibre are displaced or suppressed when the muscle is reinnervated by its normal nerve. Observations of oculomotor reflexes in goldfish after experimental cross innervation of extraocular muscles led to the proposal that correct reinnervation suppressed foreign synapses[1]. Attempts to reproduce these results in the same system[2], however, led to the opposite conclusion—that foreign transmission continued unabated after reinnervation by the correct nerve. A similar persistence of foreign synaptic function was found in reinnervated perch gill muscle[3], frog fast muscle[4], mammalian skeletal muscle[5,6] and sympathetic ganglion cells[7]. Adult salamander muscle is the one other system in which suppression of incorrect synapses has been indicated; by the criterion of muscle fibre contraction monitored during foreign innervation and correct reinnervation, Cass *et al.*[8] concluded that return of the correct nerve caused inactivation of foreign synaptic input. The present investigation examines this phenomenon at the level of transmitter

Fig. 1 Responses from a single anconeus muscle fibre 50 d after correct nerve resection. *a*, Single stimulus to the correct nerve evoked a large endplate potential with action potential superimposed. *b*, Consecutive responses to repeated maximal stimulation of the foreign nerve at a frequency of 0.2 per s. One stimulus pulse occurs near the beginning of each sweep, as indicated by artefact. With some stimuli the foreign nerve failed to release transmitter (traces 4, 5, 7 and 8 from top). Note the spontaneous miniature endplate potentials occurring randomly in (*b*). Calcium concentration normal (1.8 mM) in both. Calibration marks 40 mV and 100 ms in (*a*), 2 mV and 400 ms in (*b*). All five fibres studied in the muscle had been reinnervated by the correct nerve and had low quantal contents for foreign transmission (m = 0.66, 0.94, 1.06, 0.43, 1.47).



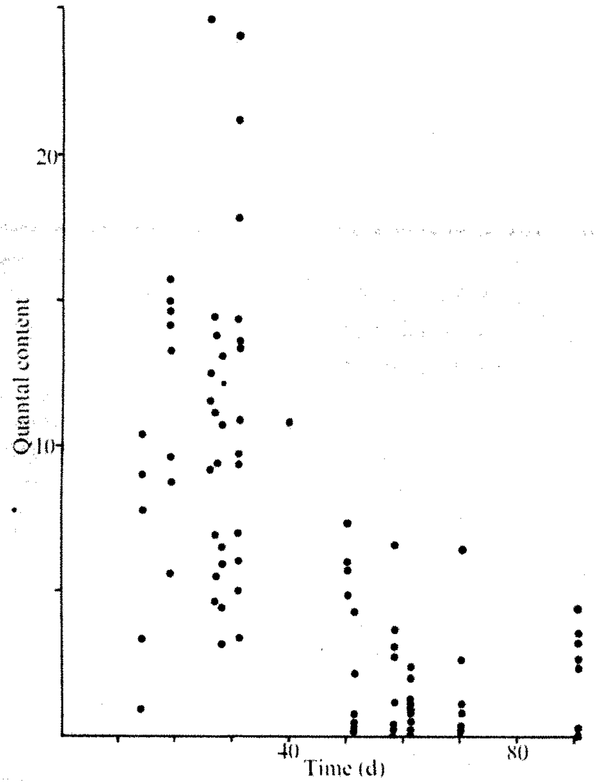


Fig. 2 Scatter diagram of mean quantal content of foreign nerve release plotted as a function of time after the correct nerve was resected. Each point represents the mean content at a single anconeus fibre, measured as indicated in the text. Correct reinnervation was first detected 26 d after resection, and was completed within 50–60 d. In some cases movement artefacts resulting from stimulation of the correct nerve prevented us from determining the absolute amplitude of the correct junctional potential. Because of variability in the rate of correct nerve regrowth, we do not know the time elapsed since correct reinnervation of any given muscle fibre. Not represented in this figure are four muscles, examined at 57, 70, 93, 135 d, in which no foreign nerve responses were found.

release from individual synapses, and provides evidence that transmission by foreign nerve terminals declines in quantal content when adult newt muscle is reinnervated by its correct nerve.

Adult newts, *Notopthalmus viridescens*, were anaesthetised with tricaine (1/1,000 in Ringer solution). The forelimb flexor (humero-antibrachialis) muscle was excised completely and its nerve was displaced laterally to the surface of the antagonistic anconeus muscle. The animals were then held in tanks of water and fed weekly on liver or brine shrimp. Two weeks after the initial operation the correct nerve to the anconeus muscle was crushed, or cut and resected. In some animals the correct nerve was crushed a second time 2 or more weeks after the initial denervation. At various times after the final denervation intracellular recordings were made from single fibres of the anconeus muscle in normal amphibian Ringer, with independent stimulation of the correct and foreign nerves.

The quantal content of the foreign transmission was determined in individual fibres from the coefficient of variation of the evoked responses[9], obtained by stimulating 200 times at a frequency of 0.2 per s. In 25 fibres this value for quantal content was compared with that obtained by the method of failures[9]; there was no significant difference between the values determined by these two means.

Muscles examined within the first week after lesion of the correct nerve showed no functional transmission from either nerve. Between the first and second week transmission from the foreign nerve was detected in a few fibres; in these, stimulation evoked endplate potentials of low amplitude, with frequent failures. The longer the period of correct denervation, the greater was the extent and efficacy of foreign innervation. Thus, when the correct nerve was cut rather than crushed initially, or when it was crushed a second time 10–14 d after the first denervation, a greater proportion of the fibres developed functional foreign transmission and the average amplitude of the responses evoked by foreign nerve stimulation was larger. In some fibres the amplitude of foreign response became large enough to cause an action potential and twitch, like that seen in normally innervated adult fibres[10,11].

Approximately 2 weeks after the correct nerve was crushed, or 3–4 weeks after it was resected, its axons began to reinnervate the muscle. At this stage individual fibres were found which received functional contact from both correct and foreign axons. The correct synapses rapidly developed to their normal state of transmission since correct input, when detected, was almost always sufficiently strong to cause normal action potentials (Fig. 1*a*). Within 3 months after the final denervation all fibres had received correct reinnervation.

The synaptic potentials resulting from foreign transmission were usually subthreshold in those fibres which had received correct reinnervation (Fig 1*b*). The mean quantal release from the foreign nerve was measured in individual fibres at various times after correct nerve resection. The pooled results from 84 fibres of 13 muscles in which the correct nerve had been resected or crushed twice are presented in Fig. 2. These data reveal that foreign transmission declines in quantal content with time after the correct nerve returns. A similar series of experiments in which the correct nerve was crushed only once gave the same general result, although the maximum values of foreign quantal content were lower and the decline occurred more rapidly.

Although correct reinnervation resulted in a decline in the amount of transmitter released per impulse from foreign terminals, the average size of the quantal events remained unchanged; release failure was frequent yet the mean amplitude of foreign evoked quanta was normal (0.5–2 mV) and equal to that of spontaneous potentials in the same fibre, as illustrated in Fig. 3 (presumably the spontaneous events result from release by correct and foreign terminals). This indicates that the suppression of foreign inputs involves a decline only in the number of packets of transmitter released, and not in the amount of transmitter per packet nor in the sensitivity of muscle membrane to transmitter at the site of foreign nerve contact.

One potential difficulty with such physiological analysis arises from the fact that not all the fibres in the anconeus muscles can be assumed to receive innervation from foreign axons. Thus, after correct reinnervation a complete lack of response to foreign nerve might result either because a fibre had never received foreign innervation or because such innervation had been suppressed. But this does not seem to present a real problem in our experiments: in the set of animals with correct nerve resection, all muscles ($n=10$) examined in the first 2 months had some fibres with foreign transmission whereas in only half (4/8) of those studied 2–4 months after denervation could fibres with foreign transmission be found.

In six animals the correct nerve was recrushed 6 months after the first lesion; foreign transmission reappeared within as little as 2 days, and developed sufficient strength to elicit action potentials within 1 week. This rapid return of foreign transmission, as compared with the 10–14 d delay preceding the initial establishment of foreign innervation, suggests that foreign synapses, suppressed on correct reinnervation, may remain in close proximity with the muscle fibres.

Neither the morphology nor the relative position of correct and foreign synapses along individual muscle fibres is known. In normal muscles single fibres are innervated

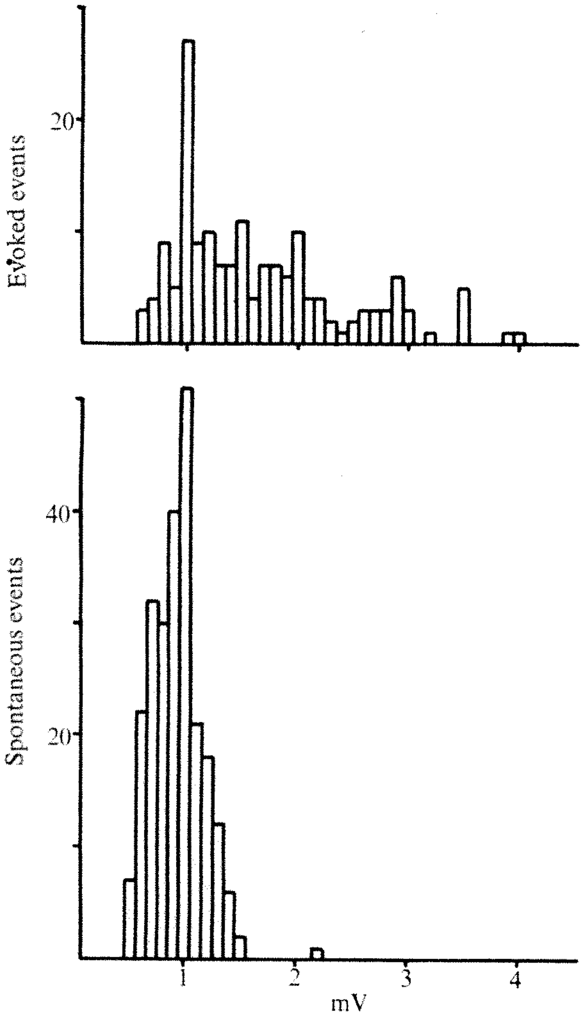

Fig. 3 Histograms comparing the amplitudes of spontaneous miniature endplate potentials (top) and of responses evoked by foreign nerve stimulation (bottom) in the muscle fibre from which examples in Fig. 1 are taken. The foreign nerve was stimulated 251 times, with 87 failures: $m = 1.1$. The calcium concentration was normal (1.8 mM). Noise level, 100 μV.

at several sites along their length, as revealed by electrophysiology[10,11] and by cholinesterase staining (unpublished). This suggests that here correct and foreign synapses occur in close proximity to one another.

Our results indicate that muscles of the adult newt differ from those of higher vertebrates in that they can discriminate between correct and incorrect innervation, and suppress the incorrect synaptic input. Urodele amphibia, with the ability to regenerate limbs, may retain in adulthood a capacity usually confined to embryos which permits them to correctly reconnect their peripheral innervation.

This work was supported in part by a training grant from the Sloan Foundation and a grant from the National Institutes of Health.

Note added in proof: The proportion of anconeus fibres with functional foreign synapses has been determined at short and long periods after correct nerve resection. In eight muscles examined 19–47 d after resection all of 176 fibres received foreign input, whereas in nine muscles 57–135 d after resection only 37 of 151 fibres (25%) had functional foreign input.

Effect of muscle disuse on acetylcholine receptors

MOTOR nerves have an important rôle in the trophic regulation of many properties of skeletal muscle, including acetylcholine receptor (AChR) distribution[1]. In innervated muscle, the density of AChR at neuromuscular junctions is at least 2,500 times greater than at extrajunctional regions[2]. When the motor nerves are sectioned, extrajunctional AChR density increases markedly[2–5]. The trophic mechanisms by which the nerves normally prevent this denervation change are not yet well understood. It has been suggested that muscle use contributes to the control of AChR. This hypothesis has been tested in two ways. First, electrical stimulation was applied directly to denervated muscle, and the extrajunctional ACh sensitivity was determined. The results indicated that stimulation-induced use largely prevented the denervation effect[6,7]. Second, attempts have been made to assess the effect of disuse of muscle on extrajunctional ACh sensitivity. Various methods have been used to eliminate muscle contraction but all have had shortcomings. In some cases, the 'disuse' has been incomplete[8–10]; in others, the methods used to block nerve conduction[7,11] have produced blockade of axonal transport[12,13], which may itself result in denervation effects[14,15]. Using a new model of disuse free of these problems, we have now compared the effects of disuse and denervation with respect to extrajunctional AChR density. We report here evidence that disuse produces a significant increase in extrajunctional AChR, but does not completely reproduce the effect of surgical denervation.

In our model, complete blockade of nerve conduction, without alteration of other nerve functions, has been produced by repeated local application of tetrodotoxin (TTX) to the sciatic nerves of rats. TTX interferes with conduction of electrical impulses in excitable membranes by blocking sodium conductance channels[16]. Quantitative determinations of extrajunctional AChR density in disused and denervated muscles have been made by means of a technique using ^{125}I-α-bungarotoxin binding[17].

Experimental procedures were carried out on Sprague–Dawley female rats (190–215 g) under chloral hydrate anaesthesia (400 mg kg^{-1}). The sciatic nerve was exposed by an incision in the thigh, and a subperineurial injection of TTX or Ringer solution was made by means of a glass micropipette coupled to a micrometre-driven syringe, mounted on a micromanipulator. In initial trials, we found that intraneural injection of 2 μg of TTX in 2 μl of Ringer solution produced complete paralysis beginning within 10 min, and lasting usually for more than 48 h. More detailed studies of the physiological effects of the TTX treatment were made in six clinically paralysed animals 48 h after intraneural injection. To determine whether the nerve block was complete, the sciatic nerve was stimulated *in vivo* proximal to the injection site, while electrical recordings were made at high gain from the surface of the soleus and extensor digitorum longus (EDL) muscles, and the exposed muscles were observed under the stereomicroscope. The nerve and muscle were then removed in continuity, and intracellular recordings were made *in vitro* (during nerve stimulation) with conventional 3 M KCl-filled microelectrodes. By these criteria, nerve conduction was totally blocked at the level of the TTX injections, although the distal portion of the nerve and the muscle functioned normally (see below).

In the experiments reported here we therefore adopted a uniform protocol in which the injections were repeated at 48-h intervals. Just before each repeat injection of TTX and at the termination of each experiment, blockade was tested by nerve stimulation. When blockade was incomplete the animals were discarded.

At 0, 4, and 7 d, the rats were anaesthetised and the EDL and soleus muscles from each were dissected out and prepared for measurement of extrajunctional AChR density. This measurement depends on the specific, quantitative and irreversible binding of ^{125}I-α-bungarotoxin with AChR. The number of bungarotoxin-binding sites is proportional (perhaps equal) to the number of AChR sites[18].

The results (Table 1) show that disuse produced a significant increase in extrajunctional AChR in all groups. Denervation always produced a significantly greater increase in AChR than did disuse. The disused soleus showed significantly greater increase in extrajunctional AChR than did the comparable EDL at both 4 d ($P < 0.01$) and 7 d ($P < 0.05$).

The injection procedure itself could not account for these effects since subperineurial injections of Ringer solution did not produce an increase in AChR density above control levels. TTX did not exert an inhibitory influence on extrajunctional receptors, since treatment with denervation plus TTX resulted in levels of AChR similar to those of denervation alone.

The effects of the experimental treatments on the morphology and function of the sciatic nerve were evaluated. Nerves of all the 7-d TTX and Ringer-injected animals were embedded in Epon, and 1-μm thick sections, stained with toluidine blue, were coded and examined microscopically. No morphological differences between TTX and Ringer-injected nerves were found; in both only occasional degenerated axons were identified. The distal segment of the blocked nerves and the muscle fibres could function normally, since stimulation distal to the TTX block resulted in brisk muscle contraction. Intracellular recordings of minature endplate potentials showed normal frequency (soleus=2.0±0.18 s^{-1}; EDL=2.4±0.27 mV) and amplitude (soleus=0.37±0.03 s^{-1}; EDL=0.46±0.05 mV, corrected[19] to 75 mV RMP), indicating that the motor nerve terminals remained intact. Fast axonal transport of protein and glycoprotein was measured after injection of ^{3}H-leucine or ^{3}H-fucose into the lumbar ventral horns. In nerves treated with TTX for 7 d the rate through the level of injection was normal (385±34 mm d^{-1})[20] and equal to that of the control side. Delivery of ^{3}H-fucose-labelled glycoproteins to the motor nerve endings was also similar in control and TTX-treated nerves, as shown by autoradiography of hindfoot lumbrical muscles 24 h after labelling of the ventral horns[21].

Table 1 Effects of treatment on extrajunctional AChR density

Treatment		Time	
		4 d	7 d
Soleus muscle			
Untreated	22±2 (30)†		
Denervation		195±16 (11)*	381±39 (14)*
TTX		96±23 (5)*†	243±46 (7)*§
Ringer		22±1 (3)†	12±3 (6)†
TTX+denervation		200±23 (5)*	
EDL muscle			
Untreated	10±1 (36)†		
Denervation		168±26 (11)*	356±35 (13)*
TTX		15±4 (5)†‡	130±33 (7)*†
Ringer		6±1 (3)†	7±2 (6)†
TTX+denervation		141±29 (5)*	

*Greater than normal $P < 0.001$.

†Less than denervation $P < 0.005$.

‡Greater than normal $P < 0.05$.

§Less than denervation $P < 0.02$.

Muscles were teased longitudinally into three or four pieces, pinned at resting length and incubated for 3–4 h in modified Ham's F-12 culture medium containing 0.2–0.3 μg ^{125}I-α-bungarotoxin per ml (specific avtivity 2–5×10^4 (Ci mol^{-1}). The muscles were then washed thoroughly, fixed in 4% glutaraldehyde, and neuromuscular junctions were stained for acetylcholinesterase[25]. Junction-free muscle strips were further dissected under the stereomicroscope into small bundles of 10–100 fibres. The number and length of fibres in each bundle were determined and the radioactivity was measured in a gamma counter. Frozen muscle sections stained with haematoxylin and eosin were used to compute average fibre diameters. Results are expressed as AChR per $μm^2$ (mean±s.e.m.). Numbers in parentheses indicate number of muscles.

Based on these observations, the TTX-blocked preparation seems to fulfil the requirements of a pure disuse model. Nerve impulses were effectively blocked throughout the experimental period, thereby eliminating all nerve-mediated muscle usage. The experimental procedure did not damage the nerves structurally, interfere with spontaneous transmitter release, or block axonal transport and delivery.

The observation of a denervation-like increase of extrajunctional AChR in disused muscles is generally consistent with previous reports[8–10]. Our quantitative studies demonstrate that the effect of disuse is large, but is not as great as that of denervation. This implies that some additional neurotrophic influence also contributes to the regulation of AChR. Many possible factors have been postulated, including substances carried by axonal transport[14,15], spontaneously released ACh[22], and nerve–muscle membrane interaction[23,24] but further studies are needed to clarify the role of each. We conclude that use has a prominent but not exclusive role in the neurotrophic regulation of extrajunctional AChR.

Phospholipid exchange proteins in synaptosome and myelin fraction from rat brain

ACETYLCHOLINE stimulates the turnover of phosphatidylinositol (PI) and phosphatidic acid (PA) in brain *in vitro* and *in vivo*[2,3]. It has been suggested that this effect on phospholipid metabolism is related to synaptic nerve pulse conductance[4,5], and that phospholipid exchange proteins transfer PI from the site of synthesis—the endoplasmic reticulum—to the synaptosomal plasma membrane[5]. Exchange proteins have been isolated from bovine brain that transfer PI to membranes deficient in this phospholipid *in vitro*[6-8]. These proteins also catalyse the transfer of phosphatidylcholine (PC) and PA, although to a lesser extent[7]. We report here the presence of phospholipid exchange proteins in the soluble protein fractions derived from a synaptosomal membrane and myelin fraction.

Myelin and synaptosomes were prepared from rat brain cerebral hemispheres according to a slightly modified centrifugation scheme used by Morgan *et al.*[9] (legend to Fig. 1). The myelin fraction consisted mainly of irregularly formed multilamellar structures of vesicular appearance, often enclosing remnants of axonal contents (Fig. 1*a*). Electron micrographs of the synaptosomal fraction showed a rather homogeneous preparation of nerve-ending particles containing the characteristic synaptic vesicles and mitochondria; myelin fragments were absent (Fig. 1*b*).

The identity of the membrane fractions was further established by analysis of free cholesterol and total lipid phosphorus in the lipid extracts (Table 1). The values expressed in mg per mg protein compare favourably with those reported by Cuzner *et al.*[15] for myelin (0.460 mg of cholesterol and 0.868 mg of phospholipid) and Lapetina *et al.*[16] for synaptosomes (0.172 mg of cholesterol and 0.450 mg of phospholipid). The phospholipid–cholesterol molar ratio of 1.13 for myelin and 0.55 for synaptosomes agree with reported values[17]. Lipids from myelin and synaptosomes were further identified by two-dimensional, thin-layer chromatography[18]. Only the lipid extract from myelin contained cerebrosides and sulphatides. This confirms that the synaptosome fraction is devoid of myelin, as the electron micrographs indicated.

Soluble proteins were released from the synaptosome and myelin fractions by resuspending the fractions in 1 mM phosphate buffer, *p*H 7.1. After centrifugation at 105,000*g* for 2 h, approximately 15% of synaptosomal protein and 6% of myelin protein were recovered from the membrane-free supernatants. These soluble protein fractions were assayed for phospholipid transfer activity (Table 2). Compared with the crude 105,000*g* supernatant from total brain, the PI and PC transfer activity per mg of soluble protein was enriched eight- and fourfold, respectively, in the synaptosomes, and seven- and twofold in the myelin.

Because the transfer activities in the synaptosomal supernatant may not be representative of most activities found in the 105,000*g* supernatant, activities were compared by isoelectric focusing. The synaptosomal soluble protein fraction contains two major activity peaks at *p*H 5.02 and 5.34 (Fig. 2). Two major activity peaks were also observed with the 105,000*g* supernatant at *p*H 5.05 and 5.30. Each of the four peaks contained PI and PC transfer activity in a PI/PC activity ratio of approximately 2. Since the relative proportion which gave the two activity peaks was similar in both cases, the major phospholipid exchange proteins in the synaptosomes seem to be identical to those in the total brain cytosol. The relatively high transfer activities in the

Table 1 Phospholipid and cholesterol content of membrane fractions

Lipid class	Myelin	Synaptosome
Phospholipid	0.835 ± 0.048 (4)	0.495 ± 0.026 (3)
Cholesterol	0.427 ± 0.069 (4)	0.136 ± 0.008 (3)
Cholesterol* Phospholipid	1.13 ± 0.12	0.55 ± 0.01

Lipid extracts were prepared according to a modified Folch procedure[12]. Lipid phosphorus and membrane protein concentration were measured as before[13]. Cholesterol was determined by the method of Zak *et al.*[14]. Values are expressed in mg per mg protein. Quantities of phospholipid were obtained by multiplying the value of lipid phosphorus by 25. Numbers are given ± s.d. Numbers of experiments are given in parentheses.

*Molar ratio.

Fig. 1 Electron micrographs of the myelin (*a*) and synaptosome (*b*) fraction. Myelin sedimented at 1,000*g* for 15 min was resuspended in sucrose–EDTA–phosphate buffer; the suspension was centrifuged at 1,000*g* for 5 min followed by centrifugation at 1,000*g* for 15 min. The latter pellet was resuspended, layered on 8.5% Ficoll–0.32 M sucrose, and centrifuged at 95,000*g* for 60 min in the Beckmann SW-27 rotor. The myelin fraction was collected at the 8.5% Ficoll interphase. The crude mitochondrial fraction containing the synaptosomes was sedimented and washed three times at 7,500*g* for 25 min (ref. 10). The synaptosomes that collected at the 9–12% and 12–16% interphases of the Ficoll gradient, were pooled. The membrane fractions were prepared for electron microscopy as described before[11].

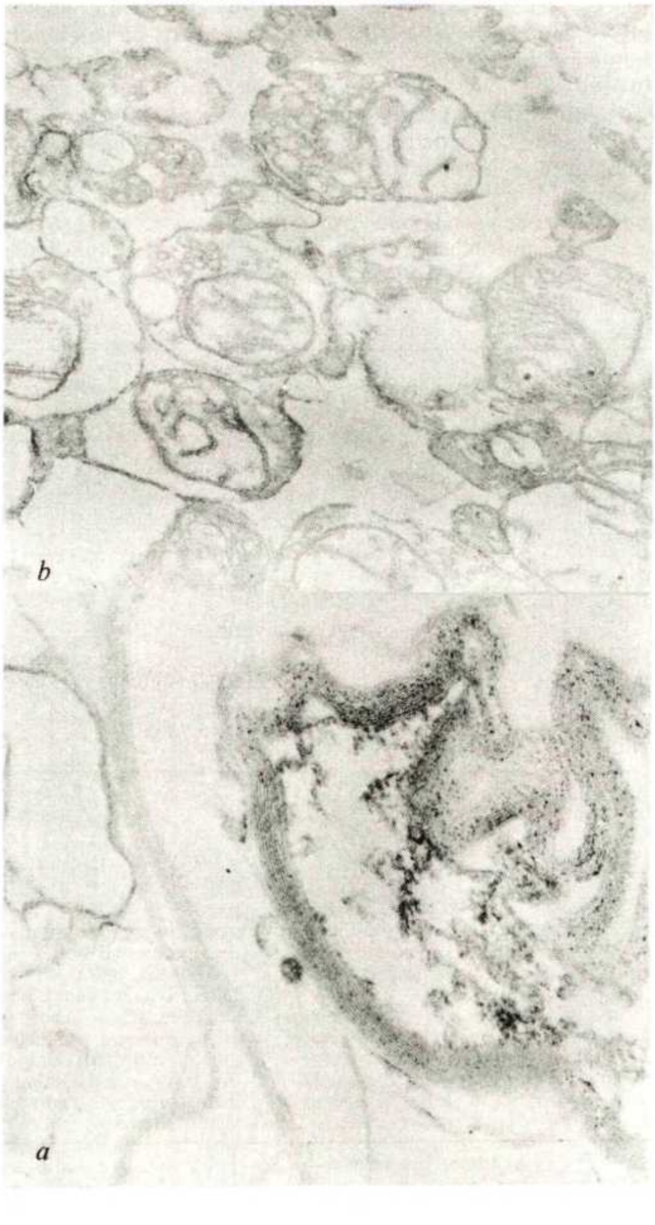

Table 2 Phosphatidylinositol and phosphatidylcholine transfer activities in membrane fractions and cytosol from rat brain

Protein fraction	PI transfer (%)*	PC transfer (%)*
Synaptosomal	28.2±4.2	7.6±1.5
Myelin	25.5±6.5	4.4±0.1
105,000*g* supernatant	3.7±0.4	2.0±0.1

PI and PC transfer activities were determined as before[6,13]. The assay systems consisted of rat liver microsomal donor membranes (1.25 mg of protein) and liposomal acceptor membranes (1 μmol of egg PC, 0.02 μmol of egg PA, 0.01% (by weight) of ^{3}H- or ^{14}C-cholesteryl oleate). The microsomal membranes were labelled specifically with methyl-^{14}C-PC or inositol-^{3}H-PI. Activity is expressed as percentage of the microsomal radiolabelled phospholipid pool transferred to the liposomes, per 30 min per mg of protein at 37 °C.
*Numbers ± s.d. are based on three experiments.

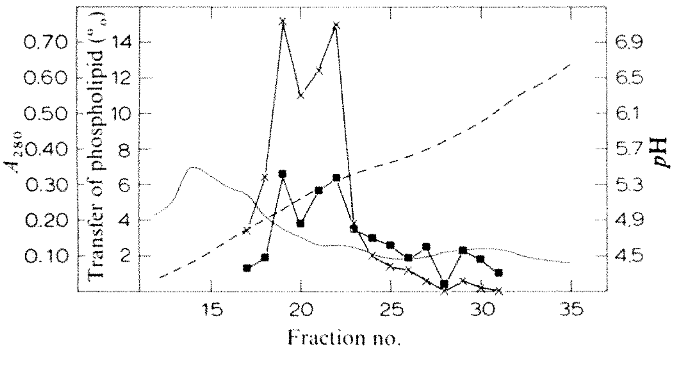
synaptosomes indicate that phospholipid exchange proteins are probably intrinsic to these membrane structures.

Some nerve impulses are propagated through the synaptosomal plasma membranes by triggering the release of acetylcholine at the presynaptic site[20]. *In vitro*, synaptosomes were found to respond to the addition of acetylcholine by an increased synthesis of PA and PI[21,22]. *In situ*, however, the effect on PI was observed throughout the neuronal cell[23,24]. This may be due to phospholipid transfer activities, present in the neurone, which would mask any localised effect by continuously distributing PI for example between the subcellular membrane structures (see also ref. 5).

Synaptosomal plasma membranes cannot synthesise their constituent phospholipids[25]. It is not known to what extent the turnover of PI in this membrane is associated with the transport of this phospholipid from its site of synthesis—the intraterminal smooth endoplasmic reticulum and/or the endoplasmic reticulum in the nerve cell body down the axon. It is assumed that phospholipid exchange proteins are involved and have a role in maintaining the phospholipid composition of a membrane[8].

The transfer activity in the soluble fraction from myelin suggests that exchange proteins are present in the axoplasm, part of which is preserved during the isolation of the myelin fraction. These proteins could be involved in the transport of phospholipids from the neuronal cell body to the nerve endings. Axonal transport of phospholipids has been demonstrated in rabbit nerves[26]. Studies with the dorsal root ganglion of the frog have provided evidence for simultaneous axonal movement of PC and protein[27]. On the other hand, part of the transfer activity may have originated from glial cytoplasm occluded in the myelin fraction.

Fig. 2 Separation of the phospholipid transfer activities present in synaptosomes, by isoelectric focusing. An LKB 8101 electrofocusing column and LKB ampholine solutions (LKB Productor AB, Stockholm) were used according to Vesterberg and Svensson[19]. Electrofocusing of soluble synaptosomal protein (3.7 mg) was carried out at 5 °C with a *p*H gradient from 4 to 8 during 5 h at 200 V followed by 64 h at 500 V; 2-ml fractions were collected. PI (×) and PC (■) transfer activity are expressed as the percentage of the microsomal radiolabelled phospholipid pool transferred per 60 min per 0.2 ml at 37 °C.



The occurrence of identical PI transfer proteins in bovine brain, heart and liver suggests that their action is not uniquely tied to processes occurring in the neuronal cell[7].

We thank Dr A. Verkley for help with the electron microscopy and Dr G. M. Helmkamp for advice.

Independence of Moloney virus-induced cell-surface antigen and membrane-associated virion antigens in immunoselected lymphoma sublines

THE nature of virus-determined cell-surface antigens (CSAs), recognised by the syngeneic host on neoplastic cells induced by RNA viruses has not been properly defined in spite of much recent speculation about the possible role of cell membrane associated virion proteins[1]. Lymphoma cells induced by the Moloney leukaemia virus (MLV) are said to carry MCSAs. It is a matter of some debate whether MCSA is identical with the tumour-associated transplantation antigen (TATA) detected *in vivo* by the rejection of small tumour grafts in syngeneic preimmunised animals. Views are divided on the origin and control of CSA and/or TATA: some authors regard them as virally induced, but distinct from virion antigens (see for example refs 2–5) whereas others believe that they are virion components, inserted into the cell membrane[6,7]. Antisera against purified virion components (designated according to the recently adopted nomenclature[8]) have been used to demonstrate that p30 and gp69/71 are present on the surface of mammalian type C RNA virus-infected cells[9–11]. We have confirmed this in the present paper using an MLV-

Table 1 Selection history of the YAC462-IR line

Passage no.	Selection: *In vitro**	Selection: *In vivo*	Inoculum: no. of cells	Cytotoxic sensitivity
1–3	Exposure to mouse	Inoculation to	10^5	0.74–0.83‡
4–6	syngeneic/anti-	preimmunised	10^5	0.37–0.64
7–8	MCSA serum and	mice†	10^4	0.24–0.34
9–11	rabbit complement		10^3	0.13–0.27
12–13	before each passage		10^3	0–0.10

The starting material was the YAC ascites line, 462nd serial passage.

*Mouse anti-MCSA serum was produced by the inoculation of 5×10^6 YAC cells irradiated with 6,000 r. to (A × C57 leaden) F_1 mice; 4–6 inoculations were given and serum was collected 1 week after the last inoculation. 5×10^6 cells were incubated with 0.1 ml of a 1:5 dilution of antiserum for 30 min at 37 °C. Antiserum was removed by centrifugation and 0.1 ml of a 1:5 dilution of rabbit complement added. Following further incubation for 45 min at 37 °C cells were counted with Trypan blue staining and inoculated to syngeneic A or (A × X) F_1 hybrids.

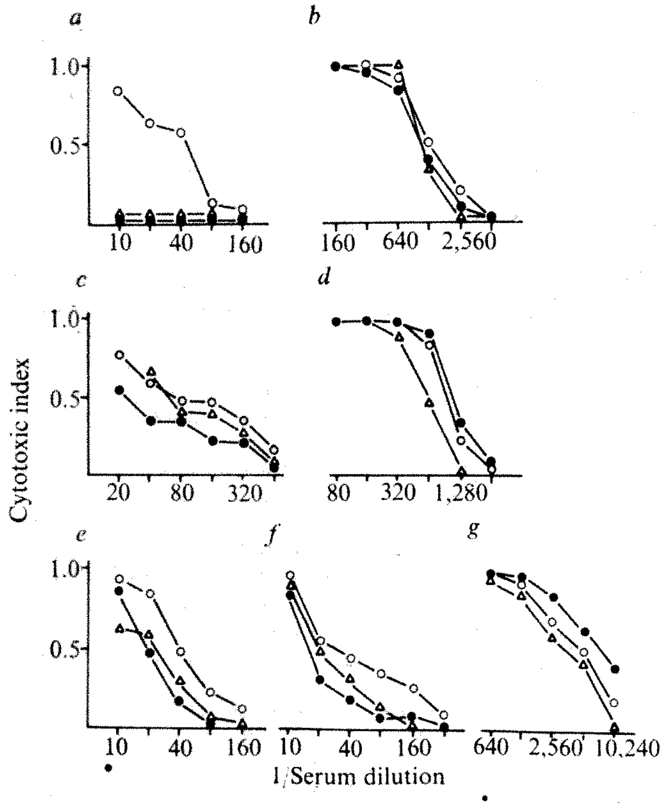
†The immunisation schedule was the same as for antiserum production.

‡A cytotoxic index was calculated by subtraction of the percentage of negative cells in the serum-treated sample from the percentage of negative cells in the control samples divided by the latter figure. The percentage of negatives in control serum ranged from 80 to 100%.

induced mouse lymphoma (YAC) and shown, in addition, that antigen(s) identical with or related to p15 and p12 are also expressed on the outer cell surface. Since these specificities were all detected with antisera produced in foreign species, the question as to which, if any of them, is responsible for MCSA, the antigen recognised by the syngeneic mouse—as mentioned above—remains open. We have approached this question by exposing the YAC lymphoma repeatedly to the immunoselective pressure of anti-MCSA sera and passage through preimmunised syngeneic hosts, until all detectable MCSA has disappeared. The immunoresistant sublines were compared with the original YAC line with regard to the expression of the various virion antigens. The results support that MCSA differs from the known virion antigens, partly or completely.

The combined *in vitro* and *in vivo* selection of the first immunoresistant subline (YACIR) was reported earlier[17]. Selection involved repeated exposure to mouse anti-MCSA sera in the presence of complement, before each passage *in vivo*. The sera were produced in A × C57BL or A × C57L F_1 mice, 3–6 immunisations with 6,000 r. irradiated YAC cells. After each cytotoxic exposure, surviving cells were passaged in syngeneic or semisyngeneic (A F_1) hosts, preimmunised with one inoculation of 6,000 r. irradiated YAC cells 2–2 weeks earlier. After ten such passages, the YACIR subline was completely resistant to the cytotoxic effect of the MCSA antiserum. Quantitative absorption experiments showed that MCSA was still present, but its concentration had decreased tenfold.

Fig. 1 Cytotoxic sensitivity of YAC (○), YACIR (●) and YAC 462-IR cells (△) to the antisera as indicated. *a*, Mouse anti-MCSA; *b*, rabbit anti-mouse; *c*, rabbit anti-FVp15; *d*, rabbit anti-FVgp 71; *e*, goat anti-RLVp30; *f*, goat-RLVp12; *g*, goat anti-RLVgp69/71.



For the present study, we have repeated the immunoselection experiment and obtained a second, independent immunoresistant subline (Table 1). Designated YAC 462–IR, it was completely resistant against the cytotoxic effect of the standard anti-MCSA serum.

For the cytotoxic tests, we used a microassay in which the serial serum dilutions in 0.002-ml volumes were injected under paraffin oil into rings of microtrays (Møller-Coats A/S, Norway) with an automatic Hamilton syringe. Cells (10^3 in 0.001 ml) were injected into the antiserum drop and the plates incubated for 20 min at 37 °C. Subsequently, 0.001 ml rabbit complement was added. The final dilution of complement was 1: 40 for YAC, RBL-5 and FLC, 1: 20 for YACIR, 3T3 and JLS-V9 cells, 1: 8 for YAC462-IR and 1 : 80 for A lymph node cells. Plates were incubated further for 45 min. Thereafter 0.0005 ml Trypan blue was injected into the same drop and the results read under an inverted microscope.

The goat anti-RLV (Rauscher leukaemia virus) sera were kindly provided by: Dr D. C. Fish, (anti-p30); Dr J. R. Stephenson (anti-p12) and Dr M. Strand (anti-gp69/71). The rabbit antisera against Friend virus proteins were kindly provided by Dr D. P. Bolognesi, (anti-p15) and Dr W. Schäfer (anti-gp71).

Figure 1*a* shows the high sensitivity of the original YAC line to anti-MCSA serum in sharp contrast against the complete resistance of the YACIR and YAC462-IR sublines. All three lines were equally sensitive to a rabbit anti-mouse serum (Fig. 1*b*) (raised by hyperimmunising a rabbit with mouse tumour cells induced by methylcholanthrene). Moreover, all lines were about equally sensitive to all tested reagents against the following purified virion components: p30, p12 and gp69/71 prepared from RLV (Fig. 1*e*–*g*); p15 and gp71 prepared from FV (Fig. 1*c* and *d*).

None of the antisera reacted with a series of control mouse cells, including normal A lymphocytes and the cell lines, NIH Swiss/3T3, BALB/3T3 and JLS-V9 (Fig. 2). The specificity of the anti-p30, anti-p15, anti-p12 and anti-gp71 sera was further confirmed by inhibition experiments with the corresponding purified protein (Table 2). These results suggest that MCSA is not identical with the p30, p15, p12 and gp71 specificities, expressed equally on the surface of YAC cells and the two IR-sublines.

It has been suggested that p30 is the principal cell surface antigen recognised by the rat[13–15]. Geering *et al.*[16] have shown that the rat can recognise "group specific" antigens

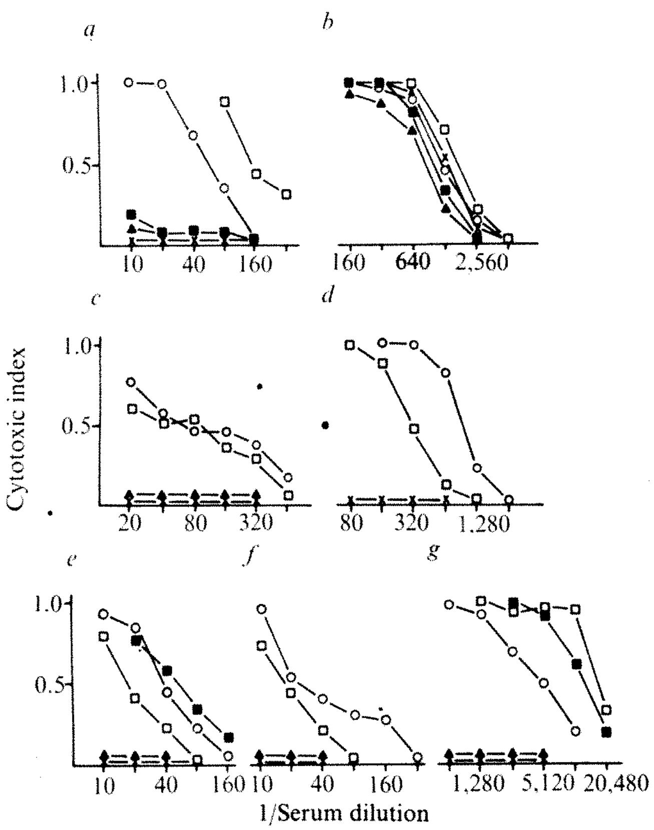


Fig. 2 Cytotoxic sensitivity of lymph node cells (×) of normal A mice, JLS-V9 cells (▲) and 3T3 cells (▲) of NIH Swiss and BALB/c origin, against YAC (○), RBL-5 (□) and F-765 (■). RBL-5 is an RLV-induced leukaemia cell line of C57BL origin and is grown *in vitro* as a suspension culture. F-745 was established *in vitro* as a suspension culture from the spleen of a DBA/2 mouse infected with FV. *a–g*, As for fig. 1.

(p30 in modern terminology) on the surface of leukaemia cells induced by mouse leukaemia virus, whereas the same antigen(s) remain unrecognised in the natural murine host[17].

It was shown recently that p15 is present on the virion envelope[18] and behaves mainly as an interspecies specific antigen. This antigen is recognised by the mouse and may even induce naturally occurring antibodies[17,19]. Both MCSA and TATA are leukaemia virus strain specific, however, in contrast to what has been claimed for p15 and in line with our findings that dissociate p15 clearly from MCSA.

In conclusion, the present work shows that repeated immunoselection, alternating between *in vitro* cytotoxic treatment with anti-MCSA sera, in the presence of complement, and passage through preimmunised mice, leads to immunoresistant sublines. Such lines are resistant to anti-MCSA sera, but their sensitivity to the cytotoxic effect of antisera directed against p12, p15, p30 and gp69/71 virion antigens remained unchanged. This suggests that the syngeneic murine host recognises a virally determined surface antigen, MCSA, that differs from known virion antigens partly or completely.

Table 2 Inhibition of cytotoxicity of antisera with the corresponding virion protein

Serum	Protein	Amount needed for 100% inhibition (ng)	
		RBL-5	YAC
Goat anti-RLVp30	RLVp30	72	36
Goat anti-RLVp12	RLVp12	100	100
Rabbit anti-FVp15	FVp15	125	62.5
Rabbit anti-FVgp71	FVgp71	125	125

The inhibition assay was carried out in the microcytotoxicity assay. The proteins were diluted in antiserum, at dilutions giving 70–90% killing. Ten twofold dilution steps of the proteins in 2 or 3 dilutions of antiserum were included in each test. The cells and complement were added to the drops containing the antiserum–protein mixtures. None of the proteins (500 ng) inhibited the cytotoxic activity of a rabbit anti-mouse serum.

We thank Dr R. Herberman for the RBL-5 cells and Dr C. Friend for the F-745 cells, and Mrs Margareta Hagelin, Miss Irma Jansson and Mrs Maj-Lis Solberg for technical assistance. Association of Epstein–Barr viral genomes with American Burkitt lymphoma

THE African form of Burkitt lymphoma (BL) is consistently associated with Epstein–Barr virus (EBV), as judged from the presence of elevated serum titres against viral antigens, and the occurrence of EBV DNA and EBV-associated nuclear antigen (EBNA) in the tumour cells[1,2]. It has been postulated that EBV has a role in the causation of BL in Africa. It has also been suggested that aetiological cofactors contribute to the high tumour incidence in the endemic areas. In particular malaria has been proposed by Burkitt[3] because of the geographical coincidence of BL and holo- or hyperendemic malaria. Rare cases of BL occur outside Africa but have not been shown to be associated with EBV[4]. We now present evidence for such an association.

We have studied 12 American patients with the diagnosis BL at the National Cancer Institute, for whom both sera and tumour tissue were available. Sera were assayed for antibody titres to several EBV-associated antigens. Tumour samples were transported frozen to Stockholm for assays of EBV DNA by nucleic acid hybridisation, using ^{32}P-labelled complementary RNA (cRNA) according to Lindahl *et al.*[2].

Among these 12 sera, two (R.A. and R.B.) had an antiviral capsid antibody (VCA) titre of ≥ 1:160, whereas the other ten had lower titres (see Table 1). Antibodies to the diffuse type of the early antigen (EA(D)) were high in only one case (R.A.), the remaining patients having low EA(D) titres (see Table 1). Only one patient (R.B.) out of 11 had a measurable antibody titre (1:40) to the restricted (R) type of EA, frequent in African BL patients; but serum from R.A. could not be evaluated in this regard.

Table 1 shows that positive hybridisation results were obtained with EBV cRNA on two separate tumour specimens from one patient (R.A.). Multiple EBV genome copies were present, as in African BL biopsies[2]. Another case (R.B.) was

Table 1 Serum titres and nucleic acid hybridisation with EBV ^{32}P-cRNA*

			Serum titres		^{32}P cRNA bound per 10 μg	EBV genome equivalents	No. of

*Initial specific activity 1.2×10^8 c.p.m. μg^{-1}.

†DNA content on each filter after the hybridisation was determined by the diphenylamine reaction and used to correct the data to 10 μg DNA filter. For further details on the hybridisation procedure see ref. 2.

‡Number of EBV genome equivalents per cell were calculated with the assumption that the molecular weight of EBV DNA is 10^8 and that of cellular DNA 4×10^{12}.

borderline positive, because the data obtained were close to the limit of sensitivity of the hybridisation technique. The ascites specimen from this patient (R.B.) was EBNA positive (20% positive cells). As noted above, R.A. and R.B. were serologically unique in the present material, in having elevated EBV antibody titres and, in the case of R.B., even a clear EA(R) tire. Material from the other 10 tumour tissues gave negative results, that is, they could not have contained one EBV genome equivalent or more per cell.

The bone marrow aspirate of the positive RA patient contained approximately 50% tumour cells, and thus harboured about 20 EBV genome equivalents per tumour cell. Solid lymph node pieces contained at least 38 EBV genome equivalents per cell, whereas tumour cells in suspension contained about 56 EBV genome equivalents per cell. This patient was a white, 16-yr-old male with no record of malarial infection or travels to Africa. His clinical course was unusual in that he presented with cervical lymph node and bone marrow involvement several months after a syndrome compatible with acute infectious mononucleosis. Patient R.B. presented with large abdominal tumour and ascites; he died during induction therapy of acute pulmonary embolus.

Thus, in agreement with the results of Pagano *et al.*[4] the majority of American patients with the diagnosis BL lack the serological or viral genome association with EBV documented in African BL biopsies. One clearly positive exception has been identified in this study and one probable (borderline) positive. In addition, a BL biopsy from Israel has been found to be EBNA positive and EBV DNA-positive (Goldblum *et al.*, unpublished). Similar data have been obtained independently in other laboratories. Bornkamm *et al.*[5] have detected EBV DNA in a biopsy from a 6-yr-old German girl and Gravell *et al.*[6] and Epstein *et al.*[7] have each reported one case of an EBV DNA-carrying American BL patient. Thus, there is at present a total of five or six cases of non-endemic BL which harbour EBV in the tumour. The relatively large series reported here would suggest a rate of approximately 8–17% EBV-associated BL[8] in the non-endemic material. Although the histopathology of the non-EBV-associated American BL cases resembles typical African BL, it is not clear whether these non-endemic cases represent the same disease entity or should be classified differently from a clinical or aetiological standpoint.

In the high endemic regions of Africa, BL is known to arise from a single EBV-carrying cell in more than 95% of cases[9,13]. EBV-negative lymphomas classified as BL do not readily become infected with EBV *in vivo* even in cases in which the patients have been demonstrated to be carriers of non-malignant EBV-transformed cells. One patient (K.K.) in the present series developed classical infectious mononucleosis while in remission; nevertheless, tumour cells collected at the time of EBV seroconversion (VCA 1:40) were EBV genome negative. Horizontal infection *in vivo* may be hampered by the presence of virus-neutralising antibodies, sensitised memory T cells, and/or the virus receptor status of the tumour. The latter varies from total resistance to *in vitro* infection, to relative susceptibility in cultured EBV-negative BL lines[10-12].

Since histology and cytology are the sole criteria for the diagnosis of BL at present, the high frequency of EBV-positive tumours in endemic regions, and their rare occurrence in non-endemic areas, may imply disease heterogeneity in spite of morphological uniformity. It has recently been proposed that EBV-associated BL and EBV-negative BL may be two different diseases with very similar histopathological features[8], and there are abundant parallel examples of this in the experimental literature on known virus-induced tumours. If EBV is aetiologically important in EBV-associated BL, it would seem likely that one or more cofactors are involved which could be mediated by environmental (for example, malaria), genetic (for example, chromosomal), immunological (for example, impaired surveillance), viral or other mechanisms which exert a major influence in endemic regions, but a sporadic effect in non-endemic areas. This influence may not be identical in nature, but similar in action in these differing regions.

The Stockholm part of this work was carried out with the support of the Virus Cancer Program of the National Cancer Institute and of the King Gustaf V Jubilee Fund.

Inhibition of the transition of a 40S ribosome–Met-tRNA$_i^{Met}$ complex to an 80S ribosome–Met-tRNA$_i^{Met}$ complex by 7-methylguanosine-5′-phosphate

7-METHYLGUANOSINE-5′-PHOSPHATE ($m^7G^{5'}p$) inhibits *in vitro* amino acid incorporation catalysed by several eukaryotic mRNAs[1]. The analogues, 7-methylguanosine-2(3)′-phosphate and unmethylated guanosine-5′-phosphate have no effect on these reactions, suggesting that the specific inhibition by $m^7G^{5'}p$ is related to the $m^7G^{5'}ppp$ cap known to be present at the 5′ end of many eukaryotic and viral mRNAs[2–12]. As a more direct test of this idea, we report here experiments with a fractionated protein chain initiating system from wheat germ in which mRNA is required for the conversion of a 40S–Met-tRNA$_i^{Met}$ complex to an 80S–Met-tRNA$_i^{Met}$ complex. Using several viral RNAs, we show that $m^7G^{5'}p$ inhibits only the mRNA-dependent step, and that this inhibition is demonstrable only with mRNAs that require a 5′ cap for translational activity.

The initiation process in the fractionated wheat system proceeds in three steps: formation of a factor–Met-tRNA$_i^{Met}$ complex, transfer of the complex to a 40S ribosomal subunit, and adjunction of the 60S ribosomal subunit to form an 80S ribosome–Met-rRNA$_i^{Met}$ complex. Figure 1*a* demonstrates the reaction leading to the formation of the 40S–Met-tRNA$_i^{Met}$ complex. This reaction requires two factors and GTP, and is unaffected by addition of mRNA. Figure 1*b* shows that further incubation at 3.6 mN Mg^{2+} with added ATP, mRNA and a third factor results in the formation of an 80S–Met-tRNA$_i^{Met}$ complex. The effect of several guanosine monophosphates on these reactions is examined in Table 1. Experiment 1 shows that the 40S reaction is unaffected in all cases. In the 80S reaction, $m^7G^{5'}p$ is strongly inhibitory, while the other guanosine mononucleotides have only a small effect (experiment 2), a specificity similar to that observed for the inhibition of overall amino acid incorporation[1]. The localisation of the inhibition by $m^7G^{5'}p$ to the reaction in which the 80S–Met-tRNA$_i^{Met}$ is formed, that is, the sequence in which mRNA participates, supports the idea that $m^7G^{5'}p$ inhibition is related to its structural analogy with the 5′-$m^7G^{5'}ppp$ present on most eukaryotic mRNAs.

As a further test of this conclusion, we studied the effect of $m^7G^{5'}p$ on the 40S–Met-tRNA$_i^{Met}$ to 80S–Met-tRNA$_i^{Met}$ reaction catalysed by RNA of satellite tobacco necrosis virus (STNV RNA). This RNA has been reported to have a 5′-terminal sequence of either ppApGpUp...[16] or pppApGpUp...[17] and we have further confirmed that it lacks an $m^7G^{5'}p$ terminus by examining the products of HIO_4 oxidation and ^3H-borohydride reduction (unpublished experiments with S. Muthukrishnan and A. Shatkin). We have also ascertained that STNV RNA does not require a $m^7G^{5'}ppp$ cap for its translation. Translation of STNV RNA is unaffected, either quantitatively (Table 2) or qualitatively (Fig. 2), by addition of *S*-adenosylhomocysteine (SAH), a methyl-transfer inhibitor known to prevent the 'capping' reaction[18]. Thus STNV RNA is ideal for testing whether the inhibitory action of $m^7G^{5'}p$

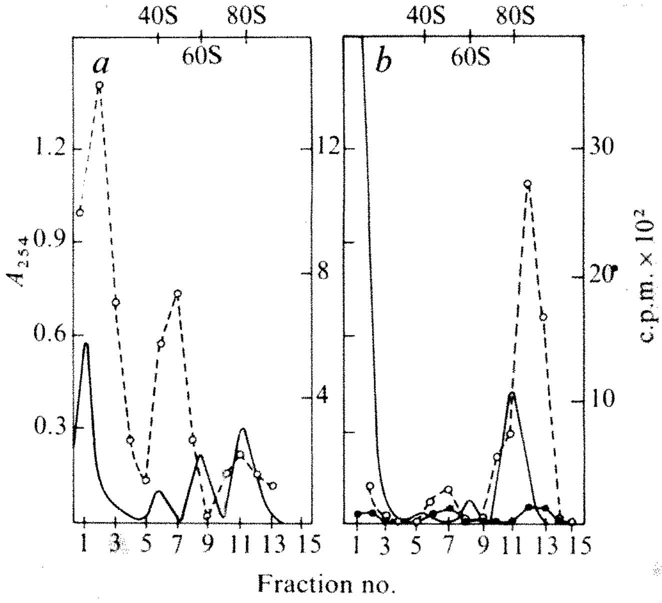

Fig. 1 Sequential formation of 40S–Met-tRNA$_i^{Met}$ and 80S–Met-tRNA$_i^{Met}$ ribosome complexes. *a*, 40S reaction. A reaction mixture (0.34 ml) containing 1 mM unlabelled Met; 30 mM Tris acetate, *p*H 8.0; 2.6 mM dithiothreitol; 60 μM GTP, 70 mM K acetate; 5 mM KCl; 1.3 mM Mg acetate; 7 mM phosphoenolpyruvate; 11.2 μg pyruvate kinase; 39 μg tRNA containing 6.6 pmol (CH_3–^3H)Met-tRNA$_i^{Met}$ (2,300 c.p.m. pmol^{-1}); 25 μg factor C3β; 150 μg factor D, and 115 μg ribosomes was incubated for 10 min at 20 °C. The samples were fixed with glutaraldehyde, centrifuged through a 13–21% sucrose gradient, and the fractions were analysed for bound aminoacyl-tRNA by nitrocellulose filtration. *b*, 80S reaction: the reaction was carried out in two steps. A reaction mixture identical to that of (*a*) was first incubated for 2 min at 20 °C, then 35 μg factor C3α, 6 μg AMV RNA, ATP (1 mM), Mg acetate (3.6 mM), and K acetate (70 mM) were added to a volume of 0.40 ml and the incubation was continued for 10 min at 20 °C. The samples were centrifuged without glutaraldehyde fixation through sucrose gradients and analysed as in (*a*). The open circles denote the data with the complete reaction mixture, while the solid circles denote data for a reaction mixture in which mRNA was omitted. AMV RNA is the RNA of the top "*a*" component of alfalfa mosaic virus[13] and was provided by Dr Lous Van Vloten-Doting. A complete description of the preparation of the wheat factors will be reported elsewhere.

Table 1 Effect of guanosine monophosphates on the formation of 40S–Met-tRNA$_i^{Met}$ and 80S–Met-tRNA$_i^{Met}$ complexes

	Addition	Met-tRNA$_i^{Met}$ bound (c.p.m.)	Inhibition (%)
(1) 40S reaction	—	1,701	
	$m^7G^{5'}p$	1,640	3.6
	$m^7G^{2(3)'}p$	1,829	
	$G^{5'}p$	1,876	
(2) 80S reaction (TMV RNA)	—	1,706	
	$m^7G^{5'}p$	342	80.0
	$m^7G^{2(3')}p$	1,468	14.0
	$G^{5'}p$	1,397	18.1
(3) 80S reaction (STNV RNA)	—	1,953	
	$m^7G^{5'}p$	2,147	
(4) 80S reaction (AMV RNA)	—	5,297	
	$m^7G^{5'}p$	1,363	74.3

The reaction systems were those of Fig. 1, with the viral RNAs added at 6 μg per 0.34 ml total volume. The data are a calculated sum of the nitrocellulose bound radioactivity; in experiment 1 for the region of the 40S complex and experiments 2–4 for the region of the 80S complex. The data in experiments 2–4 are corrected for a control in which mRNA was omitted. Procedures for preparation of TMV RNA and STNV RNA are described in refs 14 and 15, respectively. $m^7G^{5'}p$ and $G^{5'}p$ (PL Biochemicals) and $m^7G^{2(3')}p$ (TerraMarine Bioresearch) were added as indicated at a concentration of 0.25 mM.

is related to its structural similarity to the $m^7G^{5'}ppp$ 'cap' of an mRNA. If it were, one would predict that $m^7G^{5'}p$ would have little or no effect on the reaction catalysed by STNV RNA. Experiment 3 of Table 1 verifies this prediction. STNV RNA-catalysed conversion of the 40S–Met-$tRNA_i^{Met}$ complex to an 80S–Met-$tRNA_i^{Met}$ complex is unaffected by $m^7G^{5'}p$. Viewed in contrast to the results with tobacco mosaic virus (TMV RNA) (experiment 2) and alfalfa mosaic virus (AMV RNA) (experiment 4), both of which contain the 5′ 'cap'[10-12], the action of $m^7G^{5'}p$ indeed seems to be related to its structural analogy to the $m^7G^{5'}ppp$ 'cap' of mRNA.

The maximal inhibition that we have been able to obtain with either TMV RNA or AMV RNA is 80% even at $m^7G^{5'}p$ concentrations as high as 1 mM. With TMV RNA, it has been reported that only 70% of the viral RNA population contains the $m^7G^{5'}ppp$ 'cap'[10,11]. Thus the incomplete inhibition by $m^7G^{5'}p$ might be ascribed to residual activity of those RNAs lacking the 'cap'. We favour, however, an alternative explanation; that the translational requirement for the $m^7G^{5'}ppp$ 'cap' is not absolute even for those mRNAs containing the 5′ 'cap' but rather that the $m^7G^{5'}ppp$ 'cap' provides an additional binding site in the initiation system, thereby augmenting the translation of a particular mRNA. This possibility would allow that mRNAs might differ widely in the translational advantage gained by the 'cap', with the extreme situation being that exemplified by STNV RNA, where translation occurs readily in the absence of the 5′-$m^7G^{5'}ppp$.

This research was supported by grants from the National Institutes of Health, and by an appropriation from the Commonwealth of Pennsylvania. We thank Dr Corrado Baglioni for making available his results before publication.

Table 2 ^{14}C-leucine incorporation catalysed by STNV RNA in presence and absence of SAH

Additions	^{14}C-leucine incorporated (c.p.m.)
—	1,200
STNV RNA (2.5 μg)	24,331
STNV RNA + SAM (4 μM)	26,752
STNV RNA + SAH (320 μM)	25,250
reovirus RNA (2.5 μg)	8,873
reovirus RNA + SAM (4 μM)	13,944
reovirus RNA + SAH (320 μM)	2,480

A 0.1-ml incubation mixture containing 20 mM HEPES-KOH, *p*H 7.6, 1 mM ATP, 20 μM GTP, 8 mM creatine phosphate, creatine phosphokinase (40 μg ml^{-1}), 2.5 mM dithiothreitol, 2 mM Mg acetate, 80 μM spermine, 20 mM KCl, 120 mM K acetate, 30 μM 19 amino acids–leucine, ^{14}C-L-leucine (0.625 μCi ml^{-1}), wheat tRNA (15 μg ml^{-1}), 25 μl wheat germ S23, and viral RNA as indicated, was incubated for 60 min at 25 °C. The hot TCA-insoluble radioactivity was determined as before[14]. Wheat germ S23 was prepared by a modification of the earlier procedure developed for wheat embryo[19]. A sample of 1.5 g of commercial wheat germ (General Mills) was ground in 10 ml 1 mM Mg acetate, 2 mM $CaCl_2$, 90 mM KCl using a chilled mortar and pestle. The homogenate was centrifuged at 23,000*g* for 10 min (pellet discarded), adjusted to 20 mM Tris acetate, *p*H 7.6, 2 mM Mg acetate and recentrifuged as above. The supernatant was then passed through a 25 × 1.5 cm column of Sephadex G-25 and eluted with 1 mM Tris acetate, *p*H 7.6, 50 mM KCl, 1 mMg acetate, 4 mM β-mercaptoethanol. The turbid fraction was collected, centrifuged at 23,000*g* for 10 min (pellet discarded), and stored in small samples at −70 °C. Reovirus RNA with a 5′-terminus of 75% ppGp and 25% GpppG was a gift of M. Morgan and A. Shatkin. *S*-adenosylmethionine (SAM) and *S*-adenosyl homocysteine (SAH) were obtained from Sigma.

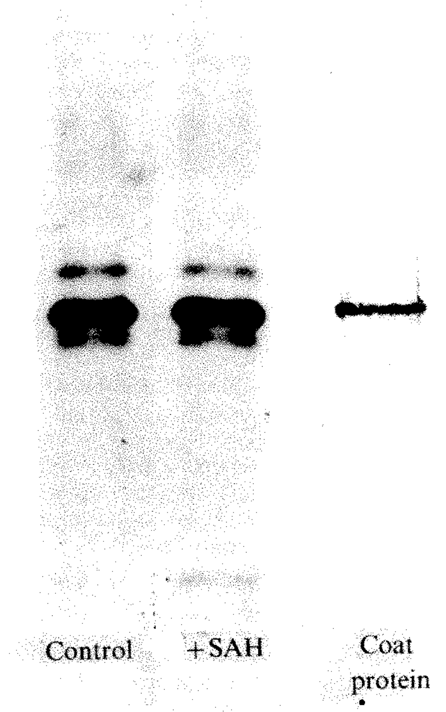

Fig. 2 *In vitro* products synthesised in response to STNV RNA. The *in vitro* incorporation reaction was carried out as in Table 2 except that a 19-methionine amino acid mixture and 20 μCi ^{35}S-L-methionine were used in place of leucine. The reaction was terminated by the addition of 10 mM Na_2-EDTA, *p*H 7.0, 10 mM L-methionine, and ribonuclease (0.1 mg ml^{-1}). After 15 min at 25 °C the mixture was cooled and precipitated with 9 volumes of cold acetone. The precipitated protein was air dried, dissolved in 4 M urea, 2.5 mM dithiothreitol, 1% sodium dodecyl sulphate, 50 mM Tris-HCl, *p*H 6.8, 1 mM Na_2-EDTA, *p*H 7.0, and heated at 100 °C for 2 min. Aliquots of the sample were applied to 15% polyacrylamide–urea–SDS slab gels prepared according to Studier[20], and electrophoresed at 80 V for 5–6 h. The gel was stained with 0.75% Coomassie blue, destained with H_2O–methanol–glacial acetic acid (7:4:1), dried and autoradiographed. Authentic STNV coat protein was prepared according to Lesnaw and Reichmann[21].

Structure of the lactose operator

THE *lac* operon has long been an important model system for developing an understanding of the control of gene expression. Since the early studies of Jacob and Monod[1] on the *lac* operon, much work has been devoted towards determining the mode of interaction between repressor and operator. Although it has been shown clearly that repressor physically binds operator[2,3],

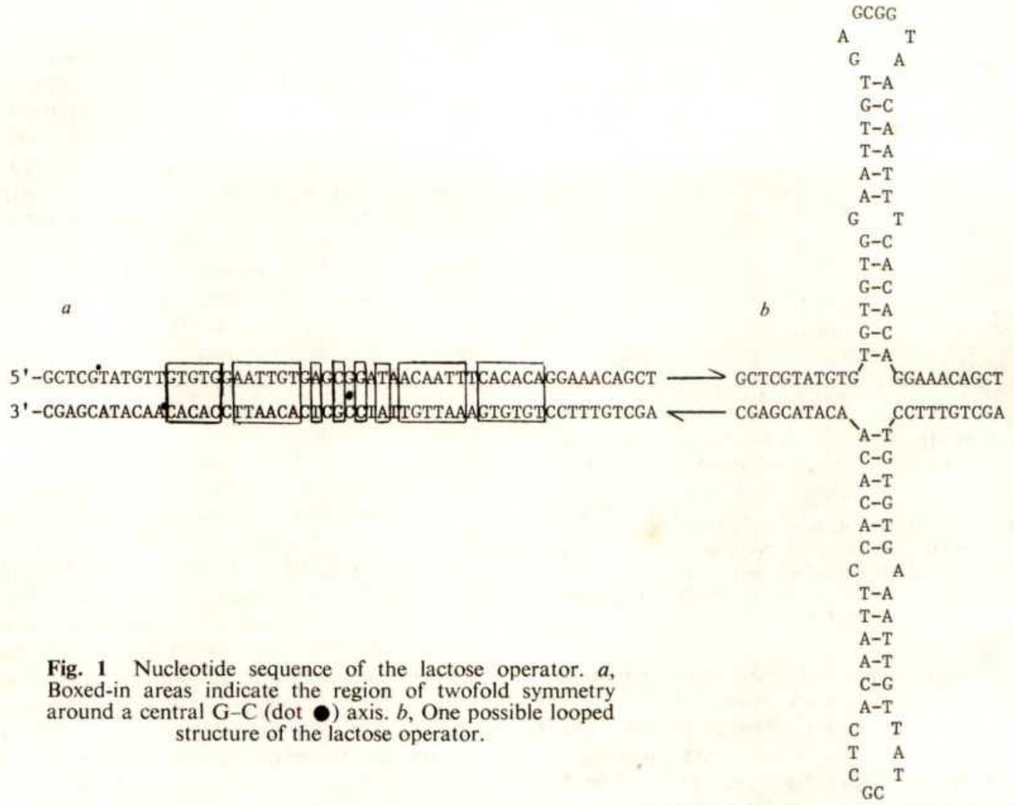

Fig. 1 Nucleotide sequence of the lactose operator. *a*, Boxed-in areas indicate the region of twofold symmetry around a central G–C (dot ●) axis. *b*, One possible looped structure of the lactose operator.

the details of this interaction remain unknown. We report here results of experiments designed to investigate further the structure of the operator and its interaction with the repressor.

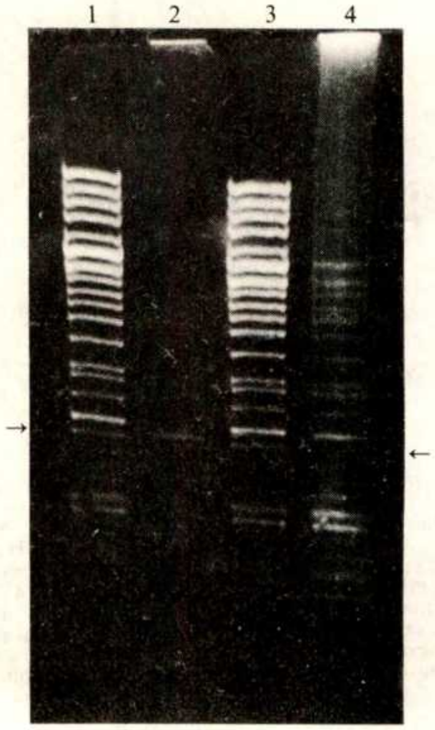
The interaction between *lac* operator and *lac* repressor is one of the most highly selective processes in nature. What is it about the *lac* operator, a sequence of approximately 25 nucleotides[4], which allows *lac* repressor to select it from among one million bases in *E. coli*? Basically, when considering the mode of interaction between repressor and operator, theories fall into two categories: those which call for a major alteration such as single-stranded loop formation of the operator DNA, and those which do not. It has been proposed that twofold symmetry would be important in DNA–protein interactions[5], that regulatory proteins would bind to and stabilise single-stranded loop structures in DNA[6], and that formation of a loop structure would allow a protein with two or four subunits to interact with symmetrical DNA sequences[7].

The determination of the nucleotide sequence of the *lac* operator[4,8] (Fig. 1) served to amplify all the above questions. The *lac* operator does show twofold symmetry, in fact the type of symmetry within the *lac* operator, termed a complementary palindrome[9], theoretically allows the *lac* operator to form a looped structure (Fig. 1). We have tried to determine whether such a looped structure is indeed present, by using single-strand specific nucleases as probes.

We have examined the actions of two single-strand specific nucleases, S1 and mung bean, on a DNA fragment containing part of the *lac* operon (see Fig. 2 for identification). The fragment, produced from λp*lac* 5 DNA by digestion with the *Hin*d restriction enzyme is approximately 700 base pairs long[10,11] and contains the carboxyl terminal sequence of the *i* gene, the entire *lac* control region and about 30% of the *z* gene. The *lac* operator region is located almost in the centre of the fragment.

Figure 3 shows the results of control experiments carried out by incubating heat-denatured ^{3}H-salmon sperm DNA with S1 nuclease (Fig. 3*a*) or mung bean nuclease (Fig. 3*b*). In 15 min, S1 nuclease at a concentration of only 0.1 U per μg DNA rendered 50% of the single-stranded DNA acid soluble, and mung bean nuclease at a concentration of only 0.0065 U per μg DNA rendered 80% acid soluble. Thus, at the much higher concentrations of S1 nuclease and mung bean nuclease used in

Fig. 2 λp*lac* 5 DNA (250 μg; prepared from strain G141 (λC$_1$857 λp*lac*5), a gift from Dr W. Gilbert, by the method of ref. 18) was digested with the *Hin*d restriction enzyme (prepared as in ref. 19 and a gift from Dr E. Jay). After phenol extraction and ethanol precipitation this digest was mixed with 1.5 μg of *lac* repressor (prepared as in ref. 20) and passed through a Millipore HAWP, 0.45-μm filter. The filter-bound material was eluted with 1 mM IPTG. All samples were precipitated in ethanol before application to a 20 cm × 20 cm × 0.3 cm slab gel of 1.4% Agarose (Seakem) and run in the presence of ethidium bromide. Electrophoresis was run at 80 V for 6 h. Slots 1 and 3 show the total *Hin*d digest of λp*lac*5 DNA. Slot 2 shows the fragment eluted from the filter with IPTG. Slot 4 shows the filtrate. The arrows indicate the region of interest. Note that in slot 2 there is only one fragment which is bound specifically by *lac* repressor and can be eluted from the filter by IPTG. This fragment is absent in the filtrate (slot 4).



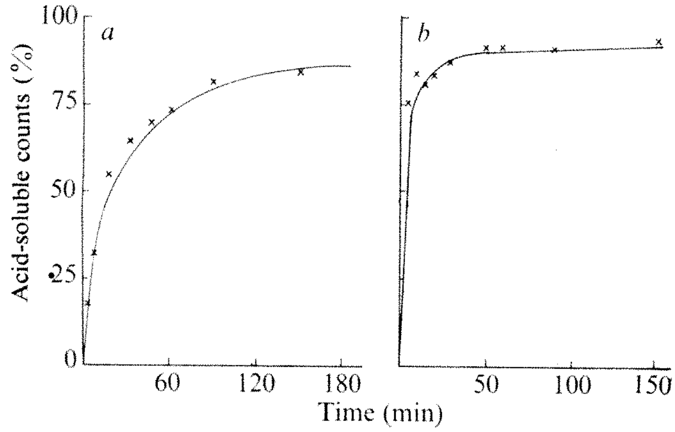


Fig. 3 Heat-denatured ^{3}H-salmon sperm DNA[21] was incubated with: *a*, S1 nuclease at 0.1 unit per μg DNA at 37 °C; and *b*, mung bean nuclease at 0.0065 unit per μg DNA at 37 °C. S1 nuclease was prepared by the procedure of Vogt[17] and was a gift of Dr G. Ghangas; the unit is as defined by Vogt[17]. Mung bean nuclease was a gift of Dr S. Laskowski, Sr, and the unit is as defined in Ardelt and Laskowski[22]. Incubations are as in the legend to Fig. 4. Each time point is the result of a triplicate determination.

the experiments below, single-stranded DNA would be hydrolysed to acid solubility in a few seconds.

The action of S1 and mung bean nuclease on the fragment is shown in Fig. 4. The incubation mixtures were analysed on 20×20×0.3 cm slab gels of either 1.4% Agarose or 4 or 5% acrylamide–7 M urea. Figure 4*a* shows an Agarose gel of *lac* DNA fragment after treatment with various concentrations of S1 nuclease. No specific cleavage of the fragment can be detected, even at high concentrations of the nuclease. Since *lac* operator lies almost in the centre of the *Hin*d-700 DNA fragment (arrow *A*), specific cleavage by S1 nuclease should yield two fragments about 350 base pairs long which would be clearly resolved (arrow *B*, expected location) from the starting material in the gel system. Analysis on acrylamide–7 M urea gels, which has a greater power of resolution, also failed to reveal any specific cleavage. Figure 4*b* shows the result of treating *Hin*d-700 *lac* DNA fragment with high concentrations of S1 nuclease as analysed on 4% acrylamide–7 M urea. S1 nuclease incubations were normally done at 50 mM NaCl, and varying the NaCl concentration at low S1 nuclease concentrations did not change the patterns shown. Results with mung bean nuclease were essentially identical to those with S1 nuclease. Even at the highest enzyme concentrations used, no specific cleavage of the fragment could be detected on either 1.4% Agarose (Fig. 4*a*) or 4% acrylamide–7 M urea gel (Fig. 4*b*). Fragment reisolated from the gels after nuclease treatment can still bind *lac* repressor with nearly the same efficiency as before. In some parallel experiments involving *lac* DNA fragment and S1 nuclease, a small amount of single-stranded ^{3}H-salmon sperm DNA was included in the reaction mixture. An aliquot was taken, after S1 nuclease treatment, to determine the extent of acid solubility. In all cases the single-stranded DNA was rendered at least 70% acid soluble.

Some streaking of the DNA band on gel and a reduction in the intensity of the starting material was observed when very high concentrations of the enzyme or low concentrations of salt were used. This may be due to either a nonspecific degradation of the *lac* DNA fragment by a contaminant nuclease or nonspecific degradation by S1 nuclease of the DNA fragment at areas where "breathing" occurs. That this degradation is nonspecific and not due to a single-stranded looped structure in the *lac* operator was demonstrated by treating a control DNA fragment that does not contain the *lac* operon with the same concentrations of S1 nuclease or mung bean nuclease. Gel patterns identical to those given in Fig. 4*b* were found.

If the *lac* operator existed as a single-stranded structure single-strand specific nucleases would be expected to cleave the *Hind* fragment carrying the *lac* operon into two pieces of about equal size. We did not find this to be the case and conclude, therefore, that in the absence of repressor, the *lac* operator does not contain single-stranded regions to any appreciable extent. The same conclusion was reached by Wang *et al.*[12], who measured the changes in superhelicity of *lac* DNA on binding of repressor, and also by Richmond and Steitz[13] who studied the binding of *lac* repressor to poly d(A)-d(T) fragments and suggested that the repressor binds to native DNA. On the other hand, Chan and Wells[14] have shown by competition binding assays that S1 nuclease- or mung bean nuclease-treated λp*lac*5 DNA loses the ability to bind *lac* repressor. This result implies

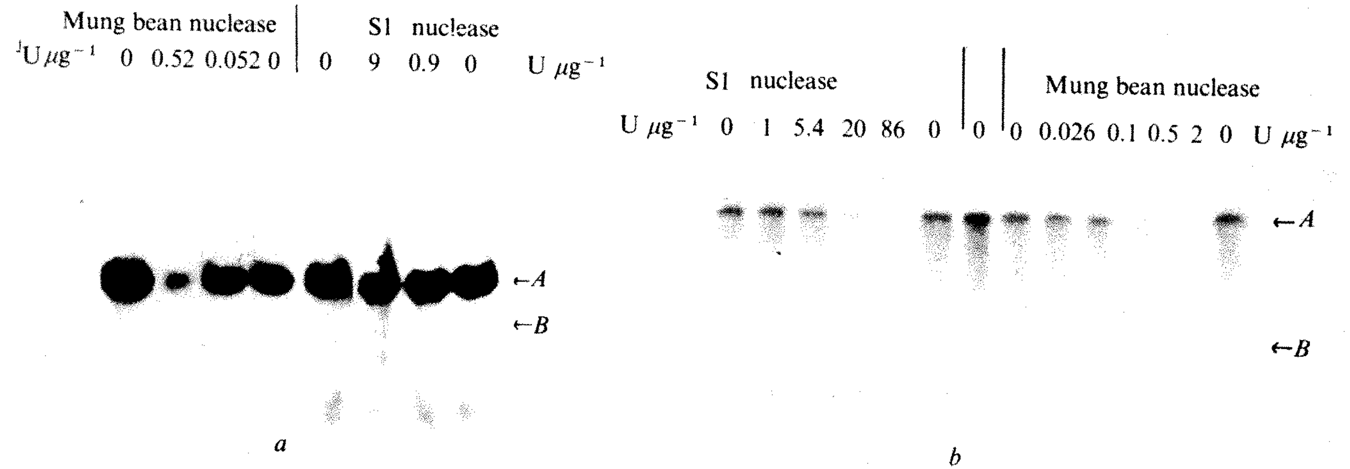

Fig. 4 *lac* fragment, identified as in Fig. 2 and purified as described[23], was labelled terminally at the 3′ end with α-^{32}P-GTP or CTP using terminal transferase as described by Kossel and Roychoudhury[24]. The fragment was then treated with a nuclease as follows. S1 nuclease: 30 mM NaOAc, *p*H 4.6, 1 mM $ZnSO_4$, 5% glycerol, NaCl varied between 10 and 150 mM in 100 μl. DNA concentration was from 1 to 10 μg ml^{-1}. Mung bean nuclease: 25 mM NaOAc, *p*H 5.0, 1 mM 2-mercaptoethanol, 10 μM $ZnSO_4$ and 0.001% Triton X-100 in 100 μl. DNA concentration was from 0.1 to 1 μg ml^{-1}. Digestions were stopped by the addition of EDTA to 25 mM. Protein was removed by phenol extraction (twice). The DNA was then ethanol precipitated. The samples were dissolved in 20 μl of loading dye (*a*, 10 mM Tris-Cl, *p*H 7.9, 1 mM EDTA, 10% sucrose, 0.2 mg ml^{-1} bromophenol blue; *b*, as in *a* plus 7 M urea). Electrophoresis is from top to bottom on 20×20×0.3 cm vertical slab gel apparatus. The wet gels were autoradiographed. *a*, *lac* fragment treated with S1 and mung bean nucleases at the indicated concentrations and then electrophoresed (80 V, 3.5 h) on 1.4% Agarose gel. *b*, *lac* fragment treated with S1 and mung bean nucleases at the indicated concentrations were boiled in loading dye plus 7 M urea for 5 min before electrophoresis on 4% acrylamide–7 M urea at 80 V for 24 h.

that S1 nuclease is cutting at or near the *lac* operator since binding of *lac* repressor before nuclease treatment abolishes the effect. Our experiments clearly demonstrate that a specific cleavage by a single-strand specific nuclease is not occurring within the *lac* operator region.

The nuclease concentrations used in our experiments are extremely high compared with those needed to hydrolyse single-stranded nucleic acid. Rushizky *et al.*[15], have shown that 0.0017 U of S1 nuclease per μg of MS2 RNA hydrolysed the RNA to acid solubility in 3 h at 23 °C. In addition, Shenk *et al.*[16] have cleaved linear SV40 DNA, nicked in only one position, into two intact and distinct double-stranded pieces with S1 nuclease at a concentration equivalent to 90 U (of Vogt[17]) per μg DNA at 25 °C in 30 min. They were also able to cleave DNA containing one mismatched base pair with the same concentration of nuclease.

We have been able to duplicate (qualitatively but not quantitatively) the results of Chan and Wells[14] in intact λp*lac*5 DNA using competition binding as an assay, however, the same experiments analysed by electrophoresis in 0.4% Agarose gel showed no specific cleavage of the DNA. We therefore conclude that Chan and Wells may be observing a secondary or indirect effect of the nuclease which, perhaps by nicking certain A–T-rich regions of the DNA, somehow alters the repressor binding of the *lac* operator region.

Cycling of RNA-directed DNA polymerase on natural and synthetic RNA templates

RNA-DIRECTED DNA polymerase (reverse transcriptase) catalyses *in vivo* the synthesis of DNA complementary to the RNA of tumour viruses. The DNA is integrated into the host genome and is therefore implicated in the subsequent tumorigenesis[1]. The mechanism by which reverse transcriptase replicates the viral RNA into complementary DNA (cDNA) and its resultant integration, as well as the interaction of the viral components in the host, remain unclear[2]. Reverse transcriptase has been used *in vitro* to synthesise cDNA to mRNA; this cDNA can be used to identify and characterise the cellular processes dependent on nucleic acids. The conditions of the reactions have been optimised[3,4]; however problems remain with both the quality and quantity of the cDNA[5,6,15]. We report here *in vitro* conditions such that each RNA-directed DNA polymerase molecule synthesises several to more than 100 transcripts, depending on whether natural or synthetic templates are used. As noted previously[3,4], the fidelity of the cDNA transcript, the amount, and the time course of polymerisation depend strongly on the reaction conditions.

Highly purified DNA polymerase from avian myeloblastosis virus (AMV) strain BAL was prepared by the method of Kacian and Spiegelman[7]. Purification included collection of the virus from plasma by high speed centrifugation, batch elution from DEAE–cellulose and chromatography on phosphocellulose. The enzyme was concentrated by dialysis against: 50% glycerol; 0.2 M KPO_4, *p*H 7.2; 2 mM dithiothreitol and 0.2% Triton X-100. This preparation (No. XL 13-75) contained 61 μg of protein per ml and had an activity of 2,476 U ml^{-1}. The protein concentration was determined by the method of Lowry.

Examination of this preparation of DNA polymerase by sodium dodecyl sulphate (SDS) polyacrylamide gels[8] demonstrated three distinct bands corresponding to the α and β subunits of the DNA polymerase and a contaminating band corresponding to a polypeptide chain of molecular weight 80,000. Based on the relative intensities of the stained bands the enzyme preparation was approximately 80% pure.

The reaction conditions are modified from those previously described[9] and are optimised for the reinitiation and elongation of the cDNA. The increased purity of the enzyme preparation facilitated the establishment of conditions for the maximum synthesis of cDNA per unit of enzyme (Table 1). The optimal

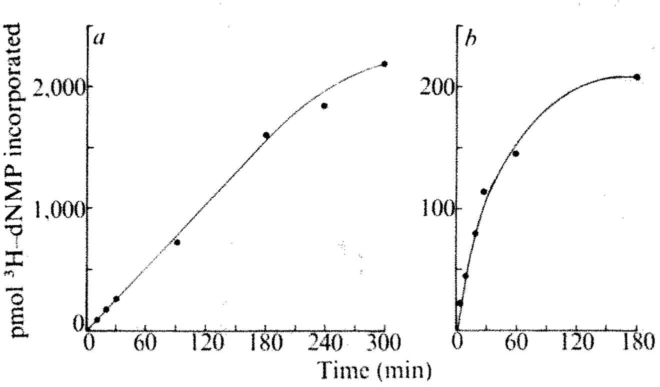

Fig. 1 Time course of cDNA synthesis as directed by poly(C) and rabbit reticulocyte globin mRNA. *a*, Time course of dGMP incorporation into cDNA directed by poly(C). The amounts of template, primer and radioactive nucleotide per ml were 570 μg of poly(C), 460 μg of $oligo(dG)_{10}$, and 25 μCi of 8-^{3}H(*N*)-deoxyguanosine 5′-triphosphate, specific activity 9.4 Ci $mmol^{-1}$ (New England Nuclear). *b*, Time course of dCMP polymerisation into cDNA directed by globin mRNA template. The concentrations of primer, template and radioactive nucleotide per ml were 54 μg of globin mRNA, 24 μg of $oligo(dT)_{10}$ and 25 μCi of 5-^{3}H-deoxycytosine 5′-triphosphate, specific activity 22.8 Ci $mmol^{-1}$ (New England Nuclear) or CH_3-^{3}H-deoxythymidine 5′-triphosphate (specific activity 49.8 Ci $mmol^{-1}$, New England Nuclear). Oligoguanylic acid and oligothymidilic acid primers were obtained from Collaborative Research; poly(C) template with an $S_{20,w}$ value of 3.08 was obtained from P.L. Biochemicals, and rabbit reticulocyte 10S mRNA was prepared as before[10]. Each 50 μl of reaction mixture contained the following components: 50 mM Tris-HCl, *p*H 7.9; 100 mM KCl, 10 mM $MgCl_2$; 8 mM dithiothreitol, actinomycin D (100 μg ml^{-1}) and AMV DNA polymerase (30 U ml^{-1}). The substrates were 320 μmol of each of the four deoxynucleoside triphosphates. The reaction mixtures were incubated at 32 °C for the times indicated. The reaction was terminated by the addition of ice-cold 10% trichloroacetic acid (TCA)–2.0% sodium pyrophosphate solution. After 30 min on ice, the TCA-precipitable material was collected by filtration on to prewashed (5% TCA–2.0% pyrophosphate) nitrocellulose filters. (Millipore type HA). The filters were then washed with 20 ml of TCA pyrophosphate, dried and the radioactivity determined by liquid scintillation spectroscopy.

Table 1 Effect of AMV DNA polymerase concentration on globin cDNA synthesis

Enzyme (pmol)	Globin mRNA (pmol) / Enzyme (pmol)	dCMP incorporated (pmol)	Product* (pmol)	Product (pmol) / Enzyme (pmol)
1.96	6.6	361	3.21	1.7
0.95	13	313	2.78	2.9
0.48	26	230	2.03	4.3
0.24	54	148	1.32	5.7
0.12	104	66	0.59	4.9

Reactions were run for 20 min as described in the legend to Fig. 1*b*.

* Calculation of cDNA synthesised is discussed in the text.

concentration of DNA polymerase was 0.24 pmol per 50 µl of reaction mixture. Although the turnover number (cDNA molecules synthesised per unit of enzyme per incubation) was maximised, the population of cDNA molecules synthesised was heterogeneous. We find that the ratio of DNA polymerase to template concentration affects both the quality and quantity of the cDNA polymerised. In the "slippage" reaction of the homopolymers (A) and (I), (which depend on multiple initiations) synthesis initiated with 400 ng of DNA polymerase synthesised an homogeneous product[9]; but polymerisation at 40 ng of enzyme results in a heterodisperse size distribution of the cDNA. This has also been observed for the globin mRNA-directed synthesis, although the shift in the size distribution was not as marked.

The ability to follow cDNA synthesis at prolonged time intervals (probably due to reduced RNAse activity in the enzyme preparation) is another improvement. The time course of globin mRNA-directed dCMP synthesis was compared with dGMP incorporation directed by poly(C) (Fig. 1). Incorporation differed in that the globin mRNA-directed synthesis of cDNA remained linear for only 20 min compared with more than 180 min for poly(C)-directed polymerisation. The homopolymer poly(A) or poly(I)-directed synthesis of a homopolymer cDNA was also linear for more than 180 min. The decrease in linearity observed with globin mRNA was not caused by template degradation as no stimulation was found when further mRNA was added (unpublished).

The comparison of the different cDNA products polymerised with globin mRNA, poly(C), poly(A) and poly(I) as templates is shown in Table 2. Poly(C)-directed incorporation of dGMP yielded 1,601 pmol and since the average template size was 55 nucleotides, 29 pmol of full sized product were formed. Dividing the moles of product formed by the moles of enzyme input, more than 100 cDNA molecules were formed per enzyme molecule. Repeating this calculation for globin mRNA as template the turnover number is 7, assuming the mRNA to be 650 nucleotides long[11] and composed of 17.3% GMP[12]. Synthesis directed by poly(A)$_{\overline{25}}$ or by poly(I)$_{\overline{35}}$ results in a product size larger than the starting material (16S to greater than 22S)[9]. The difficulty in estimating the ratio of enzyme molecules to product synthesised in a reaction which slips[13] (that is, the product is larger than the template) is that the product size is heterodisperse. Poly(A) and poly(I) templates directed the incorporation of 827 pmol of dTMP and 573 pmol of dCMP, respectively. Since these amounts are less than that incorporated into poly(C)-directed cDNA and since the products are much larger, the turnover numbers for the slippage reactions are small (≤ 1).

The calculation of turnover numbers assumes that the protein preparation is homogeneous and completely active. In this instance, a protein contaminate in the enzyme preparation was demonstrated. In the poly(C)-directed synthesis the primed portion of the cDNA is unlabelled and this may represent as much as 20% of the template molecule, and potentially more than 50% of the newly synthesised DNA. Finally, the product synthesised was assumed to be full sized. Although this seems to be true for the cDNA to poly(C) template (Fig. 2*a*), which

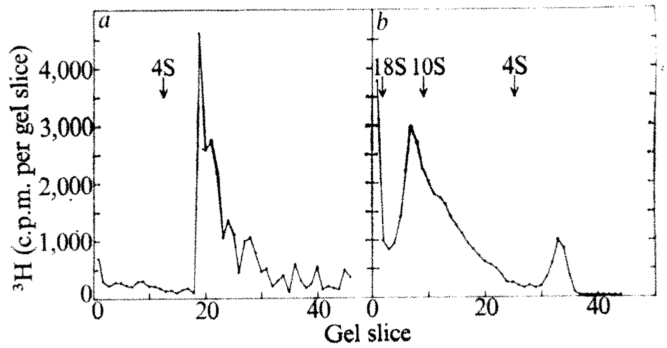

Fig. 2 Sizing of the cDNA product synthesised by DNA polymerase and directed by poly(C) and rabbit reticulocyte globin mRNA. Both reactions were carried out as described in the legend to Fig. 1 and incubated for 3 h. Poly(A) and poly(I) sizing was done as previously described[9] and is not shown here. The reaction mixtures used to obtain cDNA product for size analysis by polyacrylamide gel electrophoresis were stopped by heating to 100 °C for 2 min and then quickly frozen on dry ice. The RNA was hydrolysed with 0.33 N NaOH at 37 °C for 18 h. After neutralising the hydrolysate, unreacted nucleotides were removed by dialysis at 4 °C against 0.5 M NH_4HCO_3 and finally distilled water. The lyophilised samples were resuspended and a 20-µl sample was applied to 3.5% polyacrylamide gels containing sodium dodecylsulphate. The gels were standardised with rabbit reticulocyte 28S, 18S, 10S, and tRNA; poly(C), $S_{20,w}$ 3.08. *a*, Size distribution of the cDNA product directed by poly(C); *b*, size distribution of the cDNA directed by globin mRNA (as discussed in the text).

Table 2 Comparison of AMV DNA polymerase-directed synthesis with different templates

Template	Primer	Size of template	dNMP incorporated (pmol)	Product (pmol)	Molecules cDNA per enzyme molecule
Globin mRNA	$(dT)_{10}$	650	206*	1.8	7.2
Poly(C)	$(dG)_{10}$	55	1,606	29.2	115
Poly(A)	$(dT)_{10}$	25	827	?	?
Poly(I)	$(dC)_{10}$	35	573	?	?

Reactions were run for 3 h as described in the legend to Fig. 1. All calculations correspond to a 50-µl reaction volume. The size of the product was shown in Fig. 2*a* for the poly(C)-directed synthesis and Fig. 2*b* for the mRNA-directed synthesis. Slippage of poly(I) and (A) was described previously[9] and confirmed by sodium dodecyl sulphate (SDS)–acrylamide gels (standardised with MS2 RNA and φX174 DNA, Miles) as discussed in the legend to Fig. 2. Question marks indicate that product size was not calculated for these reactions because of the non-discrete product size, which occurs due to the slippage reaction with both poly(A) and poly(I) templates[9].

* The quantity of dCMP incorporated into rabbit globin cDNA. Calculation of cDNA synthesised to globin mRNA is discussed in the text

showed an electrophoretic mobility faster than the 4S marker and corresponds to the template size, the mobility of globin cDNA was considerably more heterogeneous (as demonstrated in Fig. 2*b*). As the poly(C) or globin mRNA-directed product was no larger than its template, the turnover numbers listed in Table 2 must represent minimal values.

The size distribution of globin mRNA-directed cDNA is broader than the homopolymer-directed cDNAs (Fig. 2*b*). This distribution may represent either intrinsic heterogeneity of the template as demonstrated by Vournakis *et al.*[14], or infidelity in the transcription reaction. No large (dT) homopolymers were detected and therefore there was no anomalous transcription of the poly(A) region as described by Falvey *et al.*[13].

In summary, RNA-directed DNA polymerase initiates many template primer complexes and transcribes full sized cDNA from a template of either globin mRNA or poly(C). *In vitro*, the enzyme is amenable to Michaelis–Menton analysis since a stoichiometric reaction has been ruled out. Whether this ability to utilise more than a single template applies *in vivo* or whether reverse transcriptase is intrinsically controlled to polymerise only a single viral molecule awaits future study.

Polymorphism of a synthetic DNA in solution

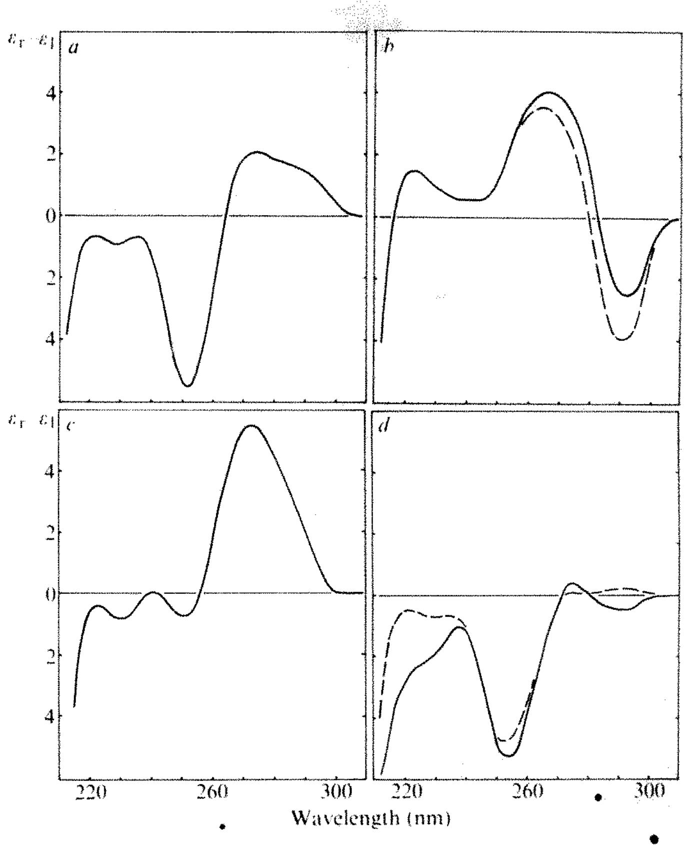
EARLY work on the X-ray diffraction of DNA fibres showed that DNA can adopt different conformations, and up to now at least four different double-helical models have been described in detail: the A, B, C, and D forms[1-4]. During recent years, it has become likely that DNA in solution also occurs in different conformations[5-7]. For studying such helix–helix transitions synthetic polynucleotides with a defined sequence offer an important tool, since in natural DNA only a very small fraction of the molecule usually has a particular sequence and, sequence-specific effects of the conformation will therefore escape detection.

We have previously shown that the alternating desoxypolynucleotide–poly(dG-dC)·poly(dG-dC) — undergoes a salt-induced, very cooperative helix–helix transition in neutral solution, which is most easily followed by the inversion of the circular-dichroism spectrum in the near ultraviolet[5]. X-ray diffraction studies by S. Arnott on fibres of the same sample of poly(dG-dC) have led to diffraction patterns characteristic for the D form and, at high relative humidity, for the B form, respectively[4,8] (personal communication). Since the fibres were pulled after ethanol precipitation of the polymers, it is possible that ethanol induces such a conformational change, which is then preserved in the fibres. I therefore measured the CD spectra of poly(dG-dC) as a function of the ethanol concentration. Figure 1 shows examples of CD spectra of poly (dG-dC)·poly(dG-dC) in different solvent conditions at room temperature. Between 0 and 45% ethanol the conservative spectrum observed is similar to that of natural DNA[9] (Fig. 1*a*). At 50% ethanol a drastic and fully reversible change of the CD spectrum occurs, giving rise to a conservative, but inverted spectrum (Fig. 1*b*). The absorption and CD spectrum, the high cooperativity of the transition and the relative slow kinetics closely resemble the observations at high NaCl concentration in the absence of ethanol[5]. It is very likely that both solvents induce a change to the same double helical form.

At still higher ethanol concentrations a more gradual change to a non-conservative spectrum (Fig. 1*c*), typical for double-helical RNA-like conformations is observed[5,6,10]. Figure 2 shows these changes of the optical properties as a function of the solvent composition. Thus, in ethanolic solution three distinct forms for poly(dG-dC) are observed.

A similar situation with three types of spectra exists in CsCl solutions in the absence of ethanol. Up to about 4 M CsCl the spectrum in Fig. 1*a* describes the data; around 4 M

Fig. 1 Circular dichroism spectra of poly(dG-dC)·poly(dG-dC) at different solvent composition. The polynucleotide was synthesised and characterised as described previously[5]. Ethanol was mixed with 1 mM Na phosphate buffer (*p*H 7.2) and a small volume of stock solution of poly(dG-dC) to a final concentration of 50–150 µM was added, and the CD spectra measured at 20 °C in a Cary 60 spectropolarimeter with CD attachment. Absorption spectra were measured with a Zeiss PMQ 3 photometer. *a*, 0-40% (w/w) ethanol or 10^{-3}–2 M NaCl. *b*, 56.2% ethanol; the broken line gives the spectrum in 3.9 M NaCl in the absence of ethanol[5]. *c*, 80 w/w % ethanol. *d*, Solid line, 7.1 M CsCl; broken line, 3.8 M LiCl.



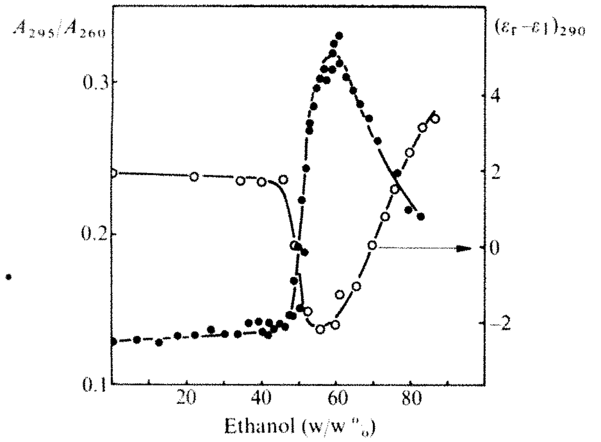


Fig. 2 Optical properties of $(\text{dG-dC})_{100}\cdot(\text{dG-dC})_{100}$ as a function of the ethanol concentration. Titrations were performed by adding 1 mM phosphate buffer or ethanol, respectively. Circular dichroism at 290 nm; absorbance at 295 nm divided by the one at 260 nm.

CsCl a cooperative transition to an inverted spectrum, like the one in Fig. 1*b*, is observed. At still higher CsCl concentration there is a gradual change to the spectrum shown in Fig. 1*d*, which is similar to the one obtained in LiCl solutions where no such inversion of the CD spectrum is observed.

The change of the solvent composition alone thus gives four different types of CD spectra for this polynucleotide and it is very likely that each one reflects a different double helical conformation. The type of spectrum in Fig. 1*a* together with the data on the Raman scattering of poly(dG-dC)[11] suggests that in "physiological" conditions the B form is adopted. At very high ethanol concentration the similarity of the CD spectrum (Fig. 1*c*) with the one for the corresponding RNA[5] is a strong indication for an A form of DNA, which is observed in fibres or films at very low water activity[12,13]. On the other hand, the non-conservative spectra at high CsCl or LiCl concentrations (Fig. 1*d*) closely resembles the one of Li-DNA in films[13] and may be attributed to the C form.

Assigning a known double-helical conformation to the inverted spectra of poly(dG-dC) in Fig. 1*b* leaves the D form as the most likely candidate. This hypothesis is supported by the Raman spectrum of this form, which does not show the features characteristic of the A, B or C conformation[11]. It also offers an explanation for the results of the X-ray diffraction studies with poly(dG-dC) mentioned above. For this type of diffraction pattern models for a right-handed[4] and a left-handed double helix[14] have been proposed. Although the CD spectrum is suggestive for the second alternative, no clear decision is possible, since calculations show that similar "inverted" CD-spectra can also be obtained for right-handed double helices (unpublished results). Although the assignment of these different double helical forms to the observed CD spectra has to be regarded as tentative, the experiments show nevertheless that relatively small changes of the medium around the DNA, as compared with the binding of proteins, allow a variety of conformational changes to occur in DNA in solution.

At the interface between two different helical conformations within a long DNA molecule one has to postulate for stereochemical reasons 'point defects' of 'dislocations' involving one or more base pairs. Such 'point defects' can also lead to 'kinks' within DNA molecules[15] facilitating the tight packing of DNA chromosomes or viruses.

Concentration quenching in chlorophyll

IN the primary process of plant photosynthesis it is generally accepted that efficient energy migration occurs between about 300 molecules of chlorophyll *a*, with subsequent light collection by a chemical trap. Solutions of chlorophyll *in vitro*, whether in fluid solvents[1], monolayers[2,3], multilayers[4,5] or, as shown recently in our laboratory, in rigid matrices of PMMA and in bilayer lipid vesicles, exhibit the phenomenon of concentration quenching of the excited state at concentrations much lower than those which are present in the chloroplast. At a chlorophyll concentration of 10^{-1} M, which is comparable with that in the chloroplast, none of the *in vitro* systems has a fluorescent yield as high as is found *in vivo*, especially when the photochemical traps are closed. To try to understand the apparent absence of concentration quenching *in vivo*, we have re-examined its mechanism *in vitro*, and conclude that each chlorophyll molecule in the light-collecting system must be separated from other chlorophyll molecules, so as to prevent trap formation by orbital overlap and so that the minimum distance, averaged over all orientations in a random array, is 10 Å.

A comprehensive review of the earlier work on concentration quenching has been given by Rabinowitch[6]. The fact that quenching occurs equally efficiently in media of high viscosity and in fluid solvents rules out diffusional processes and several authors have recognised that the concentration range of chlorophyll self quenching, in polar solvents such as ether and alcohols, indicates the involvement of Förster-type inductive resonance transfer between chlorophyll molecules[7,8]. There is no theoretical reason why this, in itself, should result in quenching but it could do so efficiently if a fraction of the molecules present acted as traps. This would be the case when non-fluorescent dimers are present and these undoubtedly account for most of the concentration quenching in such non-polar solvents as hydrocarbons and carbon tetrachloride, where the presence of the dimer is well established and characterised by a new absorption at longer wavelengths. We have made careful studies of absorption spectra in polar solvents such as ethanol and find no evidence of dimer formation at concentrations where extensive quenching occurs, nor are there any concentration-dependent changes in the absorption spectra of the varied systems mentioned earlier. At the highest concentrations used, the dimers would have had to exceed 10% of the total chlorophyll if they were the only traps present.

We therefore propose that the mechanism of concentration quenching in chlorophyll solutions is energy transfer between chlorophyll molecules by inductive resonance, followed by capture at a non-fluorescent trap which, in polar solvents, is merely a pair of chlorophyll molecules the separation of which, although part of the equilibrium statistical distribution, is less than a critical distance R_t. When one of a pair of molecules within this separation is excited, it interacts to form an excimer (fluorescing in the infrared, if at all) or other excited complex, as has been shown to occur in some aromatic hydrocarbons, even in rigid matrices[9].

To test this mechanism we calculated the rate of a random

SCIENCE COLLEGE
92, Upper Circular Road
CALCUTTA

walk of the excitation in a random three-dimensional array of molecules by a process in which the intermolecular transfer rate is proportional to R^{-6} (R being the intermolecular separation). The approximations which have to be made to obtain an explicit solution to this problem introduce uncertainties which are difficult to assess and we have therefore used a Monte Carlo method of calculation. By selection of pseudo-random numbers from a uniform distribution, 1,620 molecules are positioned among 27×10^6 coordinates in a regular three-dimensional lattice. This is equivalent to placing points in a cube consisting of 300 planes with separation D Å. Excitation is introduced by selecting one point at random. Rates are then calculated for all the possible processes available to the initially excited molecule, namely, fluorescence, intersystem crossing and resonance energy transfer to all molecules in a sphere of radius $35D$ Å around the excited molecule. The energy is then transferred to a new molecule and the process is repeated until it is terminated by fluorescence, intersystem crossing or trapping by a pair of molecules closer than a distance R_t. The whole random walk was then repeated using further selections of arrays and the results averaged. The complete process was repeated for a range of concentrations, the concentration being changed by varying D. The lattice is large enough for the probability of excitation reaching the edge of the lattice to be negligible.

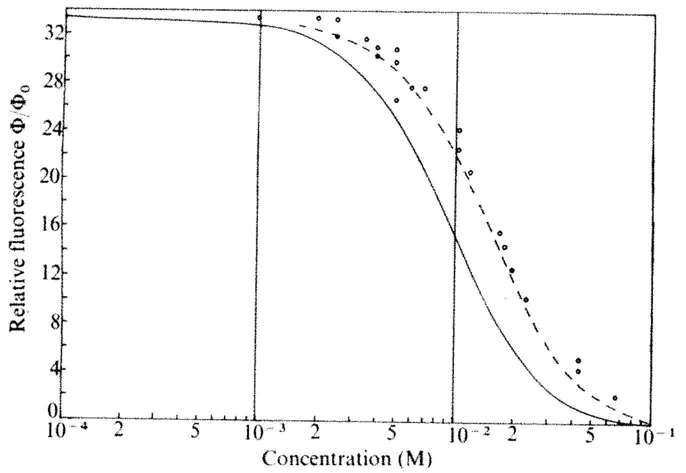

Fig. 1 Relative fluorescence yield of chlorophyll *a* as a function of concentration. ○, Experimental data of Watson and Livingston[1]; ———, calculated curve with $R_0 = 70$ Å and trap = 14 Å; - - -, calculated with $R_0 = 70$ Å and trap = 10 Å.

Complete fluorescence quenching curves for chlorophyll *a*, calculated in this way, are shown in Fig. 1. A separation of the statistical-pair trap was chosen for the calculation of each curve and the process stopped whenever the excitation reached such a pair. In Fig. 1, we have compared our calculations with the classical results of Watson and Livingston[1] for chlorophyll self quenching in ether. The shape of the curve of relative quantum yield against concentration is well reproduced and a quantitative fit is obtained for a statistical-pair trap separation of 10 Å. This may be compared with the diameter of the porphyrin ring in chlorophyll which is 15 Å. In these calculations, the Förster transfer distance R_0 was taken as 70 Å, the fluorescence and intersystem crossing rates as 5×10^7 s^{-1} and 1×10^8 s^{-1} which are appropriate for chlorophyll *a*. R_0 was obtained from the overlap of the measured absorption and fluorescence spectra in ethanol using the formulae given by Förster (see ref. 10). Obviously, the average distance of 10 Å between centres in the trap is so small that the orientation will become important. Our purpose here is merely to show how concentration quenching can occur, even in rigid media, when no dimers in the ground state are present. If dimers or oligomers are present, concentration quenching will be expected at even lower concentrations.

We now return to the mechanism of light collection by chlorophyll molecules in the photosynthetic unit. At a chlorophyll concentration in the chloroplast of 10^{-1} M, the fraction of molecules in statistical-pair traps with separation 10 Å would be 0.22 (if they were in random distribution) and efficient photosynthesis would be impossible. Transfer to a chemical trap would have to occur rapidly enough to compete efficiently with trapping by statistical pairs, which is not consistent with the rather high fluorescence yield of the antennae chlorophyll and the correspondingly long fluorescence lifetimes of ~100 ps, or even more when the chemical traps are closed[11].

Two molecules, which are within the statistical-pair quenching distance, may be prevented from quenching if they are separated by another molecule. Infrared, X-ray diffraction and other structural studies have shown[12,13] that chlorophyll molecules, whatever their environment, tend to coordinate the Mg atom, either to another chlorophyll or to a solvent molecule, so that chlorophyll with only four bonds coordinated to Mg probably rarely exists. The dimers and oligomers, which Katz suggests[12] comprise the antennae chlorophylls of the chloroplast, are almost non-fluorescent and strongly quenching. We therefore conclude that chlorophyll molecules in the chloroplast antennae, although at close distance, are separated from each other by strongly coordinated molecules which prevent collapse to an excimer or other quenching configuration. It is not yet certain whether antennae chlorophylls are associated with protein, with lipid or with the lipid–protein interface[14]. Galactolipids are present in a concentration two or more times that of the chlorophyll[15] and models show that the galactose part of the lipid coordinates well with the Mg of the chlorophyll within the lipid layer, which could thus ensure isolation of each chlorophyll molecule from other chlorophyll molecules. S. E. Carlin (unpublished results), has shown that when lecithin, in lecithin–chlorophyll vesicles, is replaced by galactolipids, the chlorophyll concentration required to give half quenching is approximately doubled, an effect which, although too small to explain the efficiency of the chloroplast, suggests that further work on these lines may be profitable.

Since this work was completed, Fenna and Matthews[16] have reported the first structure determination of a chlorophyll-containing protein, in which they find an irregular arrangement of the rings of the seven chlorophyll molecules, an average nearest-neighbour separation between centres of 12 Å and no evidence of interaction between them. Although this is a bacteriochlorophyll–protein, which is not part of the antennae system, its structure is admirably designed to promote energy transfer while inhibiting concentration quenching.

Morphological transformation and chromosome aberrations produced by two hair dye components

A POSSIBLE carcinogenic hazard from hair dyes has been suggested recently by mutagenicity studies using the *Salmonella* tester strains developed in Ames' laboratory[1,2]. We had previously found a good correlation between mutagenicity produced by specific cigarette smoke condensate fractions in the *Salmonella* mutagenesis system[3] and oncogenic transformation in the mouse C3H/10T½CL8 cell line[4] developed in Heidelberger's laboratory. I have therefore studied transformation in this cell line after exposure to two hair-dye components, 2-nitro-*p*-phenylenediamine (2-NPPD) and 4-nitro-*o*-phenylenediamine (4-NOPD), both of which had been found to be highly mutagenic in the tester strain TA1538. Although 2-NPPD has greater mutagenic capacity in the presence of a microsomal activation system[1], I thought that 2-NPPD might be able to transform C3H/10T½CL8 cells since there is sufficient microsomal activity to convert certain carcinogens such as polycyclic hydrocarbons to their active form(s)[5]. Both 2-NPPD and 4-NOPD were found to produce significant morphological transformation in the C3H/10T½CL8 cell line. In addition, in view of the reported correlation between specific chromosome changes and the expression of malignant transformation[7,8] and the fact that known carcinogens rapidly produce chromosome aberrations[9], I sought and found chromosome changes after treatment with these hair dye components.

2-NPPD and 4-NOPD, provided by Dr Bruce Ames, were dissolved in dimethyl sulphoxide (DMSO) and incubated at various concentrations with the C3H/10T½CL8 for 24 h as described before[4,6]. Approximately 1 month later the dishes were stained and scored for the presence of transformed foci. Only type III morphologically transformed foci were scored since these produced sarcomas in most cases when isolated and injected into syngeneic C3H mice immunosuppressed by irradiation or rabbit anti-mouse thymocyte serum[6]. The results of two experiments are shown in Table 1. Morphological transformation was found in each experiment after treatment with 2-NPPD in doses from 10^{-3} M to 10^{-5} M, with an increase in transformation frequency at higher concentrations. Morphological transformation was also produced by 4-NOPD in the same range of doses. A concentration of 10^{-6} M 4-NOPD produced no morphological transformation. Fifteen transformed foci were observed in the dishes treated with 2-NPPD and 4-NOPD, whereas no transformed foci were seen in the control dishes treated only with DMSO. Only one type III focus has been found in DMSO-treated control dishes during the 2.5 yr that the C3H/10T½CL8 cells have been used in our laboratory for transformation studies. Transformation was also observed at non-cytotoxic doses of 2-NPPD and 4-NOPD, which further supports the fact that the two hair dye components induce morphological transformation rather than select for it.

Table 1 Morphological transformation produced by 2-NPPD and 4-NOPD

Agent	Dose (M)	Average PE (%)	Total type III foci/total dishes	Transformation frequency (%)
Control (DMSO treated)		15	0/61	<0.01
2-NPPD	10^{-3}	5	3/21	0.29
	10^{-4}	12	2/22	0.08
	10^{-5}	14	1/21	0.03
4-NOPD	10^{-3}	7	2/26	0.07
	10^{-4}	10	2/20	0.10
	10^{-5}	15	5/30	0.11
	10^{-6}	15	0/10	<0.07

Cells were seeded from log-phase mass cultures into 60-mm dishes (1,000 cells per dish) and treated 24 h later with the indicated doses of 2-NPPD or 4-NOPD. Exposure was for 24 h, after which the cultures were washed and maintained for 4–6 weeks. Type III morphologically transformed foci were subsequently scored in stained dishes as previously described[4,6]. Cytotoxicity was determined in similarly treated cultures containing 200 cells and stained after approximately 10 d. The transformation frequency is the percentage of cells that gave type III transformed foci corrected for the plating efficiency (PE), number of colonies formed as a percentage of number of cells seeded.

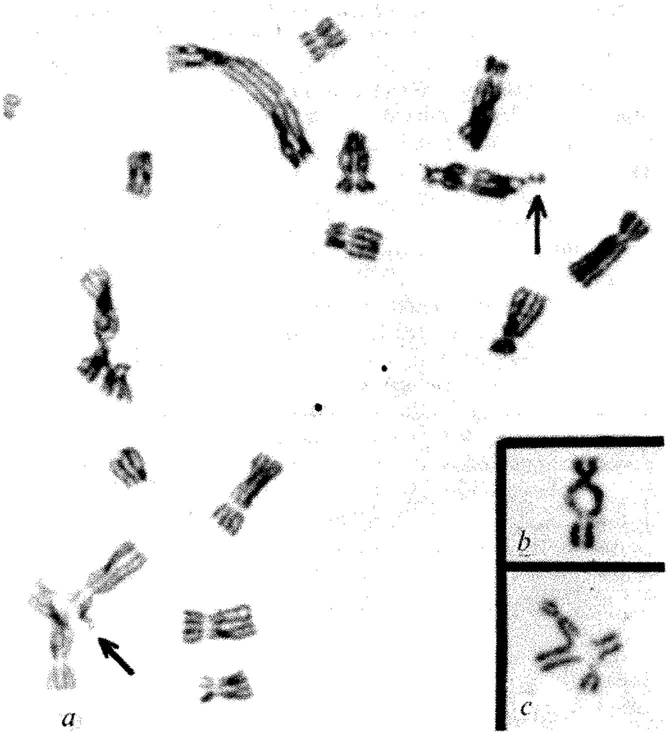

Fig. 1 *a*, Partial metaphase after treatment with 10^{-5} M 2-NPPD showing endoreduplication and two isochromatid fragments (arrows). *b*, An example of a dicentric chromosome seen after 2-NPPD exposure. *c*, A quadriradial chromosome configuration found after treatment with 2-NPPD.

The transformation frequency found with these hair dye components was approximately 10 times less than that produced by the potent carcinogenic polycyclic hydrocarbon, 3-methylcholanthrene, at equimolar concentrations[6]. This quantitative comparison, however, is made with caution for several reasons, including the fact that 2-NPPD, 4-NOPD and 3-methylcholanthrene represent different chemical classes and utilise dissimilar activation systems.

The hamster cell line, $A(T_1)Cl$-3, developed in our laboratory was used for the chromosome studies since this cell line contains a diploid number of hamster chromosomes[8] and is being developed as a rapid screen for chemical carcinogens[10]. The results are shown in Table 2. Both 2-NPPD and 4-NOPD produced significant chromatid breaks, with 2-NPPD yielding more chromatid breaks at the highest concentration tested. Several abnormal quadriradial and triradial chromosome formations as well as dicentric chromosomes were seen in metaphases after treatment with 2-NPPD (Fig. 1). The presence of dicentric chromosomes may indicate that 2-NPPD can be active in the G_1 phase of the cell cycle since this type of chromosome abnormality occurs after exposure to a chemical during G_1. Chromatid

Table 2 Chromosome breakage and other chromosomal aberrations produced by 2-NPPD and 4-NOPD

Agent	Dose (M)	No. of metaphases with indicated breaks per cell		Metaphases with indicated chromosome abnormalities
		0	1–4	
Control		50	0	None
2-NPPD	2×10^{-4}	30	20	1 Quadriradial, 3 triradials, 1 Dicentric
	10^{-4}	42	8	1 Quadriradial, 1 triradial, 2 Dicentrics
	10^{-5}	46	4	None
4-NOPD	3×10^{-4}	41	9	None
	10^{-4}	46	4	None
	10^{-5}	47	3	1 Ring chromosome

Hamster cells, A(T_1)Cl-3[8], were exposed for 24 h to various concentrations of 2-NPPD and 4-NOPD. One hour before collection colcemid (1 μg ml^{-1}) was added to arrest the cells in metaphase. The chromosome preparations were made as previously described and 50 metaphases for each time period were scored for the presence of chromatid breaks or gaps as well as other chromosome aberrations[11]. A gap was considered to be a lesion at least the width of a chromatid and a break was a gap with a different angle than the adjacent chromatid arm All lesions were reported as 'breaks' for simplicity.

breakage is indicative of chromosome damage produced in other phases of the cell cycle.

An endoreduplicated cell was found, after exposure to 10^{-5} M 2-NPPD, which contained two chromosome fragments (Fig. 1). This type of abnormal metaphase may be highly significant in the production of malignant transformation since at this non-toxic dose of 2-NPPD the surviving cell could easily be aneuploid, with chromosome imbalances. We believe such chromosome changes may be related to malignant transformation and oncogenesis[8,9]. The production of chromosome aberrations by 2-NPPD after exposure of human peripheral lymphocyte cultures has also been noted, although no chromosome abnormalities were found after treatment with 4-NOPD[2].

Considerable evidence now suggests that certain hair dye components could be potential hazards to humans, especially as these agents can be present in hair dye at concentrations as high as 10^{-2} M (ref. 11). The evidence includes their mutagenic activity in *Salmonella*, their ability to produce morphological transformation in the C3H/10T½CL8 cell line and their capacity to yield a significant number of chromosome breaks and rearrangements. Thus further studies of these and other hair dye components for carcinogenic and mutagenic potential *in vivo* seem advisable.

Mechanism of selective nonspecific cell-mediated cytotoxicity of virus-infected cells

STUDIES of mechanisms of resistance to herpes simplex virus (HSV) in mice have demonstrated antibody-dependent cell-mediated cytotoxicity (AD-CMC) of HSV-infected cells exposed in suspension cultures to anti-HSV sera and normal mouse peritoneal cells (PC) or human peripheral blood leukocytes. In this system it was impossible to demonstrate T-cell-mediated cytotoxicity[1–3]. In an attempt to adjust the assay conditions to permit detection of such cytotoxicity by immune spleens or PC, the "monolayer" system of Gardner *et al.*[4] was examined in syngeneic, allogeneic and xenogeneic combinations. Target cell monolayers were infected with HSV and exposed to immune or normal mouse PC. The latter produced unexpectedly high levels of nonspecific release of ^{51}Cr by the monolayer HSV-infected cells. Because nonspecific or non-selective killing of human tumour cells[5] by lymphocytes from normal patients has been a major problem in human tumour immunology, we have investigated the mechanism of this nonspecific cell-mediated cytotoxicity in the HSV system. Our results indicate that selective nonspecific killing is a consequence of the cross linking of effector and target cells through aggregated immunoglobulins.

When HSV-infected cells, either Chang human liver cells or neuroblastoma C1300 clone N_2A cells of A strain mice[6], were exposed to normal uninduced mouse PC, either in "suspension" cultures as described before[1] or in monolayer cultures in which monolayers were infected for 18 h before addition of the PC, strikingly different patterns of cytotoxicity were observed (Table 1). While only low levels of ^{51}Cr release were found in suspension cultures of HSV-infected cells, quite high levels of cytotoxicity were found in monolayer cultures of HSV-infected cells and normal PC in a ratio of 1 : 20. This was a selective non-immune cytotoxicity and not an artefact of the culture conditions, for no such cytotoxicity was produced in identical cultures containing uninfected target cells (Table 1), or target cells infected with measles virus (unpublished observation). Addition of rabbit anti-HSV sera, as reported previously, generated a marked increase of ^{51}Cr release in suspension cultures attributed to an AD-CMC. In contrast, antibody-inhibited cytotoxicity in the monolayer cultures. The effector cells in this system were almost totally removed by passage over nylon wool columns[7] and were destroyed by preincubation with silica, known to be cytotoxic for macrophages[8]. Thus the nonspecific cytotoxicity in the monolayer system seems to be related selectively to HSV infection and is probably produced by macrophages.

It is known that infection of various non-lymphoid cells with HSV induces the expression of a receptor for the Fc region of immunoglobulins on the cell surface[9,10], and this was confirmed on our target cells. These observations suggested that the selective, nonspecific cytotoxicity observed in the HSV system might be mediated by cross linking of effector cells and target cells, both displaying Fc receptors, by aggregated immunoglobulins or immune complexes. Since most commercial foetal calf sera (FCS) contain some immunoglobulins, the monolayer assay was

Table 1 Cytotoxicity of peritoneal cells for HSV-infected Chang cells in monolayer or suspension cultures

Cells	Serum	% Specific cytotoxicity* HSV-infected Chang cells Monolayer	% Specific cytotoxicity* HSV-infected Chang cells Suspension	Uninfected Chang cells Monolayer
PC	—	65±6.3†	5±3.1	8±1.8
PC	Normal rabbit (1/100)	60±6.0	0±3.8	NT
PC	Rabbit anti-HSV (1/100)	41±5.3	89±8.3	12±3.5
—	Rabbit anti-HSV (1/100)	10±1.5	8±1.2	3±1.3

For the monolayer assay Chang human liver cells were dispensed in 1 ml of MEM + 10% FCS into flat bottom wells of multi-dish tissue culture trays (Linbro FB-16-24-TC) at a density of 1 × 10^5 per well. Three hours later the cells were infected with the HFEM strain of Herpes simplex (HSV) at an input multiplicity of 10. Twenty-four hours later each well was labelled with 2 μCi of $^{51}CrO_4$ (Amersham) for 1 h at 37 °C. Cells were washed three times. Uninfected cultures handled similarly served as controls. The suspension assay was carried out as before[1]. Uninjected normal rabbit serum or rabbit anti-HSV (neutralising titre of 1/800), was added to the monolayer or suspension cultures of target cells. PC were collected from C57BL/6 mice and were added at a ratio of 20:1 in a final volume of 1.0 ml. All assays were carried out in triplicate. Spontaneous leakage of ^{51}Cr was 15–20%.

*Percentage specific cytotoxicity was calculated according to the following formula:

$$\frac{\text{mean } ^{51}\text{Cr release in test group} - \text{mean spontaneous } ^{51}\text{Cr release}}{\text{mean } ^{51}\text{Cr release after freeze and thawing} - \text{mean spontaneous } ^{51}\text{Cr release}} \times 100.$$

* + s.e.m. in six to eight experiments.

carried out in medium containing certified agamma-FCS (Microbiological Associates, lot 87839). As Table 2 shows, the nonspecific cytotoxicity of HSV-infected murine neuroblastoma cells was markedly diminished in the agamma-FCS, and specific cytotoxicity could be seen. Introduction of rabbit immunoglobulins aggregated chemically by *biz*-diazotised benzidine[11] into the monolayer system significantly augmented the level of cytotoxicity in the agamma-FCS. This rabbit Ig had no detectable neutralising antibody against HSV. In parallel these aggregates blocked the formation of EA rosettes of sheep red blood (SRBC) cells coated with rabbit anti-SRBC antibodies[12] which detect Fc receptors on the effector cells. Nonspecific cytotoxicity-inducing activity of ordinary FCS could be diminished by ultracentrifugation at 100,000*g* for 1 h and use of the upper third of the serum (Table 2).

We believe that these results may have more general significance than just for the HSV system. Nonspecific cell-mediated cytotoxicity has been a serious problem in the interpretation of microcytotoxicity assays used to assess tumour immunity in man[5,13,14]. In this regard it is noteworthy that various primary tumours have been shown to exhibit Fc receptors[15]. Hersey *et al* reported nonspecific killing of melanoma lines by activated T lymphocytes possessing Fc receptors[14]. Similarly, complement receptor-bearing cells from blood of patients with infectious mononucleosis indiscriminately killed lymphoblastoid cell lines, whereas purified T cells had specificity only for target cells infected with Epstein–Barr virus[16] Stott *et al.*[17] found that bovine alveolar macrophages were cytotoxic for parainfluenza virus-infected targets but uninfected cells, and immune serum blocked this killing—findings similar to ours with the monolayer system. If this model were applicable to human tumour systems, nonspecific or nonselective cytotoxicity *in vitro* might similarly be mediated by linkage of effector and target cells through aggregated Ig or immune complexes. Cross linking through Fc receptors may be one mechanism of selective but nonspecific cytotoxicity, but it is unlikely to be the only one[18].

Table 2 Effect of aggregated Ig and FCS on Fc rosettes and cell-mediated cytotoxicity of HSV-infected neuroblastoma cells in monolayer cultures

Effector system (normal PC plus)	% ^{51}Cr release	% EA rosettes of P C
FCS	45	NT
FCS + anti-HSV serum (1/100)	11	NT
aγ−FCS	14	33
aγ+FCS+150 mg Agg, Ig	27	9
aγ+FCS+15 mg Agg, Ig	19	20
aγ+FCS+1.5 mg Agg, Ig	8	30
aγ+FCS+0.5% FCS	29	NT
FCS − after ultra-centrifugation (top third)	7	NT
(bottom third)	20	NT

Agg., aggregated

Monolayer ^{51}Cr cytoxicity tests were carried out as described in Table 1. Target cells were HSV-infected neuroblastoma cells. Ig aggregates (Agg.) were prepared described by Ishizaka *et al.*[11] by mixing rabbit Ig (10 mg ml^{-1}; Cohn fraction II, Pentex) with *bis*-diazotised benzidine (1/5 v/v) Inhibition of EA rosette formation on effector cells was tested as described by Westmorland *et al.* using rabbit anti-sheep red blood cells antibodies[8]. FCS was ultracentrifuged at 100,000*g* for 1 h.

Although it may be tempting to speculate that such a nonspecific cytotoxicity of cells exhibiting Fc receptors provides some level of non-immune surveillance or resistance to HSV infection or tumour growth, there is no evidence that this mechanism of cytotoxicity *in vitro* can provide protection *in vivo*.

matters arising

Maze-learning ability of *Drosophila melanogaster*

HAY[1] reported that the probability of right–left choices by *Drosophila melanogaster* in a uniformly illuminated multiple-step maze depends on the path through the maze before reaching the choice point. Animals which had initially turned right and were subsequently forced to take five right turns, by blocking the alternatives, had a greater tendency to turn right again than to turn left and vice versa. Hay interprets these findings to demonstrate that "*Drosophila* "learn" that this sequence of turns enables them to proceed through the maze towards the light" and "that the flies display associative learning. With no apparent positive or negative reinforcement they associate passage through the maze towards the light with a sequence of turns or, more accurately, with a particular orientation towards the light at each choice point, . . ."

In two-step maze experiments (designed for a different purpose) with *D. melanogaster* we observed similar deviations from binomial distribution[2]. These deviations were also found, however, in dark controls and, furthermore, when none of the alternatives in the maze was blocked such that the flies could proceed to the end of the maze by either route. We therefore do not agree with Hay's interpretation but would tend to relate these observations to the correcting behaviour or reverse turning observed from several different species[3–7].

To demonstrate our point of view we have performed several experiments which we report here. Figure 1 shows a scale drawing of the Plexiglas maze[8] used for these experiments. All dimensions are large compared with the size of *D melanogaster* except for the inner diameter of the funnels used to provide a one-way passage[2]. The collecting vessels were empty *Drosophila* culture flasks. The experimental setup was different from that of Murphey[9] in that our maze included forced turns between first and second choice points. The maze was washed and carefully cleaned before each run. Experiments were performed in complete darkness, at 22 ± 1 °C. Of approximately 400 flies (*Drosophila* wild type, Berlin, males plus females, age 3–10 d after eclosion) placed in the starting vessel usually 250 had completed the run after 12 h.

Table 1 shows the results of a typical experiment together with the total of 16 experiments. To eliminate the possibility that an inherent asymmetry of the maze causes the observed distribution, eight experiments were performed in orientation I (*a,b,c,d,*) and eight in orientation II (*b,a,d,c,*) by permuting the parts of the maze.

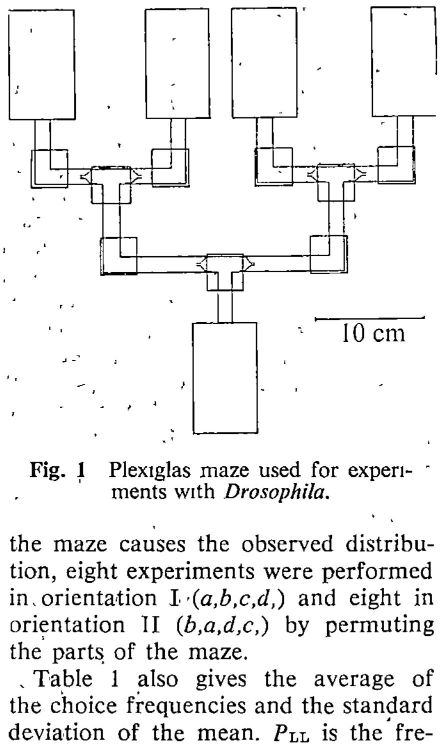

Fig. 1 Plexiglas maze used for experiments with *Drosophila.*

Table 1 also gives the average of the choice frequencies and the standard deviation of the mean. P_{LL} is the frequency of two subsequent left choices, P_{LR} is the frequency of a left choice and a subsequent right choice in the maze. It is obvious that $P_{LL} > P_{LR}$ and $P_{RL} < P_{RR}$. The differences are highly significant as tested with a *t*-test and a Wilcoxon rank sign test. The effect observed in our maze, however, is only about half as large as that reported by Hay[1].

Table 1 Performance of *Drosophila* in maze

	LL	LR	RL	RR
No. of flies counted in collecting vessels in a single experiment	75	45	39	69
Total of 16 experiments	1,331	903	903	1,391
Average of the choice frequencies	$P_{LL} = 0.296 \pm 0.019$	$P_{LR} = 0.202 \pm 0.012$	$P_{RL} = 0.196 \pm 0.015$	$P_{RR} = 0.306 \pm 0.015$
In Hay's notation	$P^*_{LL} = 0.602 \pm 0.021$			$P^*_{RR} = 0.604 \pm 0.021$

Hay reported an experiment in which all passages in the evenly illuminated maze were allowed and yet a nonbinomial distribution of flies was found. For our purposes we have only found it necessary to report that the effect is still observed in the dark. Thus it can hardly be associated with a successful "passage through the maze towards light". It is not intended to give an explanation[5] of this reverse turning behaviour; however, associate learning seems to be an unappropriate description.

HAY REPLIES—I welcome the opportunity to expand the arguments in my report[1] on associative learning in *Drosophila.* There I listed and eliminated alternative explanations of the behaviour. Bicker and Spatz[2] have pointed out that one of these alternatives, namely correcting behaviour, could affect my results. Although I did not use the term 'correcting behaviour', it encompasses two of the variables I considered, namely centrifugal swing and spontaneous alternation.

The crucial experiment, however, (at the top of page 46 in my report), by which I distinguished correcting behaviour from associative learning is impossible in their case as they used only one strain of *Drosophila.* I demonstrated that, although there are strain differences in the probability of following the outer walls of a maze where all choices are available (which is what a correcting behaviour explanation would require), these strain differences are unrelated to the performance in the maze where choices are forced. That is, I accept that correcting behaviour is involved, but it cannot account for my strain differences in the latter maze in CL and CR (the changes between the first and second choice points in the probabilities of turning left or right) and it is necessary to introduce another variable, namely genetic differences in associative learning.

All Bicker and Spatz have done is to confirm Murphey's[3] demonstration that *Drosophila* show spontaneous alternation. This would explain why they obtained similar results in the dark and need not refute my suggestion that the flies associate passage through the maze with visual cues. In any case, one would expect very little learning in their maze, where there is only one forced turn between the two choice points, whereas my maze had a sequence of six forced right–left or left–right turns.

Finally, I should like to stress the need to consider both genetic variation and apparatus differences in maze learning work with *Drosophila*. First, I found large strain differences in learning, and other workers should similarly use a wide variety of strains, rather than just one, if they wish to demonstrate learning Second, Hay and Crossley (submitted for publication) showed with a maze rather like the one used by Bicker and Spatz but with an extra forced turn, that such apparently minor apparatus variations as the length of the connection between the start-tube and the first choice point can have very large effects on the probabilities of turning left or right. For example, the values of CL for males of the LM 20 strain varied from a mean ± s.e. of -0.069 ± 0.058 to $+0.491 \pm 0.102$ depending on the apparatus. Thus apparatus specifications need to be considered carefully in replicating the maze-learning work but in turn offer a means of studying in more detail some of the factors that determine turning preferences in *Drosophila*.

Comments on a closed galaxy model for cosmic-ray propagation

Rasmussen and Peters[1] have presented a model of cosmic-ray propagation in which the particles do not escape from the galactic confinement region, but are eventually absorbed by meson-producing interactions with the interstellar gas. This contrasts with the generally accepted 'leaky-box' model in which cosmic rays escape from the Galaxy after traversing ~ 4 g cm^{-2} of interstellar gas. We consider here the intensities of positrons and γ rays implied by the two models.

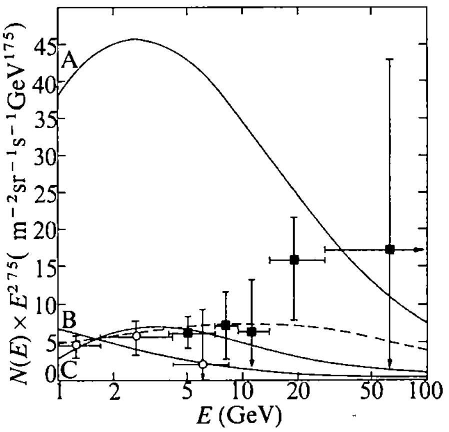

Fig. 1 Positron intensities above 1 GeV. — — —, Leaky-box model with average matter traversal of 4 g cm^{-2} and $E_{\mathrm{mod}} = 0.4$ GeV; ———, closed galaxy model with various values of E_{mod} and n_{H} (see text). ○, From ref. 3; ■, from ref. 4.

In Fig. 1, which is adapted from a figure of Orth and Buffington[2], the dashed line shows the positron intensity calculated by them for the leaky-box model. For the case of no escape of positrons, appropriate to the closed galaxy model, the solution of the diffusion equation for the positron intensity is

$$N(E) = q_0 E^{-\Gamma}(\Gamma-1)^{-1}(Eb+a)^{-1}$$

where $q_0 E^{-\Gamma}$ is the rate of production of positrons by the observed equilibrium nuclear flux. Their rate of energy loss is bE^2+aE, the first term corresponding to synchrotron and inverse Compton losses and the second to bremsstrahlung. Both q_0 and a are proportional to n_{H}, the effective mean density of interstellar gas traversed by the cosmic rays (nucleons cm^{-3}). Taking the rate of production of positrons given by Orth and Buffington; and $b = 10^{-16}$ GeV^{-1} s^{-1} the interstellar positron intensity is

$$N(E) = \frac{514E^{-2.65}n_{\mathrm{H}}}{(E+8.0n_{\mathrm{H}})}\,\mathrm{m}^{-2}\,\mathrm{sr}^{-1}\,\mathrm{s}^{-1}\,\mathrm{GeV}^{-1}$$

To compare this with observations, the modulation of the intensity by the interplanetary magnetic field has to be included. The modulation factor is expected to have the form

$$\exp(-E_{\mathrm{mod}}/E) \text{ for } E > 1 \text{ GeV}$$

The leaky-box spectrum in Fig. 1 was obtained using $E_{\mathrm{mod}} = 0.4$ GeV and $n_{\mathrm{H}} = 1$ cm^{-3}. Curve A is our calculated closed galaxy positron spectrum for the same values of these parameters. The observations show that either a lower n_{H} or a higher E_{mod} is required. It is not unreasonable to reduce n_{H} as a larger confinement volume is natural for the closed galaxy model. Curve B is obtained by fixing $E_{\mathrm{mod}} = 0.4$ GeV and varying n_{H} to give a weighted best fit to the observations. The optimum value is $n_{\mathrm{H}} = 0.027$ cm^{-3} implying that the lifetime of cosmic rays in the Galaxy is ~ 5×10^9 yr. If we regard E_{mod} as a free parameter we obtain the joint optimum values for n_{H} and E_{mod} of 0.1 cm^{-3} and 2.3 GeV respectively (curve C). It is not possible to rule out a modulation as large as this, at least down to 1 GeV, although the non-thermal radio background would favour the smaller value.

Independent evidence is provided, however, by the galactic γ-ray emission above 100 MeV from around the anticentre direction. Dodds *et al.*[5] have shown that if nuclear cosmic rays at their local interstellar density filled the disk out to the edge of the Galaxy, their interactions with the observed neutral hydrogen would produce twice as many γ rays as observed. Agreement with observation is obtained if, for instance, the cosmic-ray intensity decreases with galactic radius, R, in proportion to the mass density or if the intensity remains constant out to $R = 12$ kpc and is zero beyond. This type of behaviour is unlikely for the closed galaxy model, which favours a large confinement volume with a uniform cosmic-ray intensity. The γ rays are produced by cosmic-ray nuclei in the 1–10 GeV range. $E_{\mathrm{mod}} = 0.4$ GeV was assumed in deriving the local interstellar intensities of nuclei used by Dodds *et al.* from those observed at the Earth. For $E_{\mathrm{mod}} = 2.3$ GeV the intensity could be greater and the discrepancy in the γ-ray flux would be increased by a further factor of two. Thus we conclude that, although the closed galaxy model can be reconciled, as its authors state, with the observed positron flux, there are difficulties in making it agree at the same time with the observed γ-ray flux from the anticentre direction.

We thank A. W. Wolfendale and D. Dodds for helpful discussions.

Tide turns for fisheries research

Fish Communities in Tropical Freshwaters. Their Distribution, Ecology and Evolution By R. H. Lowe-McConnell. Pp xvii+337. (Longman: London and New York, 1975.) £10.

To those accustomed to the restricted fish fauna of British freshwaters, the diversity in tropical freshwaters is bewildering. More than 8,000 of the 20,000 modern fish species live in tropical rivers and lakes; these include many suborders not represented in higher latitudes, for example, the electric fishes of the unrelated Gymnotoidei and Mormyroidei. The need to refer to many species which will be unfamiliar to most readers poses a problem to the author, who tackles it by providing a general chapter about the fish faunas of Africa, South America and South-east Asia, including five pages of excellent drawings of representative genera, by listing all the families in an Appendix and by giving a separate index of fish names, including synonyms.

Five chapters compare fish communities in the four main types of tropical freshwaters: equatorial forest rivers; seasonal rivers; natural lakes; and manmade lakes. All the lakes are African but Dr Lowe-McConnell is able to compare rivers in the three continents. For each locality, she outlines the topography and geological history, and then describes climate and resulting changes in water conditions. This treatment brings out clearly the similarities between physical and chemical conditions in rivers of the three continents and helps to explain the remarkable convergences in the adaptations of the fishes and the general structure of the communities in these waters. In contrast to temperate waters, there is usually a diurnal and a nocturnal fauna which never meet. The regular flooding of large rivers is associated with the habit of feeding and breeding in the shallow productive flooded areas and then facing the problem of retreating to the restricted river channels when the floods subside.

In three other chapters, Dr Lowe-McConnell makes a valuable contribution to current discussions about the origin and maintenance of diversity in tropical ecosystems by considering topics such as trophic relationships, breeding behaviour and speciation, especially in the African lakes. Her own wide experience in the tropics makes her comments vivid and penetrating.

This book should appeal to a variety of readers: it presents a comparative view of complex fish communities for all those interested in ecology and evolution; it provides a good basis for anyone starting detailed work on tropical fishes, either from an academic or from a practical point of view. The 20-page bibliography will be especially useful to fishery workers since it includes many papers which are relatively unknown because they are difficult to obtain. The only major complaint to make is the price—at £10, few students are likely to buy their own copies but it is a 'must' for teaching libraries as well as for many research workers. **Margaret Varley**

Fisheries Resources of the Sea and their Management. (Science and Engineering Policy Series.) By David Cushing. Pp. 87 (London: Oxford University, 1975.) £3 50.

THIS book is a brief but useful review of the world's fisheries to inform the uninformed. The first chapter deals with the recent history and development of the fisheries and fishing gear The world catch of fish amounts to 65–70 million tons, the predominant species being the anchovies, sardines and herrings, followed by the cod-like fishes, together amounting to 25 million tons.

Japan and the USSR have become the biggest fishing nations but fisheries research is practised in most maritime countries, its foundation being based mainly on work in the N.W. European countries. Dr Cushing gives a potted survey of age, growth, fecundity and migrations of fish, and the delimiting of stocks, with a longer chapter on fish population dynamics Following the earlier regulation of fisheries by mesh sizes of nets, minimum sizes of fish for landing or by close seasons, there has been a trend towards allocating quotas to countries. In spite of research and control, overfishing is still prevalent Nevertheless it is considered that up to 100 million tons could be taken annually, mainly by the exploitation of new stocks.

Dr Cushing surveys the history and practice of fisheries management and the various international councils and commissions. The international structure of management is extremely complex and these chapters are especially useful in giving a brief account of the efforts being made to control fisheries in a rational manner. Alas, national interests, fishermen's lobbies and disagreements between governments and scientists have meant that attempts at conservation have often ended in failure.

J. H. S. Blaxter

Principles of Fishery Science. By W. H. Everhart, A. W. Eipper and W. D. Youngs. Pp. 288. (Comstock: Ithaca, New York and London, September 1975.) £6.85.

Principles of Fishery Science is an updated abridged version of *Fishery Science: Its Methods and Applications* by Rounsefell and Everhart, first published in 1953 and aimed at graduate and upper division undergraduate students. In its original form this book soon became a classic at a time when fishery science was a rapidly expanding field. The authors have endeavoured to update the book in the light of enormous developments in fishery research during the past two decades. They stress, however, that the book is designed to present principles and applications of fishery management, and assumes that students and practising fishery biologists already have a foundation in the biological, physical and mathematical, and social sciences.

The first two chapters made me feel that the authors' endeavours had been successful. The Introduction refers to systems analysis and describes the new approach to research as a result of the general systems theory. The following chapter on Characteristics of Fisheries is also thought-provoking. The subsequent chapter on Fishing Gear, however, seems quite out of place. It interrupts the flow of the book and seems to have been lifted straight out of the 1953 edition.

Chapter 4 on Population Identification sets our train of thought back on the rails and brings us well up to date with the latest methods for separating populations using serology and X-ray fluorescence spectometry.

The following five chapters I am afraid contribute nothing new to the field. Many cheaper books (an important consideration for undergraduates), such as those produced for the International Biological Programme, deal with age and growth, population estimation, mortality, recruitment and yield in as much detail.

The authors come into their own when considering habitat improvement, pond management, screens and guiding devices and fish ways, subjects given considerable space in their earlier book. There is a slight imbalance at times (a result of three authors?), for example pollution is "written off" in four pages, although a two and a half page bibliography on the subject follows the chapter. Yet, under Control of Undesirable Species (Chapter 18), we have a 2-page description (pp263–265) of the new piscicide antimycin.

There are two useful chapters on the Role of Hatchery-reared Fish and Stocking, although the literature citations are practically all of work carried out in North America; this is a general criticism of the bibliographies at the end of all the chapters.

This is a useful working text for undergraduates, which I shall certainly suggest mine read. It is difficult, however, to recommend its purchase at its present price. I suggest that its contents be slightly reduced, perhaps by removing chapters 3, 9 and 11; and released as a paperback. It will then serve a very useful role. **Derek Mills**

Surface physics

Surface Physics. (Oxford Physics Series.) By M. Prutton. Pp viii+117. (Clarendon: Oxford; Oxford University: London, August 1975.) £2.75.

THE 'black magic' of surface effects is just starting to gell into science Physicists have seen good spectroscopic evidence of the 'dangling bonds' or 'surface states' of which they have talked for years; and now diffraction experiments can identify the reconstruction of the lattice which take place if a layer of atoms is deprived of its neighbours on one side. The concepts, although exciting, are still complex and novel; and thus any attempt to present the physics of surfaces to the undergraduate requires a controlled style, a very firm grip of concepts and will also gain tremendously from deep immersion in the prevailing currents of research. Dr Prutton qualifies in all these departments and has produced a fascinating and readable text, covering a surprising amount in an inexpensive 117 pages He also somehow manages to combine impartiality with an infectious enthusiasm.

For those solid-state device workers who may be preparing to rush precipitately to the bookshelves, it must quickly be said, however, that the systems covered here are all ultraclean vacuum-solid interfaces and the much more murky field of solid–solid interfaces will probably have to wait a long time before a similar burst of enlightenment manifests itself Ultrahigh vacuum techniques have made possible a battery of methods (LEED, XPS, UPS, ELS, AES and FEM, to name a few acronymically) which have revolutionised our knowledge of vacuum–solid interfaces but which cannot penetrate to internal interfaces. Even the device worker, however, can learn a great amount from this book about the detection of surface impurities and he can also begin to appreciate how the growth of thin films is so powerfully controlled by the surface forces described.

I particularly appreciated some clear explanations of Ewald sphere construction for two-dimensional 'nets' and the distinctions between ultraviolet and X-ray photoelectron spectroscopy. Most of the drawings are jewels of explanatory lore, the captions being nearly sufficient in themselves as a teaching instrument; the references to other texts are confined wherever possible to a few authoritative works.

Among the explanations which I found less than illuminating were those on field emission and the photoelectric effect Here, surely, are two properties well suited for demonstrating both the ideal electronic behaviour of surfaces and some direct practical uses of clean vacuum–solid interfaces as, for example, in photomultipliers. The great body of work on the effect of alkali atom adsorbates on the electron affinity of surfaces would have fitted rather well into the scheme of the book but is not mentioned. This is, perhaps the most clear example of a tendency in the book to emphasise structural features at the expense of electronic poperties; another example is the very brief treatment of the surface state as an electronic level, in spite of some classic studies recently published by Spicer, Eastman and others

With these reservations there is no doubt that this compact and inexpensive little book will engender the right kind of enthusiasm for and familiarity with surface physics in many universities and even sixth forms.

Andrew Holmes-Siedle

Mexikanischer Vulkane

Studien zur jungquartaren Glazialmorphologie mexikanischer Vulkane. (Mexiko-Projekt der deutschen Forschungsgemeinschaft, Vol. VII.) Pp 178. By Klaus Heine. (Franz Steiner: Wiesbaden, 1975.) Quarto, art. Hardback· DM82.00.

THIS work, based on an extensive field survey of the more accessible high volcanoes, sampling of sediments and mineralogical analyses, is extremely interdisciplinary. The geomorphological features are assigned to their relative sequence and absolute dates through the stratigraphical evidence afforded by intervening beds of pyroclastics and fossil soils. Both of these, being readily identifiable and very widespread in the region and often carrying at least limiting ^{14}C dates, enable correlations to be established between glacial features which are miles distant from each other, on more or less isolated volcanic piles up to 5,500 m in altitude

At no time, it seems, did even valley glaciers extend below the 2,500 m contour, whereas the three present-day, barely surviving ice caps all lie above 4,700 m. Five main glacier advances, marked by moraines, are recognised· MI, 38,000–32.000; MII, about 12,100; MIII, 1+2, about 10 000–9,000; MIV, c. 2,000; MV. 180-25 yr b p. These conclusions are supported by numerous sections distributed over a wide area described and figured in detail, and borne out by corresponding evidences on the four volcanoes most closely studied (La Malinche, Iztaccíhuatl, Popocatépetl, Citlaltépetl) Similar, but less complete, observations were made on a number of lesser peaks, which, although unglaciated today, show the signs of at least some of the late Pleistocene and Holocene events described.

A brave attempt is made to derive a palaeoclimatic explanation of the ground phenomena, which is, perhaps, less convincing than the results of the painstaking fieldwork. This is largely due to the very divergent views expressed in the climatological literature, so that any author is obliged to espouse one or other mutually exclusive theories.

An enormous Bibliography is provided of relevant literature, making this a valuable work of reference and a worthy successor to previous volumes in the series.

I. W. Cornwall

Hermetic dialogue

The Ash Wednesday Supper: La Cena de le Ceneri. By Girdano Bruno. Pp. 174. (Mouton: The Hague and Paris, 1975) 28 Dutch guilders.

The Ash Wednesday Supper (La Cena de le Ceneri) is one of six Italian dialogues written by Giordano Bruno for the Elizabethan court when he visited London in 1584–85. The underlying purpose of the dialogue was at once religious and political. Bruno hoped to achieve a union between England and France through a hermetic interpretation of the Christian religion. Historians of sixteenth century intellectual history have found Bruno's work interesting not only for this reason, but because it involves an extended metaphor grounded in Copernican astronomy. Professor Jaki's translation of *La Cena* is based on an edition by Giovanni Aquilecchia of 1955, rather than on the later and fuller edition by the same editor. Professor Jaki makes a very stern critic of Bruno's science in many of its details, and might have been a more sympathetic commentator had he not insisted on treating Bruno as something he was not, namely, a scientist in the modern sense of the word. It will cause no-one surprise to find that Bruno does not conform to the canons of modern scientific thought, and history is not likely to be much illuminated by showing how Bruno failed to do so. Does it matter that Bruno did not anticipate Olbers' paradox? Professor Jaki's translation will certainly make the work of Bruno more accessible to an English-speaking audience. The commentary propagates one or two old myths, such as that of the 50 astronomers engaged by Alfonso of Castile to revise the Ptolemaic astronomical tables. For the most part, the translation reads well, but there are a number of points where the very sense of the English should have drawn attention to a mistranslation. Lewis and Short will soon put right the translation offered for *Neque id sine lepore et gratia,* which can hardly mean "Not without a rabbit and thanks"! **J. D. North**

Porphyrins

Porphyrins and Metalloporphyrins. Edited by K M. Smith. New Edition based on the original volume by J. E. Falk Pp. xxiii+910. Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl. 275; $114.50.

THIS book will be warmly welcomed by all who work in the area of porphyrins and metalloporphyrins, as it brings up to date material covered by Falk, while changing the emphasis somewhat to cover synthetic aspects and applications of spectroscopic methods. Throughout, the authors have taken care to emphasise biological relevance, and a section dealing with porphyrin biosynthesis and catabolism is included. Apart from a lack of coverage of catalytic properties of metalloporphyrins, the choice of material and its distribution among the various chapters is excellent. The editor is to be further congratulated on the coordination and cross-referencing between various chapters and the absence of significant overlap from different contributors. The presentation is good with many helpful diagrams and formulae, but there is no distinction in the type-setting between different classes of subheadings and, in parts, this is confusing. The text contains an abundance of references to reviews and original papers up to late 1974.

The first section deals with nomenclature and general features of structure, stability and spectra, followed by a summary of recent developments in chemical synthesis. Section 2 contains chapters on biosynthesis (including an excellent account of the 'type III isomer problem') and degradation to bilins. A comprehensive account of the coordination chemistry of porphyrins including static and dynamic aspects is followed by a section on methods for determination of molecular structure. This contains a wealth of information on X-ray, mass spectrometric, infrared and Raman studies and, notably, a detailed discussion of nuclear magnetic resonance to porphyrins, metalloporphyrins and related compounds. Applications of electron spin resonance and Mossbauer spectroscopy are considered in subsequent chapters. Later sections deal with chemical reactivity (including developments in photochemistry) and with structural analogues of porphyrins. The book concludes with a detailed and useful section on laboratory methods.

At $114.50, very few workers in the field will acquire a personal copy and even libraries may prove reluctant purchasers — an unfortunate situation as such a useful book should be within reach of all interested in this field. The problem is only slightly mollified by the news that the Laboratory Methods section is to be published separately. It is to be hoped that a less expensive edition, perhaps in paperback, will soon be forthcoming. **S. B. Brown**

Understanding information processing

Understanding Language: An Information-Processing Analysis of Speech Perception, Reading and Psycholinguistics. Edited by Dominic W. Massaro. Pp. xii+439. (Academic: New York and London, September 1975.) $16.50; £7.90.

THIS volume comprises eleven chapters; Massaro is an author of six and most of the remainder are by students of his. The book has been edited purposefully so that the coverage and level of the chapters cohere. There are some highly positive general attributes of the book. A wide literature is competently summarised and the references are quite comprehensive as well as up-to-date. To focus a set of reviews of aspects of information processing on the central theme of language is worthwhile.

Massaro's introductory chapter is one of the weaker ones, expounding an overview from a basic flow diagram of the sort which shows how to get from sound waves to abstract memory using only three boxes. Such diagrams are at best a harmless device for distinguishing groups of experiments. Too often they confuse the hierarchical structure of knowledge with the psychological processes by which it is arrived at. This chapter seems to me superficial without being usefully introductory.

The speech perception section begins with a much needed chapter on basic articulatory and acoustic dimensions which facilitates access to a literature which usually takes these as read. Two chapters on acoustic features and temporal factors lead to a review of major theories. Three chapters on reading cover elementary feature processing, word recognition and eye movements. Too much space is devoted to the scholastic enterprise of compiling letter feature lists but the discussion of redundancy utilisation is thorough. Massaro denies the use of lexical redundancy, probably incorrectly. The closing section on psycholinguistics reviews matters adequately treated elsewhere but adds completeness to the volume.

This book offers few significant theoretical insights but it provides a very competent review of an important and mobile area of research and will be highly useful to the advanced undergraduate or specialist for two or three years.

Leslie Henderson

Pure gold

Lysosomes in Biology and Pathology, Volume 4. (North-Holland Research Monographs· Frontiers of Biology, Volume 43.) Edited by J. T. Dingle and R. T. Dean. Pp. xviii+614. (North-Holland: Amsterdam and Oxford; American Elsevier: New York, 1975.) $74 95; Dfl.180.00.

THE 'gold rush' following the discovery of lysosomes has now subsided. The easily accessible nuggets have been removed and it is now necessary to dig more deeply and systematically to reap rewards That they are still there is illustrated by several chapters in this volume, which report thorough analyses of old problems, such as the role of lysosomes in degradation of plasma proteins (G. Gregoriadis) and in intracellular protein turnover (H. L. Segal). Several chapters are devoted to lysosomes in different cell types (skeletal and cardiac muscle cells, blood platelets, arterial walls, skin, *Tetrahymena*) but these accounts are more than descriptive, embracing the participation of lysosomes in the physiology and pathology of the cells concerned. For example, blood platelets are rich in lysosomes, and the release of their enzymes contributes to the pathogenesis of inflammation; and storage of lipids in lysosomes of cells in arterial walls may be important in atherosclerosis.

Evidence is presented of heterogeneity of lysosomes within single cell types (M. Davies) and of multiple forms of lysosomal enzymes (R. T. Dean) Speculative chapters include those of C. M. Szego on lysosomes in nucleocytoplasmic communication and L. J. Ignarro on the regulation of lysosomal enzyme secretion. In these days when relevance is so much emphasised it is pleasing to see a beautifully illustrated account by Yolande Heslop-Harrison of enzyme release in carnivorous plants. As in previous volumes, the production is of high quality, with many illustrations, including well-reproduced half tones, and comprehensive author and subject indices. The quality of production is unfortunately reflected in the price. **A. C. Allison**

Starch structure

Starch and its Components. By W. Banks and C. T Greenwood. Pp. xi+342. (Edinburgh University: Edinburgh, 1975.) £10.00.

STARCH, particularly as it occurs in cereal grains, is the major carbohydrate food ingredient in the human diet. Yet the structure of the starch granule is still unknown and no one has synthesised a granule *in vitro*. Nevertheless a great amount is known about starch granules and particularly about the structure, behaviour and synthesis of its major molecular components, amylose and amylopectin

This book reviews the chemical nature of starch and its components, and their behaviour with enzymes The book is a highly biased presentation and as the authors state in the Preface "We make no apology for the fact that emphasis in this monograph is on our own work . " Not everyone will agree with all the authors' statements in the book, but I find the total coverage good and the many arguments and criticisms sound. A reader will carry away a fine sense of starch behaviour and a good feel for the structure and reactions of amylose and amylopectin Emphasis is placed on hydrodynamic behaviour and on the action of enzymes on amylose and amylopectin.

After a short introduction the book is separated into five major sections. The first deals with the fractionation of starch and the fine structure of its components. Several fractionation procedures are discussed and the chemical but mainly enzyme reactions of components are given. Emphasis is placed on the use of enzymes to elucidate starch molecular structure. A section of 43 pages is devoted to the reaction of starch and its components with iodine A section concerned with the conformation of amylose in solution provides a wide coverage of methods for conformational determination and possible interpretations It is agreed that the basic helical nature of amylose predominates in its complexes and is lowest, if existant at all, in neutral aqueous solution. Starch-degrading enzymes are treated by examining the action pattern of exo-, endo- and branching or debranching enzymes. Pitfalls can be numerous in the use of enzymes to deduce starch structure and many of these are clearly indicated. The final major section carries a discussion of the structure and biosynthesis of the starch granule. Attention is directed toward crystalline nature and orientation.

This is not a practical book. It does not discuss the characteristics of starch pastes nor of the preparation or use of starch or its modifications. The book is devoted to a discussion of the basic structure of starch and its components as interpreted by the authors. As such it is recommended to all those having an interest in the fundamental characteristics of starch. Biochemists will find the review useful and interesting **Roy L. Whistler**

Amateur astronomers' Bible

Astronomy: A Handbook. Edited by G. D. Roth. Translated and Revised by Arthur Beer. Pp. xviii+567. (Springer: Berlin and New York, 1975.) DM44.90, $18.50.

THIS is a revised and translated version of what was for long the German amateur astronomers' bible, *Handbuch für Sternfreunde*, described rather misleadingly on the dust jacket as "designed to fill the needs of both professional and amateur astronomers". It in fact sets out to encourage the amateur to make and reduce observations of professional quality and rigour, so that the two might be complementary.

The ground covered is naturally similar to that in other amateurs' handbooks such as J B. Sidgwick's *Observational Astronomy for Amateurs* and *Amateur Astronomer's Handbook*, but its approach is more sophisticated. The chapter on 'Applied Mathematics for Amateur Astronomers' requires maths of at least A-level standard, and several expressions elsewhere in the book would be clarified by the use of worked examples. Yet the handbook is curiously out of date in parts, the radio astronomy chapter contains circuit diagrams which abound in valves, and some of the definitions in this and other chapters have a ring of history about them. There are some strange omissions too, in what is overall a very comprehensive text. Narrow band and even white light observations of solar flares are not discussed; meteor triangulation is dismissed in one sentence, and meteor spectroscopy, where the amateur can contribute important results, is not even mentioned.

There are, however, some particularly good chapters which are not covered well elsewhere. 'Fundamentals of Spherical Astronomy' is an excellent compact reference to position and time measurements. The chapters on solar eclipses, lunar eclipses and artificial Earth satellites are also most informative, and that on 'Observation of the Planets' stresses the amateur's role in continuously monitoring changes in planetary detail. There is a useful and complete appendix; and although several of the original references in the text are necessarily in German, the very thorough bibliography suggests much in the way of alternative reading.

Although this book is unlikely to attain the popular appeal of Sidgwick's handbooks, it is a good reference work for the advanced amateur astronomer and will be welcomed by many.

Heather A. Couper

obituary

Rudolph Minkowski, an outstanding contributor to many areas of astrophysics, died on January 4, 1976, at the age of 80. As a staff astronomer at the Hale Observatories, and later at the Berkeley Radio Astronomy Laboratory, he pioneered the study of planetary nebulae, supernovae, and radio-emitting galaxies.

Minkowski was born in Strassburg and educated at Breslau. Although strongly interested in astronomy, he found the physics program more attractive at Breslau, and he took his Ph D in optics in 1921. After a year at Göttingen, he joined the physics group at Hamburg, where he rose to the rank of professor In 1935 the increasing Nazi repression drove Minkowski to leave his homeland. Encouraged by former colleague Walter Baade, who had preceded him to Pasadena, he moved to a research assistantship at the Mount Wilson Observatory, where his abilities soon earned him a regular staff position. In his 25 years with the telescopes of Mount Wilson, and later of Palomar Observatory. Minkowski became one of the World's leading investigators of the violent phenomena of the universe.

Supernovae remained one of Minkowski's central interests during his entire career He distinguished early between the two principal types of supernovae and studied the spectra of many individual supernovae in other galaxies In collaboration with Baade he studied the remnants of the few known supernovae that have appeared in our own Galaxy. Of particular importance was their thorough analysis of the Crab Nebula, an object whose importance in astrophysics has increased as it was discovered successively to be a radio source, an X-ray source, and a pulsar

After the discovery of discrete radio sources, Minkowski was a leader in their identification and interpretation. Again working with Baade, he identified some of the strongest radio sources as supernova remnants. Others were identified as disturbed galaxies; the original Baade–Minkowski interpretation of them as pairs in collision did not hold up, but their nature has continued to puzzle astrophysicists for two decades.

Another of Minkowski's long-term interests was the nature of planetary nebulae. In addition to his analysis of these objects, he set up a survey, using a 10″ telescope, that more than doubled the number of planetary nebulae known

Minkowski's greatest public service in astronomy, however, was his supervision of the National Geographic Society–Palomar Observatory Sky Survey. This incomparably valuable set of photographs has been made widely available in reproduction and is an essential part of the facilities of every astronomical library Its uniformly high quality is a result of Minkowski's painstaking care.

The study of supernovae and disturbed galaxies naturally led Minkowski to study normal galaxies as well. His pioneering study of internal motions in elliptical galaxies was superseded only a dozen years later, when a new generation of observing equipment became available. It was in his last observing run at the Palomar 200″ telescope that he determined the optical redshift of the radio source 3C 295, which remained the farthest point on the velocity–distance diagram of cosmology for 15 years.

After retirement from Mount Wilson and Palomar Observatories in 1960. Minkowski spent a year at the University of Wisconsin and then moved to Berkeley, where he retired again in 1965 Neither retirement had any visible effect on his output of scientific articles, which continued into the 1970s. Several generations of astronomers will remember the personal warmth that underlay his wisdom.

announcements

Awards

The Chemical Society, Washington, has awarded the 1975 Hillebrand prize to **Dr Ming-Chang Lin** for his work on and with chemical lasers.

Dr Harold A. Rosen has been awarded the first L M. Ericsson International Prize for his work on geostationary communications satellites.

The Institute of Physics has made the following awards for 1976·

Charles Vernon Boys Prize to **Professor S. D. Smith** of Heriot-Watt University, Edinburgh, for his contributions to the design of scientific instruments in solid state physics and in physical meteorology

Duddell Medal and Prize to **Mr G. N. Hounsfield** of EMI Limited, for his development in the use of X rays for the examination of three dimensional structures.

Glazebrook Medal and Prize to **Sir Montague Finniston** of the British Steel Corporation, for his leadership in the application of science to the large scale manufacture of steel

Guthrie Medal and Prize to **Professor A. Salam** of the Imperial College, London, and the International Centre for Theoretical Physics, Trieste, for his contributions to the theory of fundamental particles

Maxwell Medal and Prize to **Dr S. W. Hawking** of the University of Cambridge, for his contributions to theoretical astrophysics.

Rutherford Medal and Prize jointly to **Professor R. J. Blin-Stoyle** of the University of Sussex, and **Dr Joan M. Freeman** of the UKAEA, Harwell, for their work on β-radioactivity of complex nuclei

Appointments

Sir Kenneth Berrill, Professor C. C. Booth, Sir Alan Cottrell and **Mrs J. E. Floud** have been appointed to the Advisory Board for the Research Councils (ABRC).

Dr J. H. Humphrey, Deputy director of the National Institute of Medical Research, has been appointed Professor of Immunology at the Royal Postgraduate Medical School.

International meetings

April 1–2, **The Changing Environmental Conditions in Great Britain and Ireland** during the Devensian Cold Stage, London (The Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG).

April 20–23, **Human Reflexes and Motor Disorders,** Brussels (I.C.B., Chaussée de Waterloo, 715, B-1180 Brussels, Belgium).

May 14–15, **Platelets and Thrombosis,** Milan (Dr D. C. B. Mills, Specialised Centre on Thrombosis Research, Temple University, Health Sciences Centre, 3400 N. Broad St., Philadelphia, Pennsylvania 19140).

June 14–19, **4th International Conference on Marine Corrosion and Fouling,** Juan-les-Pins, France (Congress Secretariat, CREO-73, 77, rue de Sèvres, 92100 Boulogne-Sur-Seine, France).

July 13–17, **Biology and Taxonomy of the Solanaceae,** Birmingham (Mr David Langley, Conference Secretary, Department of Botany, University of Birmingham, PO Box 363, Birmingham B15 2TT, UK).

July 26–28, **2nd European Colloquium on Hypothalamic Hormones,** Tübingen (deadline: April 15) (Professor Wolfgang Voelter, Chemisches Institut, Auf der Morgenstelle, 7400 Tübingen, FRG).

January 17–19, 1977, **The Geology, Mining and Extractive Processing of Uranium with Special Reference to Europe,** London (Deadline for abstracts: May 1) (The Secretary, Institution of Mining and Metallurgy, 44 Portland Place, London W1N 4BR, UK).

Person to Person

Scientist offers exchange of comfortable 3-bedroom house in Cambridge for a similar one in Paris from May 15 to July 30. (Contact Dr M. Levitt, MRC Laboratory of Molecular Biology, Hills Road, Cambridge, UK).

Six months' notice is given of the possible use of plenary powers by the International Commission on Zoological Nomenclature in connection with the following names (see *Bull. zool. Nom.*, **32** (1976)):

260 *Dermacentor andersoni* Stiles, 1908 (Acarina: IXODIDAE): proposed conservation.

1772 *Ophiura* Lamark, 1801 and *Ophioderma* Müller and Troschel, 1840: revised proposals for stabilisation.

2097 *Ophiolepis* Müller and Troschel, 1840: proposed designation of type-species.

2112 CIRCINAE in Aves and Mollusca: proposals to end the homonymy.

2113 *Pterois zebra* Quoy and Gaimard, 1825 (Pisces: SCORPAENIDAE): proposed suppression.

2116 *Halecium* Oken, 1815 (Coelenterata: Hydroida): Proposed validation: *Thoa* Lamouroux, 1816, proposed suppression.

2119 *Lecanium acuminatum* Signoret, 1873 (Hemiptera: COCCIDAE) proposed designation of neotype.

2120 *Cystioceras* Börner, 1912 (Insecta: Collembola): proposed suppression.

Comments within 6 months to the Secretary, International Commission on Zoological Nomenclature, c/o British Museum (Natural History), Cromwell Road, London SW7 5BD, UK.

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office The section will include exchanges of accommodation, personal announcements and scientific queries We reserve the right to decline material submitted. No commercial transactions.

Too much British common sense

ASK a hardened British government watcher how he feels about the documents pushed at him, and his response will generally be equivocal, even though what he reads is often a model of clarity, coherence and common sense. The discussion paper *Future World Trends,* released last week by the Cabinet Office (HMSO, 60p), has, however, a big enough element of common sense to evoke profound worry, rather than mere ambivalence. For common sense is conservative; and the implicit no-change theme running through the content gives it an ostrich-like perspective.

The document is the product of an interdepartmental committee of (regrettably anonymous) government scientists chaired by Dr Robert Press of the Cabinet Office, and the committee's objective (apart from stimulating "informed discussion") was to make its own assessment of projections on population, food, energy, mineral resources and pollution and to "help establish the position to be taken by the United Kingdom in international matters".

Future World Trends is worrying for far more important reasons than the obvious one that the subject matter is gloomy. We knew that already. But, even allowing for its limited size and scope (and the immensely irritating lack of references), the product is below standard. Not only is it more interesting for what it leaves out, or refuses to emphasise, than for what it includes; the tone it adopts as a consequence also makes it far from suitable as a basis for genuine "informed discussion".

Amid all the interesting (if obvious) points made about exponential population growth, for example, the only real tilt made towards the now widely accepted view that high population growth is the consequence and not the cause of poverty is a mere mention of the rather woolly view endorsed at the 1974 World Population Conference in Bucharest that "voluntary reductions are primarily dependent on changing social attitudes which are more likely to come about as a result of improved living conditions". Nothing is ventured regarding the structural changes which might be necessary to allow just such an improvement.

On theoretical food needs early next century, the document says these could be met but are not in fact likely to be. But the crucial explanation is bland: there are "economic, social and political barriers to the optimal policy of concentrating the expansion of output"; "similar obstacles" restrict "equitable global distribution"; growth in the consumption of (inefficiently produced) animal protein foods in rich communities will continue. As with population, the implicit conclusion is not drawn out, namely, that there is something wrong with the global economy and its capacity to allocate resources effectively. The need for a "massive transfer" of resources to what it calls (wrongly) the "developing countries" is mentioned—but is then largely discounted.

The committee's discussion of mineral resources highlights very well the orientation which makes for its difficulties on such matters. The price mechanism, it explains, operates to bring supply and demand for mineral resources into equilibrium. Because of it, there are actually "no hard and fast physical limits to resources"; the limits are "economic and technological". But the document (thoughts of OPEC?) adds, without elaboration: "national questions of environment and security of supplies and international constraints will undoubtedly affect the availability of raw materials". Later, on the broader use of nuclear energy, nothing is said of the proliferating international trade in nuclear technology which is its precondition. The prospect of nuclear blackmail, or indeed anything else which might upset present geopolitical arrangements and global economic patterns, is apparently not relevant.

What is relevant, it seems, is the 200th anniversary of Adam Smith. A look at the all-too-brief section headed "Economic aspects" highlights once again the ubiquitous price mechanism. This, we are told, will in general maximise welfare "subject to the distribution of income and wealth being socially and politically acceptable"; government intervention may be necessary in the event of "market failure". Yet it is precisely the unacceptability of the existing distribution which identifies the weakness of the market mechanism; and it is "market failure" (did it ever succeed?) which has spawned documents like this and its predecessors.

There is no reference to the idea that, without uninhibited expansion (which is what the debate is all about), and probably even with it, the market mechanism alone cannot produce anything other than an uneven allocation of resources; nor of the idea that there must be some sort of redistributing agency if the underdevelopment which is the corollary of the industrialised countries' development is to be forestalled. Yet the so-called "developing countries" (to the extent they are discernible as that—is Iran any longer comparable to Tanzania?), with few exceptions, are not developing at all; and the population and food problems will remain until real development takes place.

It seems incredible that a document looking at the next 30 years should evade all these points about the international economy and international politics. Scientists know that nowadays they will be judged for their public comments (or lack of them) regarding society as much as for their comments within their specialities—especially when they are participating in the gloom game. Yet this committee has largely failed to acknowledge that the real problems of the future will most likely be essentially political ones.

The necessary transfer of resources to ameliorate the population and food problems will demand sacrifices; so will the commitment of resources to solving these and other problems (energy, pollution). Such an awkward reassessment of priorities demands not only leadership but also authority—or, put another way, obedience. The sacrifice may therefore be, for the few countries which have elements of it, democracy itself. And it is a measure of the problem that it is democracy which offers the best chance that the consequence of an agonising choice might lead to success. The committee has chosen not to question the survival of the west's "business civilisation". Politics, after all, wasn't within its remit. So its ostrich-like perspective has contrived a camel. And a rather ordinary one at that.

An immunological approach

Barry Bloom, professor of microbiology at New York's Albert Einstein College of Medicine, looks at the possibilities for preventing parasitic diseases in cattle

WITH projections that world population will increase from 4,000 million to about 7,500 million by the end of the century, and an estimated 500 million people currently suffering from malnutrition, the magnitude of the world food crisis has finally touched the consciousness of people everywhere. Attention has been focused primarily on the green revolution and the need for increasing production of food grains; consequently the need for increasing production of meat and cattle has for the most part been overlooked.

The present situation is grim. While reliable statistics are virtually nonexistent, millions of head of cattle die of parasitic diseases each year, and more than 700 million are estimated to be at risk. In Africa alone, at least 7 million square kilometres of grazeable land, capable of supporting 120 million head of cattle, remain largely unproductive, chiefly because of tryanosomiasis and East Coast fever. The use of pesticides, while clearly important, has been inadequate to stave off these diseases, which are carried by the tsetse fly and ticks respectively. Effective drugs either do not exist or are too expensive for general use.

As a consequence of the enormous losses in potential food resources, there has recently been some discussion of the possibility of developing vaccines for immunizing cattle against diseases caused by blood parasites. In particular, the Rockefeller Foundation has sponsored a series of meetings to discuss the prospects.

Advocates of an immunological approach to control of parasitic diseases draw encouragement from two simple observations. First, if there were no immunity to such diseases, there would probably be no cattle in most of sub-Saharan Africa. Second, although mortality from these diseases is distressingly high, animals which survive infection are often resistant to subsequent reinfection. In fact, animals native to Africa, such as the n'dama, appear to be more resistant to parasitic diseases than species introduced from Europe. The general hope is that, with better understanding of the immune mechanisms required for protection, better characterisation of the parasite antigens required for resistance, and the use of immunological adjuvants—which are used remarkably infrequently in parasitic immunology—an immunological approach to control of these diseases could be realistic.

Although research has so far been limited, there have already been some promising results. Vaccines have been developed for protecting cattle against three parasitic diseases (babesiosis, anaplasmosis and East Coast fever) and immunisation has been found to offer protection against three others in laboratory animals (malaria, South American and African trypanosomiasis).

Even beyond our current wealth of ignorance of the specific aspects of host-parasite relationships, there exist serious problems which limit real progress in this area. A major problem is money. According to recent figures from the World Health Organisation, for example, in 25 African countries for which details are available, the average annual health budget is $1.17 per capita, and in 8 countries it is less than $1 per capita. In seven of those countries, the health budget is less than 5% of the total government budget. If those figures represent levels of support for control of human disease, the prospects for control of animal diseases by the developing countries themselves are clearly dismal. Moreover, the more developed countries hardly seem to be concerned with these problems—in recent years, there has been a general reduction in bilateral and international assistance programs in health-related areas.

A further problem is the increasing criticism of meat production and consumption in the West. While this campaign has relevance to grain-intensive cattle production in the developed countries, there is a danger that it may inhibit development of important food resources in developing nations where grain-intensive feeding is neither necessary nor possible. In sub-Saharan Africa, for example, cattle feed on low grade brush and natural vegetation, on lands generally too poor to support cultivated crops.

Promising developments

In spite of those problems, however, there have been some promising developments against the following widespread parasitic diseases.

- The most enigmatic and biologically fascinating of the animal parasite diseases is East Coast fever, caused by *Theileria parvum*, a virtually unclassifiable tick-borne parasite. The disease, which takes the form of a galloping proliferation of lymphocytes, not unlike leukemia, is responsible for the death of half a million cattle a year. The extraordinary aspect of the disease in cattle is that the parasite grows only in lymphocytes, and appears to act in a manner similar to cancer-causing viruses in tranforming lymphocytes into continuously growing cell lines.

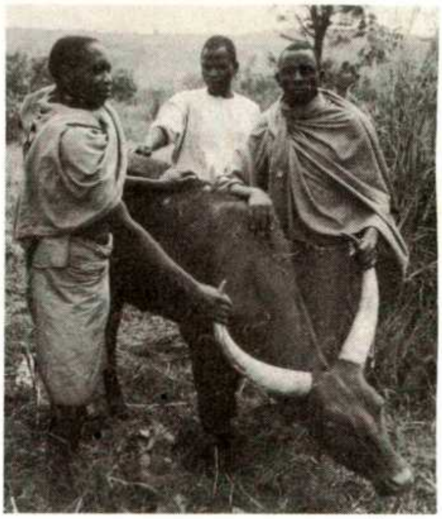

Photo: Popperfoto

Tsetse fly infection in Uganda

There has been progress in producing immunity in cattle in two ways: by infecting them with ticks, followed by antibiotic treatment, and more recently, by immunising them with infected lymphocyte cultures. The hope is that the parasite can be isolated from infected lymphocyte cultures, and the protective antigens purified and characterised.

- A million young cattle die each year from another tick-borne disease, anaplasmosis. It is caused by a family of rickettsiae which infect and multiply within mature erythrocytes. An attenuated vaccine has been produced by subjecting the parasite to gamma radiation and passing it repeatedly through an unnatural host, the sheep. Striking protection against tick infection has been observed in small scale experimental trials in the United States, and more extensive field trials are under way in Mexico and Columbia.
- A third tick-borne disease, babesiosis, is responsible for the death of about a quarter of a million cattle a year. The parasite is related to the malaria parasite, and similarly multiples in and destroys erythrocytes. An attenuated organism has been produced by passing the parasite through splenectomised cattle, and a highly effective vaccine, currently in use in Australia, has been developed.
- African trypanosomiasis, the most serious of the animal diseases, is responsible for the death of 3 million cattle a year. The animal disease and human sleeping sickness, both of which are caused by parasites carried by the tsetse fly, are clinically very similar. They represent a very difficult immunological problem because the parasite

has developed a highly effective method for eluding the immune system of the host, known as 'antigenic variation'. The disease is characterised by waves of illness, reflecting rapid growth of the parasite, followed by remission engendered by an immune response, followed by sequential emergence of antigenically different organisms.

Because the organism has not yet been grown in culture, it is not known by what genetic or regulatory mechanism it manages to change its surface characteristics to evade the immune system. Two different lines of research for potential vaccination are, however, being followed. The first would involve modifying the immune system of the host so that it would react quickly to wipe out the second appearance of the organism before it reaches sufficient numbers to produce disease. Following the recent isolation of the major antigenic surface molecule, the second would involve the production of a "cocktail" vaccine containing a mixture of antigens from the most common variants to combat the different forms of the organism. Both require better characterisation of the organism and its antigens.

● There are many similarities between the animal and human parasitic diseases, such as Chagas disease and malaria, and there are consequently common research problems and strategies. Chagas disease, caused by the organism *Trypanosoma cruzi,* affects 30 million people, chiefly in Latin America. Ten per cent of its victims, virtually all children, die from an acute disease, while the rest develop a chronic illness with invasion and destruction of heart and smooth muscle. It frequently ends in sudden death. Although there is no effective treatment at present, an irradiated vaccine has been produced from parasites grown in animal cell cultures. It provides virtually 100% protection to massive challenge in susceptible mice, which are killed by a single virulent trypanosome.

● Two hundred and fifty milion people now suffer from malaria worldwide, and at least a million people die from the disease in Africa alone. Two successful types of experimental vaccines against different forms of the organism have been produced, but practical limitations on the quantity of these vaccines preclude either of them from being useful on a large scale. One line of research is aimed at defining the nature of the protective antigens so that synthetic antigens could be developed as potential vaccine material.

There are major scientific questions to be understood and problems to be overcome that will require contributions by molecular biologists and geneticists as well as parasitologists and immunologists, and at this stage even if increased support for research were forthcoming, it would be foolish to guarantee that inexpensive and effective vaccines and drugs would result. Even if some were to be developed, there would remain two further serious problems. Although effective vaccines, particularly against African trypanosomiasis, would offer the possibility of opening vast areas in the tsetse belt to cattle production, without thoughtful assessment of the ecological consequences and intelligent regulation, marginal areas of the Sahel and tropical Africa could be destroyed by overgrazing. The second problem is the lack of an effective health infrastructure in the developing countries. There is a critical need for developing health services and training adequate health manpower to provide basic information and care for the health needs of the human and animal populations.

At the very least, it is worth considering what could be accomplished simply by supporting studies on the epidemiology of the animal parasitic diseases. It is an activity which could involve large numbers of untrained young people in an important scientific and educational enterprise. It would serve to develop a pool of talent from which the best could be selected for more advanced training in the health sciences and services. ☐

USA

Behind the politics of influenza

The idea of the United States government footing the bill to prevent the American population falling sick makes President Ford's request for funds to attempt a mass inoculation against flu something more than a medical issue in this election year. From Washington, Colin Norman gives the background

ON FEBRUARY 3, a young army recruit stationed at Fort Dix, New Jersey, came down with what seemed like a typical case of influenza. But the next day, while on a training march, he collapsed and died. His death sparked off an extraordinary series of events, culminating last week in the launching of the most extensive and controversial mass inoculation campaign ever undertaken in the United States.

The cause of the soldier's death turned out to be pneumonia, but a virus isolated from his respiratory tract immediately set alarm bells ringing in public health laboratories around the world. It was found to be a strain of influenza virus, commonly found in swine, which had not been involved in human infections for nearly 50 years. The virus, moreover, is very similar to the strain which caused the most serious flu pandemic in modern history, the 1918–19 outbreak which swept around the world killing some 20 million people.

Though only 12 other cases of swine flu were subsequently confirmed at Fort Dix, a massive monitoring effort on the base found antibodies to the flu strain in the blood of some 500 recruits, suggesting that they had been infected with swine flu during the outbreak. If the young recruit hadn't died, the outbreak would simply have been put down to the so-called Victoria/A strain which has been widespread in the United States this winter, but the isolation of the swine virus may have provided advance warning of a possible new flu pandemic next winter.

Because swine flu hasn't been abroad in the human population since the late 1930s, nobody under the age of 50 has any antibodies to guard against it. And it is likely that even those who do have antibodies are not protected against the disease. Thus, if the Fort Dix outbreak is not just a freak, isolated event, the virus could spread like wildfire through an unprotected population. Dr Edwin Kilbourne, a leading flu researcher at Mount Sinai School of Medicine in New York, said last week, for example, that "our thought is that probably the virus is seeded now in foci around the country, and when winter comes we will see it again".

For several weeks after the virus was isolated and identified, committees of scientists and government officials met at the US government's Center for Disease Control in Atlanta, Georgia, to decide what, if anything, should be done to counter the potential threat. Last week, they decided to recommend a massive inoculation effort against the virus, and President Ford appeared at a press conference, flanked by two of the most well known scientists in the United States—Jonas Salk and Albert Sabin—to announce that he is requesting $135 million from Congress for a crash programme to inoculate every man, woman and child in the United States by the end of November.

The decision was immediately controversial. Officials from the World Health Organisation expressed surprise, some scientists argued that since there's no definite evidence that the Fort Dix outbreak has spread there is no need for a massive inoculation campaign, and there have even been dark hints that the whole thing is an election-year ploy to attract votes. Nevertheless, it can reasonably be argued that Mr Ford had little choice in the matter.

One-jump-ahead virus

The influenza A virus is an amazing organism, which has managed to evade man's attempts to keep it in check for three decades. Its ability to cause epidemics lies in its extraordinary capacity to stay one jump ahead of the body's natural defence mechanisms by changing its genetic makeup every few years. (Two other classes of influenza virus, designated B and C, are rather less elusive, however.) When a person is infected by an influenza virus he develops antibodies which will give immunity from subsequent reinfection, but if the virus undergoes a slight genetic change, the antibodies often won't recognise it and the virus can slip past the body's defences and cause disease. The flu virus's ability to change its character is also the reason why attempts to develop vaccines against flu have been relatively disappointing —vaccines developed against one year's flu virus are often ineffective against a modified strain which may appear the following year.

Aside from those small elusive changes, the influenza virus is also capable of major genetic shifts. Every so often, a radically new variation of influenza virus emerges and, because there is no natural resistance to it at all, it can cause major pandemics. The last such pandemic occurred in 1968 from a strain first isolated in Hong Kong (hence its popular designation as Hong Kong Flu); another worldwide epidemic occurred in 1957 from a strain which first appeared in Asia.

President Ford : requesting $135 million

If, as seems to happen, pandemics appear in roughly 10-year intervals, a radically new flu strain can be anticipated in the late 1970s. The Fort Dix swine flu virus may be that strain. If so, it would be the first time that the world has had advance warning of a pandemic, and that warning could provide time for preventive action. But the evidence is far from conclusive; hence the controversy over Mr Ford's decision to launch a mass inoculation campaign.

Following the isolation of swine flu virus at Fort Dix, a massive study was conducted to see whether the virus is showing up anywhere else in the United States. No other cases were found, and the virus also seems to have disappeared at the army camp. It is therefore possible that the outbreak was a freak event which suddenly ended through unknown causes. But, on the other hand, it is possible that the virus has been seeded in the population and will re-emerge during next winter's flu season.

Kilbourne notes, for example, that "historically we have never recognised a new (flu virus) variant without a major pandemic following in its wake", and he added that the Asian and Hong Kong flu epidemics "smouldered before they took off" in the United States. Dr Robert B. Crouch, professor of infectious diseases at Baylor College of Medicine, is also not surprised that the Fort Dix outbreak seems to have disappeared. He pointed out that the Asian flu epidemic was first spotted in the United States as an isolated outbreak in Iowa which died off, followed by another isolated outbreak in Pennsylvania, which also disappeared; two months later, the full-fledged epidemic began to appear.

Time barrier

The problem now, however, is that there's not enough time to wait and see whether other outbreaks of swine flu occur before taking evasive action. Production of the 200 million flu shots which will be required to inoculate the entire US population must begin immediately or the programme won't be completed before next winter. Thus Ford asked Congress last week for funds to begin manufacturing vaccines from the Fort Dix strain as soon as possible, with the goal of inoculating high risk people (the elderly and infirm) by late summer, and the rest of the population by November.

Some scientists have argued, however, that even if the virus does reappear next winter, there is no need to mount a major campaign against it now. Dr Sidney Wolfe, head of Ralph Nader's Health Research Group, argues, for example, that the analogies which have been drawn between the Fort Dix strain and the swine flu virus which caused the 1918 pandemic have been greatly overstated. The huge death toll from the 1918 outbreak resulted from secondary infections such as pneumonia, which can now be cured by antibiotics, and so there's no reason to suppose that a new flu pandemic would be as devastating. It should be pointed out, however, that the Hong Kong flu pandemic killed some 20,000 people in the United States and cost more than $3,000 million in terms of lost work and medical expenses, antibiotics notwithstanding.

One particularly disturbing, but inevitable, factor is that the vaccine now being developed will only be effective against the Fort Dix swine flu strain, but the Victoria/A strain and an influenza B strain are also expected to reappear next year. People will therefore be receiving flu shots but can still expect to get a variety of influenza, a fact which won't increase public confidence in medical science.

A more alarming possibility, which cannot be dismissed out of hand, is that an entirely new flu strain could emerge in the southern hemisphere during the next few months as the harbinger of a different flu pandemic. In that case, people in the United States could be getting immunized against the wrong pandemic strain.

Be that as it may, President Ford was presented with a problem for which there is really only one solution. Though the evidence is sketchy, it is possible that a pandemic flu strain has been isolated in time to take precautionary action. Mr Ford could gamble that the virus won't reappear and do nothing, in which case he would bear a heavy responsibility if the virus did show up again, or he could ask Congress for $135 million as an insurance policy.

Though those involved in the decision vehemently deny that politics played any part, it cannot be denied that if Ford refused to initiate an inoculation program and swine flu became rampant in October, the effect on the November elections could be decisive. By the same token, it is unlikely that Congress will deny the request for the funds.

- A statement released last week by Britain's Department of Health in response to developments in the United States said that on present evidence its advisory group on influenza would not be recommending vaccination. The group suggests, however, that it would be a wise precaution to incorporate the new virus into anti-flu vaccine.

BRITAIN

ALMOST two years after it was officially adopted as a run-up to Britain's fast breeder reactor programme, the Steam Generating Heavy Water Reactor (SGHWR) made the headlines again last week with a report that a starting date has at last been set for the construction of the first commercial installation at Sizewell in Suffolk.

Even in passing that historic milestone, however, the two organisations with major development interests in the new reactor were still displaying the sort of confusion and uncertainty that has dogged the project's progress since it was first mooted at the beginning of the decade. While the Department of Energy readily confirmed that the first sod will be turned in late 1977, both the Nuclear Power Company (NPC), responsible for producing the reactors planned for Sizewell and Torness, and its main customer, the Central Electricity Generating Board (CEGB), denied that a firm date had been set.

If not cagey, NPC is at least determined not to tread on sensitive CEGB toes, seeming eager to stress only that virtually every figure ever mentioned in connection with the project has little more solid basis than the paper it is written on. NPC says that reports putting the price of the first two SGHWRs (totalling 4,000 MW) at up to £1,500 millions cannot be taken seriously as they have not outlined the separate elements contributing to the total sum or considered whether they are capital or recurring costs. With so little being said, it is an understandable omission.

The CEGB's sensitivity is, nonetheless, forgiveable in view of the fiasco that has accompanied the development of the ill-fated Advanced Gas Cooled Reactors (AGRs). Tight CEGB lips last week parted just wide enough to explain that a nominal sum spent at the drawing board could later save millions on site modifications—a lesson expensively learned with the Dungeness B AGR. So, whatever the Department of Energy may proclaim, there will be no firm starting date from CEGB or NPC until final design details have been submitted by NPC, accepted by the CEGB, and passed by the Nuclear Installations Inspectorate.

● The academic year 1974-5 will not be remembered as a great year for universities; but at least they all stayed open. That, roughly, is the conclusion of the University Grants Committee's (UGC) report for last year published recently (Cmnd 6435, 50p). Supplementation, in bits and pieces, of the basic grant could not soften entirely the cut in real terms of about 8% in the recurrent grant that UGC handed on to universities.

Many of the economies that were made in that year are not repeatable, or indeed maintainable for much longer. 500 academic posts were frozen. The consequences, the lucidly-written report points out, are "a staff distribution growing increasingly at variance with student distribution; lack of new appointments [for] promising young graduates, and failure to develop new areas of study which should be their province". Mobility is being blocked as tenured staff cling to their posts.

Building programmes, apart from those to bring medical student numbers up to 4,100 by 1979 and those to house computers, are almost at a standstill. Nothing was done for libraries, twelve of which already have proposals for expansion and another ten of which are expected to look for expansion soon. More radical proposals to alleviate library problems are likely soon.

One trend which took UGC by surprise was that a number of universities want to start new courses in food science and technology, and nutrition. The UGC wasn't convinced that there was that much need, but it might do a bit more enquiring, as those in food seem to say the opposite.

A disturbing aside to the report was that students are now arriving at universities well-motivated, with good paper qualifications but lacking some of the basic skills. Modern languages, science and technology seem to be the worst sufferers, and remedial courses are taking up valuable university time. The reasons are complex, no doubt; the lack of well-qualified school teachers, failure of universities to respond to curriculum changes in schools, too much froth and not enough staple diet in some school courses—these are all likely contributors. The Education and Science Minister himself appealed to school heads just last week to try and boost by a tenth the numbers of students with A level passes in science and maths going to universities.

● Discouraging news for the UK fishing industry. In spite of the British Trawler Federation's pressures, which have already led Foreign Secretary James Callaghan to protest in Brussels about the inadequacy of the 12-mile national fishing limit called for by the EEC Commission, it has become clear that the industry is not going to get the 100-mile limit it wants.

Facing the Select Committee on Secondary European Legislation last week Mr Callaghan's junior Minister, Roy Hattersley, left no room for doubt that UK negotiations with her European partners would not be aimed at achieving such a broad exclusive zone within the proposed 200-mile community strip. Neither Mr Hattersley nor the junior minister at Agriculture, Fisheries and Food, Ted Bishop, felt compelled to comment on speculation that the UK will press for a 35-mile national limit.

What is certain is that Britain will not use her veto to reject the Commission's proposals. Mr Hattersley told the committee that the real problem was rather whether her partners could be dissuaded from using their vetoes to block British pressure for an adapted Common Fisheries Policy. The British view is that adaptation is crucial because, while apparently hamstrung over exclusive limits by obligations under the Treaty of Rome, her industry feels that it will lose more than other EEC members if the Commission's call for national quotas based on past catches is adopted. The practical uncertainties surrounding the effective policing of an eventual agreement add to the complications.

● The Secretary of State for Energy, Anthony Wedgwood Benn, who last week withdrew from the battle for the Labour Party leadership, is continuing his fight to introduce a long-term energy strategy for Britain. He now intends to approach the issues in Britain's energy policy on a wider front, and plans are under way for a meeting in June or July, when it is hoped that several major international oil companies will line up with management and union representatives from the newly-formed British National Oil Corporation and the other nationalised energy industries. ●

INDIA

Becoming well oiled

India is increasing its investment in oil, and the aim is self-sufficiency. Our correspondent in Jullundur reports on a vital aspect of the sub-continent's energy equation

For over two years now, India has been groaning under the weight of her mounting oil-import bill. From around 3,000 million rupees a year before the 1973 Arab-Israeli war it is now running close to 12,000 million rupees—accounting for a third of her entire export earnings and a quarter of the total value of her imports. This is despite the fact that the Government, through a number of fiscal and other measures taken in early 1974, has managed to limit consumption and to curb the rate of growth of demand for oil. These measures remain in force.

Consumption rose in 1975 by only 2.7%, from 21.74 million tonnes to 22.34 million tonnes, the 1974 figure being substantially lower than an estimated 25 million tonnes calculated on the basis of an earlier average annual growth rate of about 9%. Consumption of petrol during 1975, at 1.25 million tonnes, was slightly lower than the 1974 figure of 1.28 million tonnes, despite a considerable increase in the number of powered vehicles in the country; the items contributing to increased consumption of petroleum (and products) included naphtha (14.5%), kerosene (5.5%), high-speed diesel (4.7%), furnace oil (0.5%) and cooking gas (14.3%). The increase in the offtake of naphtha was largely due to better capacity utilisation by fertiliser manufacturing units, while good rains helped dampen demand for diesel for agricultural purposes which was running some 12% higher during the first six months of 1975 compared to the same period in 1974.

India has been meeting only about a third of her oil requirements (including related products) from indigenous sources—mainly onshore wells in the states of Assam and Gujarat. She has had to import the rest from various oil-exporting Arab countries and Iran through bilateral agreements. The Union Petroleum and Chemicals Minister, Shri K. D. Malaviya, recently told the Parliamentary Consultative Committee attached to his Ministry that, because of India's adverse balance-of-payments and foreign exchange positions, the situation regarding imported oil was likely to be very difficult during 1976. Neither was it known how and when OPEC's oil facility for developing countries would be set up, nor when results would start flowing from the ongoing "north–south" conference. The country expected to produce 9.5 million tonnes of oil this year, Shri Malaviya told the committee, and his ministry was making all possible efforts to ensure an import of 14 million tonnes from external sources to meet the country's essential requirements. [It has since been reported that arrangements have now been made for the import of a major part of the crude oil India needs from other countries].

India has passed through a very difficult period but, while she is still not completely out of the woods, pressure seems to have eased somewhat due to an all-round improvement on the energy front. Among other things, coal production has increased enough to wipe out scarcities, and power generation is presently pretty close to meeting all requirements so that power cuts imposed in most states have been withdrawn. While much of the improvement has come through better management and better performance by both man and machine, good and plentiful rains during 1975 have played no mean part in transforming the picture.

For all the havoc it has wrought on the country's economy, the oil crisis has also done a few good things: the Oil and Natural Gas Commission (ONGC) has been stirred into vigorous action and its redoubled efforts to find more oil onshore and offshore are beginning to yield results. From onshore fields in Assam and Gujarat, production this year is expected to be more than 8.2 million tonnes compared to 7.5 million last year. In three to four years' time, according to the Petroleum and Chemicals Minister, the figure will go up to 11 million tonnes.

Production could commence shortly from India's first offshore wells in the Bombay High region. Two developmental wells, along with other installations including submarine pipelines to take oil to the shore, are nearing completion. Production will start at the rate of 2 million tonnes a year by the end of 1976, and will gradually be stepped up to 10 million tonnes by the end of the decade. While the ONGC explores and exploits the Bombay basin, two foreign firms are working on the Bengal and Kutch basins. The very first well drilled in the Bay of Bengal was reported to be oil bearing, raising hopes of further breakthroughs. [The Minister recently announced an oil discovery of "very great significance" at the Bassein structure off the western coast].

In 1974, the ONGC acquired three new vessels, two for drilling in the Bombay High region and a third for seismic surveys in the continental shelf near Madras. The Petroleum Ministry has also set up a "deeper continental shelf" project to explore the 20,000 km region west and north-west of the Bombay High area. Various steps are also being taken to make the country self-sufficient in the manufacture of all types of equipment needed for onshore and offshore exploration and production of oil. The first country-made rig is expected to be available in about two years' time. A variety of oil-field equipment is already being manufactured in India, and its production is being stepped up.

India has also entered into agreements with Iran and Iraq to look for oil in these countries. According to the Petroleum Minister, some 750,000 tonnes of Rustum crude from India's exploration venture in Iran will be brought to India this year.

Before the turn of the century, India is expected to become self-sufficient in crude oil. Some optimists think she could even become an exporter of oil by the year 2000. ☐

Science and religion

If circulation figures of periodicals and journals are any indication, religious subjects continue to score over scientific ones in popularity among the literate population in India, which has the world's third largest scientific and technological community. According to a recent study, there were 927 scientific and technical journals (all languages) compared to 1,221 religious and philosophical ones in the country by the end of 1973, and circulations of the latter went up by more than the former over the decade 1963–1973.

Broken down by language, the figures for the circulation of Bengali, Tamil, Kannada and Gujarati science periodicals showed a downward trend during the decade, whereas those of the religious journals in these languages went up over the same period. Marathi, the language of the state of Maharashtra, had the unique distinction of having more readers of scientific journals than those of the religious ones. Urdu was found to be another language with a distinction—it showed an increase in readership of scientific journals with a simultaneous decrease in circulation of the religious periodicals. In English and Hindi—the two languages with the largest proportion of periodicals on all subjects—readers seemed to prefer religion to science.

IN BRIEF

Group of Thirteen?

The seven nuclear powers who recently agreed terms extending safeguards against the misuse of exported nuclear technology are expected to be joined in their pact by six more nations, reportedly after Soviet pressure to have more eastern bloc countries admitted. Belgium, Czechoslovakia, East Germany, Poland, Sweden and the Netherlands would participate with Britain, Canada, France, Japan, the USSR, the USA and West Germany in an agreement which allows nuclear trade with states outside the Non-Proliferation Treaty. The report follows news that France is planning to sell nuclear reactors to Libya, a major oil producer facing none of the problems of energy shortage.

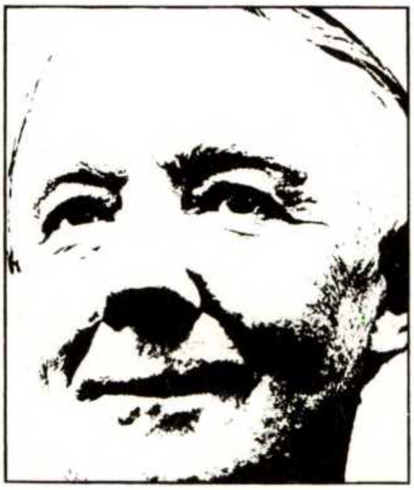
LST refocus

The US House of Representatives last week took the first step toward rescuing the Large Space Telescope (LST) from acute budgetary failure, by passing a bill which authorises the expenditure of $3 million on planning and instrument design for the mission. At the same time, however, the Senate Aeronautical and Space Science Committee approved a bill which, in tune with the Ford Administration's own decision for the coming fiscal year, contains no funds at all for the LST. But the LST seems very likely to get full backing next year.

Shtern support

The case of Dr Mikhail Shtern, the Ukrainian endocrinologist at present serving an 8-year-sentence in a labour camp near Khar'kov, continues to evoke support. On March 24 a petition was published in Paris, signed by 51 Nobel Prize winners, accusing the Soviet government of fabricating charges against him and demanding his release. Ironically, the same day, Dr Shtern, who had made an appeal for clemency on the prompting of the camp authorities that it would be favourably received, was informed that it had, in fact, been rejected.

A hundred years on



KENNETH MELLANBY

The year 1976 is the hundredth anniversary of the passing of the Cruelty to Animals Act, which still controls the way in which painful animal experimentation — "vivisection" — is performed in Britain. There is now considerable pressure to introduce new legislation, partly because of a general feeling that a law made over a hundred years ago must, in some ways, be out of date. Animal experiments have indeed changed during that period. In 1876 only a few hundred experiments were performed each year, and a high proportion involved surgery. Today we make some five million experiments per annum; the majority are to test drugs, pesticides, food additives, cosmetics and other chemicals, and consist of feeding trials which may involve little of the type of "pain" with which the original Act was concerned.

The 1876 Act is unpopular with lawyers, perhaps because it has given rise to so little litigation. It would be cynical to suggest that the lawyers' criticism stems from the fact that so few fees have been earned in this field; their more legitimate complaint is that the absence of decisions by the courts may leave the interpretation of some of the Act's provisions ambiguous. However, the exhaustive deliberations of the Royal Commission set up in 1906, and contained in their report which eventually appeared in 1912, suggested that radical changes were not required. The very thorough report, in 1965, by the Home Office's Departmental Committee on Experiments on Animals (the "Littlewood" report) came roughly to the same conclusion. The Act may not be technically perfect, but it works better than many newer pieces of legislation. Once more there is much to be said for leaving well alone, though the Littlewood proposal for a more effective Advisory Committee, containing lay members, would seem worth implementing without further delay, notwithstanding the apparent opposition of the Home Office.

In my experience most responsible experimenters have a strong feeling that certain potentially painful experiments are seldom if ever justified. This is an ethical judgement, but it may have a scientific basis. Some countries have no regulations to prevent any cruel experiment, and even some states in the USA allow practices outlawed elsewhere. Thus we read of school children inserting electrodes in monkey's brains, and I recently reviewed an American book in which children were instructed how to subject rats and other mammals to noise intensities sufficient to destroy their auditory tissues. It is sometimes argued that the controls imposed by the 1876 Act hold up medical and scientific progress. If this were so, then we would expect striking advances from the regions where ethical controls do not exist. In fact progress has generally been greatest in the laboratories where controls are most strictly enforced.

Some anti-vivisectionists insist that animals are so different from man that experiments on animals are generally inapplicable to human conditions. It is true that, in the end, new drugs and treatments must be tried out on man himself, but without preliminary animal experiments on several species most physicians would be even more reluctant than at present to make these trials. More experiments on man would probably mean doing more, not fewer, animal experiments. In fact there are already many instances where "human guinea pigs", healthy volunteers, are usefully employed, though in a civilised country, except for the often-gruesome experiments done by some scientists on their own bodies, this type of work has been considerably restricted. It is sometimes suggested that important medical problems could be rapidly solved if humans were used without any ethical constraints. This I doubt. We have the experience gained from experiments on prisoners in Nazi concentration camps. Here humanitarian concern was seldom allowed to modify the plans of the scientists, and millions of victims were killed in the name of research. Yet no major discoveries were made. It seems that the brutal scientist is generally a bad scientist, and it matters little whether he works with animals or with man.

If we are to have new legislation, research workers as a whole would welcome it if it only curbed the excesses of the minority of bad and cruel workers, but there is a danger that it might make much productive and valuable work, done under good ethical conditions, impossible.

International transfers

SIR,—The following document is communicated for publication on behalf of the 52 Fellows of the Royal Society whose signatures appear below. No doubt other members of the scientific community in this country and throughout the world will wish to affirm their support for the same principles. Those who share our concern about these matters may wish to know that a Study Group on Scholarly Freedom and Human Rights has been established by the Council for Science and Society (3/4 St Andrews Hill, London EC4V 5BY) to give further consideration to the issues involved. It would be particularly valuable to the work of the Study Group to have further detailed information or well informed opinion from any of your readers.

Yours faithfully,

J. M. Ziman

and M. F. Atiyah, C. H. Andrewes, C. Auerbach, J. F. Adams, J. G. Bolton, J. Baddiley, K. G. Budden, C. A. Clarke, S. Curran, R. E. Davies, F. Dainton, C. D. Darlington, K. G. Denbigh, L. Essen, C. A. Fleming, G. Fryer, G. Herzberg, W. Hudson, A. Haddow (deceased), J. T. Houghton, J. H. Humphrey, W. K. Hayman, A. Klug, A. Kelly, H. Kornberg, O. A. Kerensky, B. Lockspeiser, L. F. La Cour, H. Lipson, J. D. McGee, E. H. Mansfield, J. Mandelstam, K. Mahler, A. Neuberger, J. Needham, L. E. Orgel, A. G. Ogston, M. R. Pollock, J. W. Pringle, W. S. Peart, G. Rochester, A. Robertson, R. A. Raphael, N. Sheppard, G. Series, M. Seaton, M. Swann, M. Szwarc, R. Whittam, M. Wilkins, F. Young.

The following statement is proposed for consideration and adoption by learned societies, academies, governmental bodies and private corporations involved in the practical arrangements for the international transfer of scientific information by written communication and by personal travel. Although not intended to be legally binding, this statement indicates the basic principles by which we consider that particular agreements and actions in this sphere ought to be judged.

International Scientific Communication

The claim of scientific knowledge to universal validity can only be tested and maintained by international intercourse between scientists. All nations which make use of scientific knowledge benefit by the rapid diffusion of information about new discoveries, and by the submission of new ideas to the widest circle of competent critics. The free exchange of knowledge and ideas is fundamental to the health and vitality of science as an enterprise of all mankind.

The individuals and corporate bodies who benefit directly from this intercourse should be bound by certain common courtesies and mutual obligations. Although these courtesies and obligations are normally taken for granted, their neglect or violation can cause much ill will and damage to science as a whole. We therefore believe that there is value in stating the following general principles, which are based upon the experience of communities in which science has flourished in many different historical and political circumstances.

A. Written Communications

1. The published literature of science should be free to circulate, without hindrance or censorship, within and between nations.

2. All efforts should be made to ensure that relevant scientific information published in any one country be made available, as rapidly as possible, in the most convenient form, to scientists and to scientific institutions in all other countries.

3. The originality of published scientific work should be respected throughout the world by fair practices of citation or other attribution.

4. The legal rights of authors and publishers of scientific journals and books should be protected under the International Copyright Agreement.

5. All national scientific communities should contribute to the financial support and management of international facilities for the transfer of scientific information such as abstracting and indexing services.

B. Individual Travel

1. Scientists acknowledged by their colleagues as experts should be free to travel within and between different countries for the exchange of unclassified scientific information.

2. Acknowledged scientific experts making such visits should be given intellectual hospitality in the form of access to open research institutions and to individual scholars.

3. The services of scientific experts from all countries should be made available to assist in the activities of the international scientific agencies.

4. Bilateral financial and administrative arrangements for the exchange of scientists between two countries should not be regarded as excluding or limiting visits arranged by other means.

C. Conferences

1. The appropriate national scientific organisations should be encouraged to participate in open international scientific conferences by facilitating the attendance of well-qualified scientific experts in the relevant subjects.

2. All countries should endeavour to contribute to the material facilities for international scientific conferences by way of hospitality and financial support.

3. Every bona fide participant in an international scientific conference should be accorded freedom of entry to the meeting place of that conference.

4. The expert authority of properly constituted international committees of scientists should be respected in such matters as the choice of participants and speakers at international scientific conferences.

Genetics at the OU

SIR,—The article by Professor Steven Rose on the new genetics course offered to Open University students (*Nature*, **259**, 437; 1976) is misleading. In particular, it does not refer to the existence of a Consultative Committee, of which we are members, appointed by the Nuffield Foundation to advise on the development of the course, and to the sharp disagreement between that committee and Professor Rose about the suitability of the materials now being distributed for use by students at large but also by Open University students.

The Joint University Genetics Course was launched in 1973 with a grant of £20,000 from the Nuffield Foundation with the objective not merely of developing an outstanding course in genetics but also of proving a mechanism by which the Open University and other universities might collaborate in the development of educational materials. At the same time the Foundation appointed a Consultative Committee to advise the course team on academic matters and to advise the Foundation on the progress of the work. Apart from members of the course team, the committee included Professor D. Lewis (University College, London) as chairman of the committee, Professor W. Bodmer (University of Oxford), Professor J. Jinks (University of Birmingham), Professor D. Jones (University of Hull), Dr H. Kacser (University of Edinburgh), Professor R. H. Pritchard (University of Leicester) and Professor J. Sang (University of Sussex). In March 1974 the total amount of the grant from the Nuffield Foundation was increased to £88,000.

At the end of 1975, nearly three months before Professor Rose's article appeared, the committee informed the Nuffield Foundation that it was dissatisfied with the outcome of the previous three years' work and asked that the course should not be published, or even used by Open University students, without further consideration, restructuring and amendment. The Nuffield Foundation has informed the Open University of the committee's discontent but no agreement has yet been reached between the Foundation and the University.

The length and depth of the course was thought to be far beyond the capacities of the intended students. The Open University states that the study time for the average "unit" is 12 hours. Furthermore, these 12 hours must be completed, on the average, in one week since the course is a half-credit. This, for a part-time student, means a minimum of two hours daily study after normal work for the whole of the academic year. It is also a *second* level half-course. It was the committee's considered opinion that this is an impossible task if understanding at a university level is aimed at. In their experience, the course, as it stands, would be a demanding one for full-time students having no second half-credit to cope with and enjoying much greater academic support than Open University students. The committee suggested that the university should cut the course in half or offer two alternative (half-) courses.

In spite of the original remit to write a course which is suitable for other than Open University students, the Consultative Committee has not been presented with any evidence that this problem has been seriously considered. One of the principal claims for obtaining support from the Nuffield Foundation was that it was not a purely Open University exercise but that other institutions would benefit equally. It is extremely doubtful if this objective is in any way near realisation. (One of the obvious deficiencies of the course soon to be offered for general sale is that the practical manual that students at universities other than the Open University will need has not been published, or even written.)

The Consultative Committee jointly with the Nuffield Foundation suggested a number of changes which would have gone some way to meet these criticisms, but they were not accepted by Professor Rose.

It is not appropriate to comment at length about the many doubts and criticisms which the committee had both about the nature of some of the units and the manner in which the course was produced. Suffice it to say that it is the opinion of the committee that the adherence to a timetable, set down before the magnitude of the problem was appreciated, made it almost mandatory that no fundamental thinking could inform the writing of the course. We have sadly come to the conclusion that a great opportunity has been lost in making use of the generous provision of the Nuffield Foundation.

Yours faithfully,

Birds on the Chagos Bank

Sir,—The Great Chagos Bank, 6°15′S, 72°E is all that remains of a once gigantic atoll. The dry land now consists of eight small islands set on the rim of the atoll and an outlying group of six other islands collectively called Egmont. Together they constitute a terrestrial habitat of only 828 ha, of which Eagle and Egmont Islands make up 80%.

Records indicate that at some time between 1813 and 1937 all the islands came under the influence of the copra industry. Only Nelson island was left in its "natural" state which included colonies of nesting sea birds, the eggs of which were collected to supplement the diet of the copra workers on the nearby Salamon group.

Recent surveys show that:

- on all the islands broad-leaved forest is beginning to replace the coconut plantations;
- on all islands other than Eagle and Egmont there are large populations of nesting sea-birds, numbering in total more than 100,000 pairs—dominantly terns and boobies, but including 15 species in all;
- on Eagle and Egmont there are feral brown rats and only a few hundred birds; the vegetation is, however, similar to that of the other islands.

In order to realise the full potential of the island group to nesting seabirds we suggest the removal of the rats from Egmont and Eagle Islands using a combination of methods such as "warfarin" and Liverpool virus. The islands are remote from any large centre of population and are rarely visited. Such action could allow the already overcrowded bird colonies on the local islands to expand and new species to move in from further afield. For instance, pairs of Abbots Booby were seen in the vicinity of the islands on two occasions. This is the rarest of the Indian Ocean's gannets, whose only contemporary nest site on Christmas Island is threatened by development and ecological change.

We estimate that if such action were successful the total nesting population of birds in the area could rise to in excess of 0.5 million pairs.

We are planning, subject to legislative approval, to attempt to exterminate the rats on Egmont and Eagle Islands in early 1977. We invite comment on the desirability and feasibility of this course of action.

Bugs Bunny

Sir,—Schedule 1 of the Conservation of Wild Creatures and Plants Act 1975, passed recently by the UK Parliament, provides the best way of giving full protection to any animal whose survival is threatened. To be included an animal must be given a common and a scientific name ("Naming the Loch Ness Monster", *Nature,* **258,** 406; 1975). Thus, after ten years of searching, we would like to present the evidence on which we base our description and naming of the "Model E Rabbit".

The best photograph shows the head of the rabbit obscuring the DNA bands of an analytical caesium chloride gradient (below). This gradient was run in a Beckman Model E Analytical Ultracentrifuge (Wells, R., and Ingle, J., *Pl. Physiol., Lancaster,* **46,** 178–182; 1970), and the rabbit must have obscured the light path while the plate was exposed.

We feel that previous failure to observe these rabbits, for surely there must be a breeding population, is due to their shy and retiring nature; the DNA on this occasion was from cucumber hypocotyls and their inordinate fondness for these may have led to this rash exposure.

In the interest of protecting this rare and endangered species we have decided to name it *Oryctolagus barbifugenter* because of the curious and distinctive beard-like structure characteristic of the species and because the animal so readily flees from view. It has been pointed out to us that this binomial is an anagram of "Centrifuge laboratory bugs", but this is thought to be entirely coincidental. We hope for the support of the World Wildlife Fund in our efforts to preserve and study this unique rodent.

How far does pollen travel?

from Peter D. Moore

POLLEN grains contain the male gametophyte generation of flowering plants. They are rendered mobile by such forces as wind, water or insect vectors, and the distances which they travel determine to a large extent the degree of gene movement between populations of a species. It is therefore of considerable interest to a geneticist to establish how far pollen of a particular species is dispersed. Such a knowledge is also of value to the palaeoecologist, who is concerned with the interpretation of fossil assemblages of pollen grains in terms of the vegetation which gave rise to them; reconstruction of past vegetation can be considerably aided by information regarding the dispersal potential of different species.

The distances moved by pollen grains depend on their density and aerodynamic properties, which vary from one species to another. Erdtman (*Handbook of Palynology*, Munksgaard, Copenhagen; 1969) has estimated the settling velocities of various types of pollen grains from the air and has obtained such values as $3\ \mathrm{cm\ s^{-1}}$ for *Pinus*, $1.6\ \mathrm{cm\ s^{-1}}$ for *Alnus* and $0.9\ \mathrm{cm\ s^{-1}}$ for *Juniperus*. These three species are wind pollinated and one might suppose that a low settling velocity will be accompanied by a high proportion of the grains produced by a plant being transported over long distances. Precise correlation studies are complicated by the fact that some species produce far more pollen per individual than do others. The local surroundings of the pollen-producing plant will also have an important influence both upon the amount of pollen produced and upon the distance which it is likely to travel. The hazel, *Corylus avellana* for example, flowers far more abundantly on forest edges and in clearings than it does when enclosed by a woodland canopy. Tauber (*Proc. Congr. Int. Assoc. Quatern. Res.*, **7**, 131; 1967) has also demonstrated that plants surrounding the pollen-producing individual act as a filter. Pollen grains become impacted upon solid obstacles in just the way that snow adheres to tree-trunks and hence their dispersal potential is reduced. This filter acts in a differential manner, for large grains are more easily impacted than small ones. The height above the ground at which the pollen is released will also influence the distance over which it is likely to remain airborne.

In the case of wind-pollinated species, the atmospheric turbulence patterns are also of crucial importance in determining dispersal and Tauber (*Danm. geol. Unders.* **IIR 89**, 1; 1965) has devised a detailed model of pollen transport above and below woodland canopies, which takes into account the low wind speeds found within tree canopies and the slightly raised wind speeds within the trunk space. Some canopy-produced pollen will be incorporated into air masses moving at higher speeds above the woodland shelter and this may be carried considerable distances. Tyldesley (*New Phytol.*, **72**, 175; 1973) has recorded the pollen of trees, mainly birch and pine, on the Shetland Islands in densities of up to 30 grains $\mathrm{m^{-3}}$ of air. The movement of air masses before collection suggests that these could have been transported from Scandinavia. Similarly, Moar (*New Zealand J. Bot.*, **7**, 424; 1969) has reported the pollen of *Casuarina* in surface samples from New Zealand, when the nearest plants of this genus grow in Australia. On the basis of aerial transport studies on pollen in Canada, Christie and Ritchie (*Naturaliste Canad.*, **96**, 531; 1969) come to the conclusion that the mean life of pollen grains in the troposphere is about three days.

It is difficult to assess the importance of such long-distance pollen transport mechanisms to the process of gene flow. Since only a very small proportion of pollen grains produced is likely to be carried very far, one assumes that these grains are of little functional significance. Yet Mason (in *Genetics, Palaeontology and Evolution* (edit. by Jepsen, Simpson and Mehr), 356, New York; 1963) records the invasion of *Pinus muricata* genes into populations of *P. remorata* on the islands of Santa Cruz, over 30 miles offshore. This must have come about as a result of pollen movement from the mainland, hence long-distance pollen transport can be an important vehicle for gene movement.

The study of pollen movement has been rendered difficult by the problem of relating pollen grains, once dispersed, to the producer individual. The process of gene movement itself has proved a useful indicator of pollen dispersion, for example in the studies of rye grass, *Lolium perenne*, by Griffiths (*J. Agric. Sci., Camb.*, **40**, 19; 1950). Such studies have shown that wind-pollinated species have a pollen dispersion pattern which is leptokurtic; this distribution pattern resembles the normal distribution, but frequencies fall more rapidly on either side of the mode (see Proctor and Yeo, *The Pollination of Flowers*, 262, Collins, London; 1973). Wright (*J. Forestry*, **51**, 114; 1953) has expressed the dispersal capacity of certain trees in terms of the standard deviation of their leptokurtic pollen curves.

The use of radioactive labels on pollen grains has been attempted. Colwell (*Am. J. Bot.*, **38**, 511; 1951) tagged the pollen of *Pinus coutteri* with $^{32}\mathrm{P}$ and collected dispersed pollen in open Petri dishes for counting. He showed that the bulk of the pollen released was deposited within 10 m. Chamberlain and Chadwick (*Ann. appl. Biol.*, **71**, 141; 1972) have applied tracer techniques to the study of pollen impaction on solid objects. The usefulness of such techniques for the study of pollen dispersal in the field, however, is limited by the environmental hazards involved.

In this issue of *Nature* (page 422), Handel describes the use of neutron activation analysis in an experiment to determine the extent of pollen dispersal from two species of *Carex* in a woodland habitat. A solution of samarium oxide was injected into male spikelets and the day after pollen was shed, female spikelets from the same and from neighbouring plants were collected. When samarium is bombarded with neutrons it is converted into europium, ^{153}Eu, which emits gamma rays which can be counted. In this way, samarium-containing pollen can be located accurately. The results obtained obey the characteristic leptokurtic distribution, and show that very little pollen of either species tested is carried beyond 1 m, although the species with the taller culm (20 cm as opposed to 12 cm) does have better powers of dispersal. The very small distance travelled by the pollen of these understorey herbs confirms what has been assumed about pollen movement beneath tree canopies. It also suggests that there must be a limited flow of genetic material between isolated individuals or populations of such species in woodlands, even if they produce copious pollen, depend upon wind pollination and have a tall culm.

The technique of neutron activation analysis in pollen studies offers considerable opportunities. The field is now open for the study of pollen movement from canopy species, the precise influence on dispersal of impaction on tree trunks, pollen dispersal from clearings and woodland edges and also the movement of pollen in insect-pollinated species. The technique, given the basic equipment, is fast and accurate and lacks the environmental hazards associated with radioactive labels. We can now await a flow of new data which will be of value to geneticist and palaeoecologist alike. □

Hominid remains from Hadar, Ethiopia

from our Palaeoanthropology Correspondent

ALTHOUGH fossil-bearing deposits in the Hadar region of eastern Ethiopia have been explored only since 1973 it is already clear that this area is of extraordinary importance. As two recent papers indicate (*Nature*, **260**, 289, 293; 1976), extremely favourable depositional conditions have allowed the preservation of many fossil specimens, even crocodile and turtle eggs, in a virtually complete state. This is an almost unique situation for Plio–Pleistocene deposits in Africa. Moreover, appropriate geological materials are available for chronometric dating of the sequences and although the absolute dates obtained so far are not entirely satisfactory, this problem should soon be resolved. Available information indicates that the hominid sites in the Hadar area are between 2 and 4 million years.

As reported in last week's issue, fossil material from approximately 17 hominids has been recovered from sites in the Hadar region. Of these, one of the most significant is AL 288, a partial skeleton recovered from the younger levels of the sequence. The partial skeleton is of a very small hominid which bears many similarities to the australopithecines from Sterkfontein, in South Africa. Certainly one of the most interesting aspects of this individual, from information available so far, is the direct indication of limb proportions in this early Pleistocene hominid. Estimates of upper and lower limb proportions have been made previously but never on virtually complete bones from a single individual. The ratio of humeral/femoral length in AL 288 is 83.9; living *Homo sapiens* has a mean of approximately 73. By comparison, among the living great apes *Pan*=102, *Gorilla*=116, *Hylobates* =113 and *Pongo*=135. (Schultz, *Hum. Biol.*, **9**, 1937). Thus, although the length ratio of AL 288 is somewhat above the human mean it is distinctly lower than that for the living great apes. Such a relationship has been expected, especially in view of the long humerus from East Rudolf (Leakey, Mungai and Walker, *Am. J. Phys. Anthrop.*, **36**, 1972) and the long ulna from the Omo River area just to the west of Hadar (Howell and Wood, *Nature*, **249**, 174; 1974). These data clearly indicate the essential man-like body conformation of AL 288. This is of particular interest in view of Oxnard's recent claim (*Nature*, **258**, 389; 1975) of the orang-like morphology of the australopithecines. This new information on limb proportions, along with the clear evidence of erect bipedality in the morphology of the pelvis, femur and knee joint does not lend support to such an assertion. Moreover, it indicates that computer-oriented analyses on single bones, however sophisticated the statistics, may be of somewhat limited value in determining morphological and functional affinities of fossil material. This is especially true when, as Oxnard recognised, the functional pattern of the fossil specimen may have no modern parallel.

Of additional interest in these papers is the report of two palates (AL 199 and AL 200) which Johanson and Taieb claim resemble other material referred to as *Homo erectus*. This material is from the lowest stratigraphic unit known to date in the Hadar region; if the data on the Kadada Moumou basalt is confirmed then this material would pre-date 3 million years. This possible early occurrence of *Homo erectus* is of particular interest since the re-dating of the KBS tuff in the East Rudolf area (Curtis *et al.*, *Nature*, **258**, 395; 1975) would suggest that the early members of the genus *Homo* in that area are little more than 2 myr old.

Results of field work in the past few years have made it clear that at least two forms of hominid co-existed in east and possibly South Africa in Plio–Pleistocene times: one, a less advanced form usually called *Australopithecus* (or *Paranthropus*) and a more advanced form, *Homo*. This picture has achieved additional confirmation from the new material recovered at Hadar. The complexity of the fossil evidence at East Rudolf has led Richard Leakey to suggest a possible total of four hominid lineages there (*Nature*, **248**, 653; 1974) and Johanson and Taieb, in the present paper, suggest possibly three at Hadar. Whatever the total number of contemporaneous hominid taxa in this area, it is clear that we are not seeing a simple and orderly progression of ancestor–descendant populations. The most economical interpretation of this diversity is that the early hominid line, once it had come to occupy the forest-margin/savannah ecozones, experienced a number of radiations and adaptations to this habitat. Such adaptive radiations are common during the initial occupation of a new habitat zone and serve to fit the immigrant populations to the available new niches. The molecular evolutionists, who have postulated a relatively recent origin for the family Hominidae, have made palaeontologists somewhat reluctant to talk about a great time depth for the hominids. But that is exactly what this Plio–Pleistocene diversity indicates. Such diversity, with two or more lineages, clearly suggests considerable antiquity for the human line, with splits having occurred in different places, at different times and in response to different environmental situations. Perhaps the appropriate question, however, in the face of such apparent diversity is not how many hominid lineages have existed but how many hominid econiches are available in such a habitat? □

Sociobiology: a new synthesis and an old quarrel

from Robert M. May

One of the most notable books published last year was *Sociobiology: The New Synthesis* (Belknap, Cambridge, Massachusetts; 1975), by Edward O. Wilson. This massive work aims to draw together a growing body of field and laboratory observations on animal behaviour, and combine it with insights drawn from population biology and ecology, to yield an understanding of how different social systems have evolved. Sociobiology is Wilson's term for this systematic quest for an evolutionary explanation for all forms of social behaviour. Both explicitly and implicitly the book calls attention to some of the major unsolved problems: this is indeed Wilson's main aim, which would be described more accurately if the title read *Towards a New Synthesis* rather than *The New Synthesis*.

Evolution of social systems

The fundamental principle guiding this sociobiological enterprise is that an organism's evolutionary success is measured by the extent to which its genes are represented in the next generation. One road to such success is for the individual to evolve characteristics (strength, speed, camouflage, a well advertised nasty taste or the misleading mimicry of something else's advertisement) which help it survive long enough to reproduce; these relatively straightforward considerations have provided the focus for most investigations of evolutionary ecology. For many animals there are, however, advantages (such as greater foraging efficiency, or defence against predators) in living groups. Once this happens, the social structure of the community, and the behaviour of individuals within it, themselves become subject to selection. Social systems thus evolve to maximise the genetic fitness of individuals in specific environments.

If the social system is sufficiently close-knit, an individual may enhance its genetic contribution to the next generation by the apparently altruistic act of sacrificing itself in order to help its kin. An extreme example is provided by the sterile worker castes in insect societies; here recent work by Hamilton and by Trivers and Hare has produced quantitative insight into the organisation and evolution of the social insects (see *Nature*, **260**, 9; 1976).

The behaviour of birds and mammals is less stereotyped than that of insects, and elucidating the evolutionary basis of their social structure is correspondingly a more complicated and ambiguous task. Nevertheless, with the growing tendency towards long-term, analytical field studies of individual animals whose consanguinities and social histories are recorded, much progress is being made.

Consider, for example, the studies by Schaller, Bertram and others on the Serengeti lion (for example Bertram, *Sci. Amer.*, **232**, (5), 54–65; 1975). Roughly speaking, the typical female lion spends her life as a member of the pride into which she is born, and may live about 18 years. In contrast, male lions leave or are ejected from the pride at puberty, and they will usually enjoy a later brief tenure of 2–3 years, typically along with one or more brothers, as the only adult males in another pride: the more brothers sharing the rule, the longer the tenure. It seems that, soon after taking over a pride, the new males kill the resident cubs. Since the females tend not to produce a new litter until the previous cubs are 20–30 months old (which time is of the same order as the males' expected tenure as owners of the pride), and since the new males usually share no genes with the pre-existing cubs, the males' inaugural act of infanticide is adaptive from their point of view, although it is certainly not in the females' best interest.

This is a particularly brutal example of the tensions between male and female interests which arise in diploid systems when parental care is important, as it is among birds and mammals. A female's genes are represented directly only in the offspring she herself produces, and so it tends to be in her interest to care for them (at least until they begin to be able to look after themselves, whereupon at "weaning" a parent–offspring tension arises because it is in the child's interest to continue to enjoy parental care, whereas the mother will do better to turn attention to producing a new litter). A male's genes have a chance of direct representation in the progeny of every female he inseminates, and in some circumstances his genetic input into the next generation will be maximised by striving for copulations with many females (even at the expense of evolving otherwise maladaptive ornaments, and at the risk of injury in fights with other males), and giving no help in raising the children. In short, in many situations there is a built-in tendency for females to focus on ecological resources such as food and nesting sites, and for males to focus on females.

Mating systems

These notions, when combined with the ecological details of particular environments, help explain the bewildering diversity of mating systems observed in bird and mammal societies: monogamy; polygamy (either as polygyny, one male with several wives, or as polyandry, one female with several husbands); promiscuity. In some situations raising offspring is necessarily a two-person job, leading to monogamy. Monogamy is the rule among birds (92% of all bird species are monogamous), and is uncommon among mammals, where the mother suckles the young. In environments where resources are very unevenly distributed, it may pay a male to devote much energy to defending a good territory, and it may pay a female to share that territory with other wives rather than have exclusive partnership with a male who owns inferior real estate; this leads to polygyny. Polyandry should be very rare, and it is. When the female is capable of feeding both herself and her offspring, as is the case for most herbivorous mammals, we expect a tendency towards promiscuous mating systems. But carnivorous mothers need help: all raptorial birds are monogamous, and carnivorous mammals tend to have complicated mating systems (such as the lions, above).

When the environmental circumstances dictate that a male should opt for monogamy, and devote his time and energy to help rear offspring, it will be adaptive for him to react violently to the possibility of stolen copulations with his wife. In one series of experiments, Barash (University of Washington) placed a model of a male mountain bluebird near the nest, during the breeding season, while the real male bluebird was temporarily absent: on its return, the male fiercely attacked both the model and its own mate, in one case even driving her away and taking a new mate. Once the eggs had been laid, the male was much less traumatised by this mean trick, and did not attack its mate. This experiment, incidentally, shows how the manipulative techniques that shed so much light on the adaptive significance of animal behaviour cannot blithely be applied when dealing with humans.

Sociobiology summarises many other aspects of animal behaviour and social organisation that can be illuminated by evolutionary thinking. A crisp review of some of this work is due to Kolata (*Science*, **187**, 50–51 and 156–157; 1975). When one comes to the primates (excluding man), social structures become very complicated and diverse, ranging from troops with a complex social organisation (baboons), through nuclear families (white-handed gibbons, with a single mated pair accompanied by up to four immature offspring and an occasional aged male), to individuals who spend most of their lives in solitary fashion (male orangutans).

So far I have touched on 25 of the 27 chapters in *Sociobiology*, which deal with non-human animals. This work constitutes a *tour de force* of synoptic scholarship, and has not been challenged.

Human behaviour

In chapters 1 and 27, Wilson speculates upon the insights to be gained by applying sociobiological thinking to human behaviour and human societies. The social insects, for example, show how extreme forms of altruism can evolve by virtue of kin selection in conjunction with inbreeding. In the absence of any constraints, there is a strong selective advantage in inbreeding coupled with recognition and cooperation among kin. But in relatively complex organisms, such as humans, there is a severe constraint, namely the well documented increase in the expression of deleterious genetic traits as heterozygosity is diminished by inbreeding. Wilson poses the question: how are the gains through inclusive fitness and losses through inbreeding depression balanced? In which life history strategies is this balance struck so as to increase the likelihood of more intense inbreeding and social life? In particular, he observes that in human societies (excepting Faulkner's Yoknapatawpha County) the incest taboo is both universal and has the merit of minimising the occurrence of crippling genetic malformations. He suggests that this universal taboo has adaptive origins, rooted in some gene complex.

In suggesting that pervasive human behavioural manifestations such as spite, indoctrinability or courage may have aspects that are genetically controlled, Wilson is at pains to emphasise that he is not implying "that there exists one gene for spite, another for homosexuality, and so on, as one might envisage the inheritance of flower colour or seed texture in garden peas. The tendency to develop such behaviour, in a distinctively human form, is part of an immensely complex social repertory which is undoubtedly dependent on large complexes of genes" (*Harvard Gazette*, January 16, 1976). Given that the relatively simple and stereotyped behaviour of aggregation in slime moulds is under the control of a complex of about 50 genes (Cox, Princeton University, personal communication), I find Wilson's view plausible. It is, however, clear that direct confirmation, in the form of explicitly identifying particular gene complexes for particular behaviour, is out of the question.

These first and last chapters, with their suggestion that human behaviour

---

Strong fibres

from Paul Calvert

ONE long-standing objective in polymer science is the production of fibres with an elastic modulus (ratio of stress to strain) approaching the theoretical maximum value. It seems self-evident that the structure should consist of polymer chains aligned as closely as possible to the fibre axis with few folds or disoriented regions. Various methods might produce this structure. The natural and most elegant method is exemplified in the production of plant cellulose where polymerisation occurs *in situ* so that fibres grow by addition of monomer units to one end. This has never really been achieved synthetically.

The drawing process used in the production of textile fibres produces chain orientation by stretching the fibre to several times its initial length. Two fibre industry alumni now in universities have worked on modifying this process to produce high draw ratios and orientation and so high moduli. E. S. Clark of the University of Tennessee and co-workers at Du Pont have produced acetal fibres with a modulus of 35 GPa (1 giga pascal= 10^9 N m^{-2}) (*Polymer Engng Sci.*, **14,** 682; 1974). For comparison, carbon fibre has a modulus of 500 GPa and the theoretical maximum modulus of polyethylene is 220 GPa (Frank, *Proc. R. Soc. Lond.*, **A319,** 127; 1970). These acetal fibres were drawn at about 130 °C by a factor of 20 times in a two-stage process. The usual room temperature draw ratio is 7 times. The structure seems to consist of a single highly oriented phase.

I. M. Ward and co-workers at Leeds have studied the dependence of draw ratio on temperature, molecular weight and pre-draw microstructure in polyethylene. They found that the modulus increases roughly linearly to 70 GPa at a draw ratio of 30 times. The draw ratio was a maximum for a sample of high molecular weight and narrow molecular weight distribution crystallised by cooling to 110 °C then quenching to room temperature and drawn at 75 °C (*Polymer*, **15,** 233; 1974: *Nature phys. Sci.*, **243,** 143; 1973). This leaves the question as to whether it is the molecular weight itself or its influence on the microstructure that is important in allowing a high draw ratio.

Barham and Keller (*J. Materials Sci.*, **11,** 27; 1976) have taken up this point and looked at the relationship between modulus, draw ratio and starting structure. They find that the dependence of modulus on draw ratio is the same for a range of pre-draw microstructures. What did change with microstructure was the maximum draw ratio which could be attained. Sheet which had been directly quenched or made from a sample with no low molecular weight polymer could not be drawn past 20–25 times as opposed to 30–35 times. This point is somewhat confused in the paper by the fact that the figure captions are exchanged.

From this Barham and Keller deduce that the low molecular weight chains, which segregate to the spherulite boundaries during slow crystallisation, govern the drawability of the sample. In support of this they say that samples which draw well had a black line around the spherulites when viewed with crossed polars. Presumably this region is liquid at the drawing temperatures and somehow allows large deformations without fracture. This is surprising in that one would expect strong rather than weak boundaries to be necessary.

Finally, mention should be made of the high melting point, high modulus fibres produced by spinning aromatic polyamides and polyhydrazides from strongly hydrogen bonding solvents such as dimethylacetamide–lithium chloride or sulphuric acid in which they form lyotropic liquid crystals. These fibres spun from anisotropic solutions have moduli several times those of fibres spun from similar isotropic solutions and reach 140 GPa. They are reviewed by Carter and Schenk (*Structure and properties of oriented polymers*, edit. by M. Ward), where the industrial significance is evidenced by the fact that most of the important references are to the patent literature. Two fibres, called Kevlar and Kevlar 49 by Dupont, which are based on poly (p-phenylene terephthalamide) look likely to be used in tyre belting and in composites for body armour and aircraft parts.

may have some components which are genetically determined, have aroused some people's wrath. To suggest for example, that the evolutionary considerations which determine the mating systems of mammals and birds have any light, no matter how oblique, to shed on the tensions and asymmetries commonly observed in human sexual relationships is to invite reflexive dismissal as a "sexist".

A fairly typical example of this criticism is a letter in the *New York Review of Books* (November 13, 1975), written by a group of students and professors in the Boston area, in reply to Waddington's favourable review of the book. This intemperate letter begins by putting the book squarely in a historical tradition which runs from the Social Darwinism of Herbert Spencer, through the gas chambers of Nazi Germany, to E. O. Wilson. It continues with a series of selected and re-arranged quotations which form a collector's item for connoisseurs of polemical literature. The substance of this and other criticisms is that by suggesting a genetic component to human behaviour, Wilson is advocating "biological determinism": they fear that in the hands of political demagogues this can be bent to a defence of the *status quo* as the "natural", and therefore correct order of things.

Broadly speaking, the controversy revives the hoary nature–nurture debate. Wilson is suggesting that human behaviour has innate components, and that there are limits to its plasticity, whereas his critics seem to see man as standing apart from the rest of the animal kingdom, being unique in that human behaviour and social organisation have no discernable genetic elements.

Contrary to the tenor of the criticism, nowhere does Wilson say that human behaviour is totally determined by the genes. He emphasises that there is much about human behaviour that is indeed unique, the product of man's intelligence and social institutions. In an interview with the *New York Times* (November 9, 1975); he said "I see maybe 10% of human behaviour as genetic and 90% environmental. Lewontin [a population geneticist at Harvard who is prominent among the critics] would see it as zero % genetic and all environmental".

This, in turn does violence to the critics' position, which is more subtle. As I see it, their position is rather that until genes for behaviour are specifically identified, the discussion is less than definitive; this being so, and since Wilson's speculations can be perverted to evil political ends, they warrant attack. In Lewontin's words, "At present our ignorance on this question is so enormous, our investigatory techniques so primitive and weak, our theoretical concepts so unformed, that it is unimaginable to me that lasting, serious, truths about human nature are possible. On the other hand the need for the socially powerful to exonerate their institutions of responsibility for the problems they have created is extremely strong. Under these circumstances any investigations into the genetic control of human behaviors is bound to produce a pseudo-science that will inevitably be misused." (*Harvard Gazette*, January 16, 1976).

Wilson's reply in the same Gazette is that "We should be especially cautious about closing off an entire area of investigation when it is in its most vulnerable exploratory stage, because of a generalised fear about its possible eventual misuses in political life. Human sociobiology is in that early stage. I realise that its current hypotheses and facts are susceptible to perversion; equally by ideologues on the right or the left, I might add. We should discourage the perversion—but not the subject."

Shifting from defence to attack, Wilson argues that insofar as human behaviour may contain genetic aspects, social programmes which deny this fact do so to their disadvantage. "[Human] evolution took place under conditions which in many cases no longer exist; our moral precepts, and the economic and social systems that flow from them, will have to be directed to the problems of the future... One does not efficiently eliminate injustice stemming from a genetically based human nature by denying the existence of that nature or prohibiting research on it." He stresses that his views on human sociobiology should not hinder legislation towards social reform, any more than the genetic nature of near-sightedness should discourage people from getting glasses.

The attack on Wilson's book seems to me to have been conducted with a certain incivility, and lack of attention to what the book actually says. When human sociobiology finally comes of age, I hope it will explain why people who are moved to passionate concern for the well-being of Mankind (be it in small disputes such as this, or in grand revolutionary or religious movements) behave so harshly to individual examples of the species. ☐

Disturbing the radiation belts

from Kenneth G. Budden

IT has been known for many years that electromagnetic waves from the Earth's surface can enter the magnetosphere and return to Earth. The earliest known and perhaps the most striking example is the phenomenon of whistlers. These were first observed in the nineteenth century (Preece, *Nature*, **49**, 554; 1894) but were not satisfactorily explained until 1953 (Storey, *Phil. Trans. R. Soc. Lond.*, **A 246**, 113). A whistler originates as the electric impulse from a lightning flash and much of its energy is in the audio frequency range. It travels up through the ionosphere into the magnetosphere and is guided along the lines of force of the Earth's magnetic field, so that it returns to Earth near the magnetically conjugate point in the other hemisphere. During its journey through the magnetoplasma it is dispersed in time so that the high frequencies arrive first. Thus, when received on an aerial connected to an audio amplifier, it is heard as a whistle falling in pitch. Later work showed that signals from other terrestrial sources could travel through the magnetosphere in this "whistler mode". Signals of frequency 15.5 kHz from the US Navy's transmitter NSS at Annapolis, for example, were received at Cape Horn (Helliwell and Gehrels, *Proc. Inst. Radio Eng.*, **46**, 785; 1958) both by the whistler path in the magnetosphere and by the more usual path in the space between the Earth's surface and the ionosphere, which at these frequencies is like a waveguide.

In the magnetospheric plasma these audio frequency whistler waves can only travel in directions making small angles, less than about 19°, with the Earth's magnetic field. This was once thought to be the guiding mechanism but it is not enough to account for the observations. It is now believed that these signals travel in ducts of enhanced ionisation aligned along the magnetic field lines. The signals are confined in the ducts in much the same way as the waves inside a waveguide. But even this is not enough to explain the great strength of some whistler signals. Whistlers have been observed to travel back and forth between the northern and southern hemispheres as many as twenty or more times, and sometimes they get stronger as they travel suggesting that the magnetosphere must be acting as an amplifier.

Since about 1958 it has been known that there are trapped energetic particles in the magnetosphere—the Van Allen radiation belts. These are mainly electrons and protons with energies in a wide range from 10 keV or less to 50 MeV or more, which travel in bent helical paths round the lines of force of the Earth's magnetic field. At the latitudes where the lines of force come down towards the Earth and converge the particles are turned back or "mirrored". Thus they are trapped in stable helical paths with repeated mirroring in alternate hemispheres. A line of force of the Earth's magnetic field is described by its distance from the Earth's centre at the highest point, that is, where it crosses the equator. This distance is written LR_e where R_e is the Earth's radius, and we speak of the L value of a line of force. The radiation belts extend up to about $L = 7$ or 8 with two maxima of intensity around $L \sim 1\frac{1}{2}$ and $L \sim 3\frac{1}{2}$. In between there is a minimum or "slot", in the range $2 < L < 3$, which was shown in Van Allen's first map of the radiation belts (Van Allen and Frank, *Nature*, **183**, 430; 1959).

The particles of the radiation belts can sometimes generate electromagnetic waves of audio frequency. These travel in the whistler mode to the ground and are observed as the remarkable rising and falling whistles that Storey (*op cit.*) called the 'dawn chorus'. The particles can give amplification of whistler waves, operating in a similar way to a travelling wave tube amplifier and this is the amplification needed to explain the observed strengths of some whistlers. Emission of radiation from the particles can be triggered by electromagnetic waves and triggering by whistlers and by signals from radio transmitters of very low frequency has been known for many years. Triggering by the harmonics of the 60 Hz electric power system of North America has been observed more recently (Helliwell, Katsufrakis, Bell and Raghuram, *J. geophys. Res.*, **80**, 4249; 1975). Observations were made simultaneously at Siple in Antarctica and at Robertval, Quebec which is near the aluminium smelting plant at Arvida which uses roughly 1,000 MW at 60 Hz. The rectifiers generate high harmonics, up to about the 90th, that is about 5 kHz, which enter the magnetosphere and trigger emission at other frequencies. The triggering is believed to occur mainly over the equator. The triggered emissions travel to Earth in the whistler mode and can be observed at Siple.

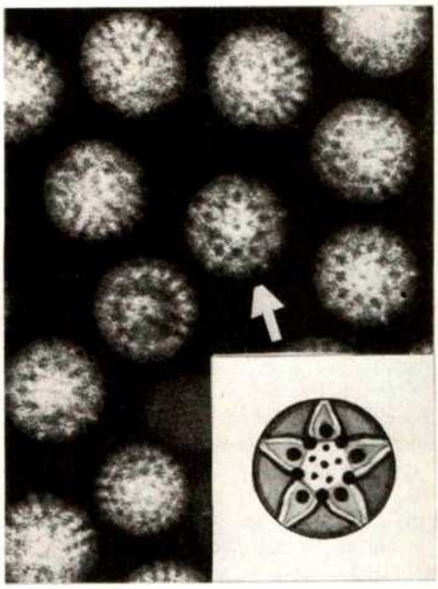
Electromagnetic waves can, in turn, influence the particles of radiation belts so as to change their orbits. One possibility is that the pitch angle of a particle's path is decreased, so that it is made to move more nearly parallel to its guiding line of force. This means that its helical path is more open and it can penetrate further down towards the ground. Then, for many of the particles, mirroring does not occur. They are "precipitated" into the Earth's lower atmosphere, and the radiation belts are correspondingly depleted. Dungey (*Planet. Space Sci.*, **11**, 591; 1963) suggested that electromagnetic signals from the Earth might modify the radiation belts in this way, and there was speculation as to whether the electron slot in the range $2 < L < 3$ could be explained by this mechanism.

A recent study of emissions, mainly in the audio frequency range, made with the satellites Ariel 3 and 4, has greatly strengthened this possibility (see Bullough, Tatnall and Denby, page 401 in this week's issue of *Nature*). The analysis shows that harmonics of the 60 Hz power system in North America might contribute appreciably to the precipitation of particles. VLF radio transmissions from NAA (Maine, 17.8 kHz) and GBR (Rugby, 16 kHz) may also play a part. But thunderstorms in the American and African continents deliver a very large amount of electromagnetic energy into the magnetosphere, and further observations and analysis will be needed before we can be certain that the man-made sources of energy are really significant. ☐

The importance of being rotavirus

from June D. Almeida and Arie J. Zuckerman

LATELY there has been considerable interest in the characterisation by direct electron microscopy of viruses in faeces (see *Nature*, **254**, 557; 1975). Recent publications report reovirus-like agents in stools (Kapikian *et al.*, *Science*, **185**, 1049; 1974), infantile gastroenteritis virus or IGV (Newman *et al.*, *Nature*, **258**, 631; 1975), duovirus (Bishop *et. al.*, *Lancet*, **ii**, 1281; 1973), rotavirus and orbivirus (Flewett *et al.*, *J. clin. Path.*, **27**, 603; 1974). To the uninitiated it might seem that there has been a vast increase in the number of virus types to be identified in acute gastroenteritis. Closer examination reveals, however, that each of these descriptions concerns the same virus, which is now associated with acute diarrhoea in the human infant, the calf, the mouse, the pig and the foal. The outstanding feature of this virus is its morphology and at least three of the terms suggested are based on this morphology. Duovirus refers to the double-shell construction, orbivirus to its overall circular appearance and rotavirus refers to the spoke-like outer projections which give it a distinctive wheel-like appearance. It now seems that under certain circumstances the same virus can reveal a distinctive star-like pattern which is shown in the figure and interpreted in the inset diagram. The structure illustrated was obtained from a specimen of faeces from a calf with diarrhoea. The titre of the particles was particularly high, estimated as being in the order of 10^{11} particles ml^{-1}. Rotaviruses consist of two concentric capsids each built up from distinctive, geometrically arranged subunits. The star-like morphology demonstrated may be a superimposition pattern formed by the interaction of these two structures. On the other hand, it may be that the stellate form shown in the figure is the intact form of this virus, and the ability to distinguish two components implies that breakdown has occurred.



A group of rotavirus particles from a calf faecal homogenate. The majority show the morphology associated with this virus type and both complete and incomplete forms are present. In addition there are two particles showing the star arrangement described. ×225,000. Inset, diagrammatic representation of the stellate particles based on the detail present in a number of them. To be compared with the arrowed particle in the main micrograph.

This finding suggests that the situation could be further confused by the name astrovirus, one already used for gastroenteritis viruses by Madeley and Cosgrove (*Lancet*, **ii**, 451; 1975) or even stellavirus. But rather than introduce yet another name for this already terminologically overladen group it seems better to fit this new morphological finding to an existing term. The diagramatic inset emphasises a certain similarity between the new morphological feature of this virus group and a mediaeval "wheel of fortune". Thus two separate aspects of this virus group exhibit a wheel-like appearance, in turn suggesting that the term rotavirus may well be the most appropriate for this group which seems to move in wide circles throughout the animal kingdom. ☐

Peaks and valleys in morphogenesis

by Miranda Robertson

A symposium on Polarity and Morphogenetic Fields was held at the Hubrecht Laboratory, Utrecht on March 4–6, 1976.

THE main obstacle to progress in understanding polarity and morphogenesis in embryos is the elusiveness of morphogens. One of the latest to confront the problem is Bruce Alberts, working in Lewis Wolpert's laboratory at the Middlesex Hospital Medical School on sabbatical leave from Princeton and DNA replication. He is attempting to isolate the morphogen from the polarising zone of the chick limb bud—an approach which Wolpert, concluding the Symposium, compared to a direct assault on Everest without oxygen. Wolpert belongs to a school which, feeling ill-equipped to scale the heights, has elected to tackle the foothills by constructing physically plausible theories to account for morphogenetic phenomena at the cell and tissue level —and thus elucidate the principles of morphogenesis rather than try to elucidate its molecular mechanism.

The predictive power of one such theoretical construct has been tested by Harold MacWilliams (Albert Einstein College of Medicine, New York), in an experiment aimed at distinguishing between Wolpert's theory of polarity and morphogenesis in *Hydra,* and that of Alfred Gierer and Hans Meinhardt (University of Tübingen).

Wolpert postulates two gradients, one activating and the other inhibitory, both with a source at the head end. The Gierer–Meinhardt model is more complex. It too is based on gradients, giving short-range activation and long-range inhibition of head formation; but it involves a further gradient, in activator source density. In the concrete metaphor used by MacWilliams, source density could be the density of cells synthesising activator, and the short-range activation gradient the concentration of free activator. The pattern of these gradients re-establishes itself after experimental perturbation. But the theory predicts that regulation involving changes in the activation gradient be quicker than those which depend on changes in source density. By means of grafting experiments, MacWilliams has been able to compare the time taken by putative high-source regions and putative high-activator regions to regulate down to the same level of activation. In his experiments, the latter took 12 hours for an adjustment that took the former forty. Wolpert's simpler theory cannot account for this result.

Most of those present at the symposium probably accepted that polarity originates in interacting gradients. Brian Goodwin (University of Sussex) offered an alternative based on work with the large single-celled alga *Acetabularia,* in which polarity seems to reside in the membrane sheath. When the cytoplasm of an isolated section of stalk is removed, homogenised and returned, the cap regenerates with the same polarity as before. Moreover the polarity of the cell corresponds to a gradient of phosphate incorporation on the inner side of the membrane, and exposure to a calcium/magnesium ionophore, which reversibly inhibits differentiation, also abolishes the phosphate gradient. Goodwin would like to attribute the phosphate gradient to a propagated wave of action potentials which can be recorded from an external microelectrode. He has suggested a graded "memory trace" in the form of a graded deposit of material left by a propagating wave to explain the establishment of polarity in multicellular animals. But as he acknowledged, there is no evidence for a causal relationship between the wave and the gradient in *Acetabularia.*

To objections that the origin of polarity in a single-celled organism may be irrelevant to multicellular ones, Klaus Sander (University of Freiburg), chairing the session, responded that all embryos develop from a single egg cell. To explain his own results with insect eggs, however, he has joined the majority in postulating gradients rather than propagating waves.

Sander has shown that the antero-posterior polarity of the chironomid midge *Smittia* can be partly reversed by centrifugation, local ultraviolet irradiation, or even a pinprick at the anterior pole of the egg. This can produce embryos with mirror-image duplication of the abdomen instead of a thorax and head.

This pattern was explained by Meinhardt in terms of the Gierer–Meinhardt theory of short-range activation and long-range inhibition. The effect of disrupting the egg is to allow the inhibitor level to drop, creating a second activation peak. The change in slope of the gradient explains the reversal of polarity. But which sequence of segments is specified depends on the gradient level at the point when it is interpreted by the cell. To explain the exact patterns produced by insect eggs disrupted at different times, Meinhardt has had to add to the theory an account of how the cells read the gradient level. He suggests that genes are sequentially inactivated, the number of genes inactivated increasing with the height of the gradient; but whereas the gradient level can change rapidly on disruption, it is read relatively slowly and because of sequential inactivation, it takes longer to read high values than lower ones. Since in *Smittia,* the gradient is read from posterior to anterior, disruption can thus cause only the specification of more posterior structures.

This particular formulation however works only for size invariant fields. Pattern regulation in insect eggs and *Hydra* is morphallactic: that is, the pattern re-establishes itself by adjustment of existing tissue, without new growth. Willem Ouweneel (University of Utrecht) and Bruce Carlson (University of Michigan) addressed themselves to the rather different problem of epimorphic growth, which occurs in the regeneration of insect and amphibian limbs, and *Drosophila* imaginal disks.

Lively discussion was stimulated by Ouweneel's account of a recent attempt by Vernon French and Susan and Peter Bryant to draw the data from cockroach and newt limbs, and *Drosophila* imaginal disks under the same theoretical umbrella. The theory was developed by French to overcome difficulties in explaining the reliable appearance of supernumerary limbs in the cockroach if one of the transverse axes of the leg is reversed by left-right grafting. Susan Bryant simultanously and independently arrived at the same explanation for analogous effects in newt limbs. The crux of the theory is that the limb is specified by polar coordinates (the "clock-face" model).

Reversal of polarity of the blastema relative to the stump creates a discrepancy between the positional values of blastema and stump at any given location, and the theory states that that discrepancy is eliminated by intercalary regeneration of a series of values completing the normal sequence by the shortest possible route (Fig. 1). Where the discrepancy causes the regeneration of a complete circle, supernumerary limbs will appear. Polar coordinates

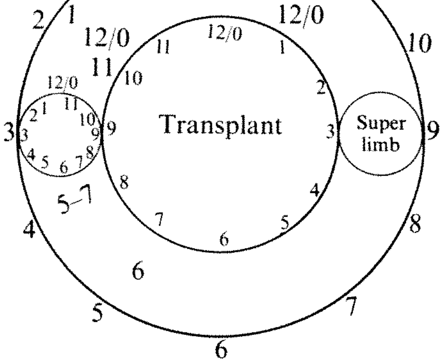


Fig. 1

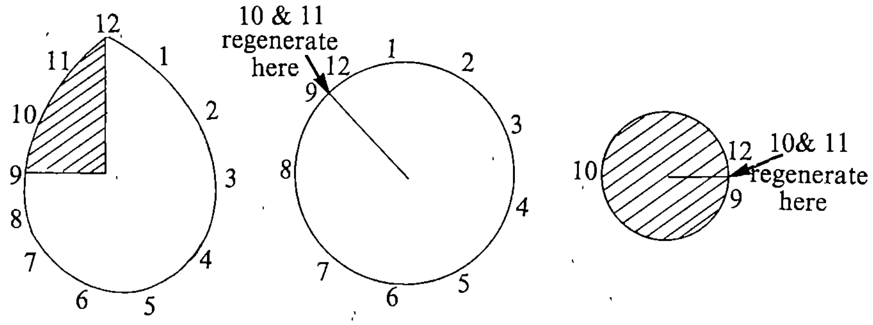

Fig. 2 The wing disk of *Drosophila*. The cut edges of the fragments come together and intercalary regeneration occurs between them.

can also account for the pattern of intercalary regeneration recently reported by Haynie and Bryant for *Drosophila* wing disk (*Nature*, **259**, 659–662; 1976). If a quadrant is removed from the disk and the two fragments allowed to complete their development, the major fragment always regenerates the missing pattern and the minor one always mirror-duplicates the existing one. If the manner in which the cut edges heal is taken into account, intercalary regeneration of polar values accurately predicts this behaviour (Fig. 2). Bruce Carlson's experiments on the regeneration of multiple digits in axolotls give results which however do not entirely conform to the pattern seen in newt blastema. Carlson has explored the effects of rotating separately the different tissues of the stump and finds that the pattern of regeneration is distorted only when mesodermal tissues (muscle or dermis) are rotated. But whereas Bryant finds supernumerary limbs after either antero–posterior or dorso–ventral reversal of the blastema, Carlson obtains multiple digits only from antero-posterior rotation.

S. Strub (Zürich) reported what seems to have been the disruption of the proximo–distal, as opposed to the circumferential, coordinates of the *Drosophila* leg disk by disaggregation of a quadrant of the disk. Such fragments develop entirely distal structures. These are normally specified at the centre of the disk, where French, Bryant and Bryant suggest that the gradient is lowest; but how disaggregation should cause such sinking to a uniform low is not clear.

It was generally agreed that if such puzzles are to be solved by theoretical modelling, the models will have to be formulated in precise quantitative terms, both for the establishment of the morphogenetic gradient and for its interpretation by the cells. Richard Gardner (University of Oxford) pointed out that whereas for example the homoeotic mutants of *Drosophila* could be used to shed some light on the cellular response, mutants affecting the establishment of gradients are unknown. The best that models can do is to provide logically consistent quantitative descriptions of experimental phenomena, as long as the molecular mechanisms of morphogenesis remain inaccessible. It is reported that a British Forces team will shortly attempt Everest without oxygen. □

Inverse square law for gravity?

from a Correspondent

'EVERY schoolboy knows' that gravitational attraction varies inversely as the square of the distance between the attracting masses—or at least it used to be common knowledge. Newton himself first gave strong support to the 'inverse square law' by comparing the rate at which the Moon accelerates towards the Earth with gravitational acceleration at the Earth's surface. He later provided compelling evidence by showing that Kepler's laws for the motion of the planets followed from the same law of attraction—that is, that they would move on ellipses with the Sun at one focus, and the square of their periods would be proportional to the cube of their major axes. Subsequent study of the motion of the planets and satellites has confirmed the truth of the inverse square law at astronomical distances (say from 1,000 km upwards) to a high degree of precision. It is therefore intriguing that in an article by D. R. Long in this issue of *Nature* (page 417), the question of the validity of the inverse square law at laboratory distances has been raised. An examination of the most accurate laboratory determinations of the constant of gravitation, G, suggests a systematic shift with the separation of the attracting masses—the larger the separation, the larger the value of G. In other words, Long suggests that the inverse square law is not valid, and that we have to add an additional short-range repulsion. The experiment reported here confirms his suggestion, by comparisons at distances of 4.5 and 30 cm.

The question of a deviation from the inverse square law has been raised most seriously in 'recent' times by Newcomb, who showed that a small change in the form of the law could explain anomalies in the motion of Mercury. These anomalies are explained naturally by Einstein's General Theory of Relativity, which may be interpreted in a sense as predicting deviations from the inverse square law of gravitation. However, at laboratory distances with laboratory masses, Einstein's theory predicts that the inverse square law should hold to a high precision. Long's suggestion will therefore not meet with ready acceptance. If substantiated, the implications, for example, for our knowledge of the interiors of the Earth and the Sun would be considerable. We infer their masses from our knowledge of the constant of gravitation, and Long's experiment indicates that the limiting values of G at large distances may be several percent higher than is presently accepted. Moreover the implications for a quantum theory of gravity would be serious.

One is tempted to echo the reaction of the bishop's wife to the suggestion that man is derived from the apes—'let us hope that it is not true—or if it is, that it won't become generally known.' More responsibly, we should affirm our willingness to submit theory to experimental proof, and hope that Long's suggestion will stimulate a critical experimental appraisal. He has drawn attention to the remarkable fact that there is no accurate experimental evidence for the inverse square law of gravitation at laboratory distances. By comparison, very accurate null experiments on the basis first indicated by Cavendish have shown that the exponent in the inverse square law for electrostatics differs from two by less than 3×10^{-16} (Williams, Faller, and Hill, *Phys. Rev. Lett.*, **26**, 721; 1971). Can anyone devise an accurate null experiment which will confirm (or deny) the inverse square law for gravitation ? □

Erratum

In the article 'Disappearing habitats' (*Nature*, **259**, 365; 1975) the floral survey mentioned was carried out by Mr and Mrs C. Scotter and not by P. M Wade.

Mason develops Milankovich Ice Age theory

from John Gribbin

ON March 17 Professor B. J. Mason, Director-General of the UK Meteorological Office, delivered this year's Symons Memorial Lecture, in which he presented strong evidence in favour of the 'astronomical' theory of Ice Ages, with his own improvements on the Milankovich model.

Mason's talk, titled "Towards the understanding and prediction of climatic change" covered some familiar ground both at the beginning, where he restated his position in the debate about whether the sunspot cycle and other solar fluctuations affect climate (see *Nature*, **259**, 367; 1976) and at the end, where he stressed the value of computer modelling in our developing understanding of the atmosphere. Professor Mason believes that this is the only way in which we may be able to understand how the climate works although there is a long way to go yet before unique predictions will be possible. In some ways, the centrepiece of the talk was also familiar, at least to readers of *Nature*, in that it dealt with the Milankovich theory of Ice Ages. But Mason presented new, unpublished evidence in support of the theory, and also offered a uniquely persuasive insight into how the energy fluctuations involved could drive both the onset and decline of Ice Ages; it may well be that as a result, March 17, 1976 is remembered as the day when Milankovich's model, after four decades of controversy, at last became established as the leading contender to explain climatic fluctuations with timescales from a few tens to a few hundreds of thousands of years.

The key to this development has been the availability in the past few years, for the first time, of reliable continuous records of both temperature and total ice volume fluctuations covering the past 10^5 yr or more. These are the records obtained by interpreting isotope fluctuations (notably the ^{18}O/^{16}O ratio) in both ice cores and in marine cores containing the remains of small creatures such as plankton. The three separate variations in Northern Hemisphere insolation produced by changes in the orbit and inclination of the Earth have periods (in round terms) of 96,000 yr 40,000 yr and 20,000 yr; all three of these periods (and no others as significant) were present in a power spectrum analysis of the planktonic data which Mason had obtained from N. Shackleton in Cambridge (as yet unpublished). Mason stressed the importance of this link between statistically significant periodic variations and a known physical mechanism, contrasting the situation with that of some of the more short term data where seemingly significant peaks often have no physical explanation, and peaks expected on physical grounds (such as the 11-yr solar cycle influence) often are not significant. With this incentive, Mason has reworked some aspects of the Milankovich model in terms of variations in the amount of heat received at different Northern Hemisphere latitudes in different seasons, using both the original astronomical data of Milankovich and modern improvements on the data. North of 45°N the variations due to these effects cover about 4×10^{18} calorie d^{-1} (1.5×10^{21} calorie yr^{-1}), which is about 1% of the total heat received by the polar cap, and Mason reported that he was "staggered" to find the very exact agreement over the past 150,000 yr between times of minimum insolation and the maximum advance of Northern Hemisphere ice.

Mason says "this is impressive, and the last thing I expected" and that the remarkable agreement encouraged him to look at the integrated effect of insolation variations during periods in which the ice cover advanced and retreated. Again for the region north of 45°N, when ice cover developed during the period from 83,000 BP to 18,000 BP the integrated deficiency in insolation produced by Milankovich variations amounted to some 1,000 calorie for each gram of ice formed using Milankovich's figures, or some 556 calorie g^{-1} with the modern figures. Since the latent heat of the water/ice transition is 677 calorie g^{-1}, the figures are impressive even without allowing for the possibly crucial significance of the fact that the variations in insolation are much greater in summer than in winter.

From 18,000 to 6,000 BP, when the ice was melting, the integrated 'excess' heat received was 4.2×10^{24} calorie on Milankovich's figures and 10×10^{24} with the modern astronomical figures, while the latent heat required for the known decrease in volume of the ice was 3.2×10^{24}; a coincidence which stretches across 24 orders of magnitude to agree so closely is certainly not to be dismissed lightly, and work is now in progress at the Meteorological Office to produce a more detailed model taking account of the capacity of the ocean to act as a reservoir of heat and the feedback mechanisms between ice and ocean. Mason even ventured if not a prediction then at least a comment on future climatic fluctuations, pointing out that we are now shifting from a situation in which the Milankovich effect has produced excess insolation in the North (above the mean for the past 150,000 yr or so) to one in which there is a deficit. Simple astronomical calculations show the dip reaching a Northern Hemisphere insolation minimum in about 10,000 yr, but bottoming out before reaching conditions quite so extreme as those which coincided with the maximum advance of the most recent Ice Age. Many members of the packed audience for Mason's lecture will undoubtedly be eagerly awaiting the full model now being developed by A. Gilchrist and others at the Met. Office; some, no doubt, will now be taking a fresh look at the Milankovich model themselves. Meanwhile, in Mason's words, "this effect cannot be laughed away... certainly all the energy quantities are in the right ball park". □

A hundred years ago

LORD SALISBURY, on Monday, named the following as Commissioners under the Oxford University Bill: —Lord Selborne (Chairman), Lord Redesdale, the Dean of Chichester, Mr. Mountague Bernard, Sir Henry Maine, Mr Matthew White Ridley, and Mr. Justice Grove. The feeling among scientific men is one of intense disappointment, leading to the conclusion that it is useless any longer to consider whether Oxford will ever be in a position to do anything for the promotion of science.

THE report of the Cambridge Board of Mathematical Studies to the Studies' Syndicate contrasts with the reports of most of the other boards in the paucity of its suggestions for improvement. They do not seem to think that very much is required in order to perfect the system of mathematical teaching. They believe in the probable stability and development of the system of intercollegiate lectures, but say very little to assist its development, and they say nothing about the present vehement competition by means of private tuition, and the defective method of study that it induces. In answer to the question how university teaching may be organised so as to give the greatest encouragement to the advancement of knowledge, "the Board offer no suggestions under this head." Is this quite what might have been expected in a report bearing the signatures of Stokes, Cayley, Adams, Clerk-Maxwell, Sir W. Thomson, Tait, Lord Rayleigh and James Stuart? May there not be some unobvious explanation of this phenomenon? The whole report consists of only forty-one lines.

Visual illusions in geology

Peter K. Chadwick

Department of Psychology, Eleanor Rathbone Building, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK

Examples of visual illusions in the laboratory are well documented, but what about illusions that occur during field observation of geological structures? In this article I discuss a study involving geologists and non-geologists and define some of the problems that may arise during geological field and laboratory work.

THOUGH visual illusions have been studied mostly in controlled laboratory situations[1,2], Poggendorff, Zöllner and other illusional distortions can also occur during observations of rock formations. Depending on the interaction of psychological and geological hypotheses, these can lead to false deductions. Problems may arise especially in the observation of elliptical ooids, crenulation cleavages and intersecting veins and fractures. Illusions in geological contexts are of psychological interest: judgements of area, for example, are found to be the reverse of those predicted on the basis of the Helmholtz irradiation illusion.

Four versions of the Poggendorff illusion in geological contexts are shown in Fig. 1. The inclined traces in Fig. 1*b* seem to be offset across the stippled bands. Were the bands representative of veins then these illusory offsets could lead to an interpretation suggesting dilational origin, whereas replacement is more appropriate. To some observers the linear elements seem also to be slightly rotated anticlockwise in the centre gap. This could be taken to imply the operation of shear strain of a different magnitude within and outside of the stippled layers. In Fig. 1*c* the rock cleavage traces seem to be displaced by interfacial shear at the layer boundaries, especially at the arrowed locations. The illusory displacements in Fig. 1*d* occur across the dark layers, suggesting a greater independence of the strain histories of the lighter layers above and below, than is justified; in fact, the cleavage traces are precisely in line.

The context effect of the fault at *A* in Fig. 1*a* and the gap in data caused by, say, a river course, increases the probability of an incorrect fault inference at *B*. The stippled layer is straight and continuous. For purposes of terminology in psychological studies it is convenient, however, to take the data gap band in the Poggendorff illusion as analogous to a geological fault. Then the displacement directions in this illusion can be described by labels which are usually reserved for tear faults. The line on the far side of the data gap is sinistrally displaced ('sinistral Poggendorff') when the apparent offset is to the left, dextral when it is to the right. Although such illusory offsets and rotations can be minimised by viewing along the interrupted linear elements—with the direction of view positioned at a low angle to the rock surface—this is rarely done when observing cleavages, since refraction is expected.

When exploratory mineral and petroleum investigations are at the reconnaissance stage, the use of image analysing computers for percentage area estimation is uneconomical. Visual estimations of rock porosity and percentage volume occupied by a diagnostic mineral are frequent, and monochromatic[3,4] and chromatic percentage area comparison charts have been devised to facilitate judgment. But monochromatic charts invariably present black grains on a white background, and single black shapes on white appear smaller than equal area white shapes on black (Fig. 2).

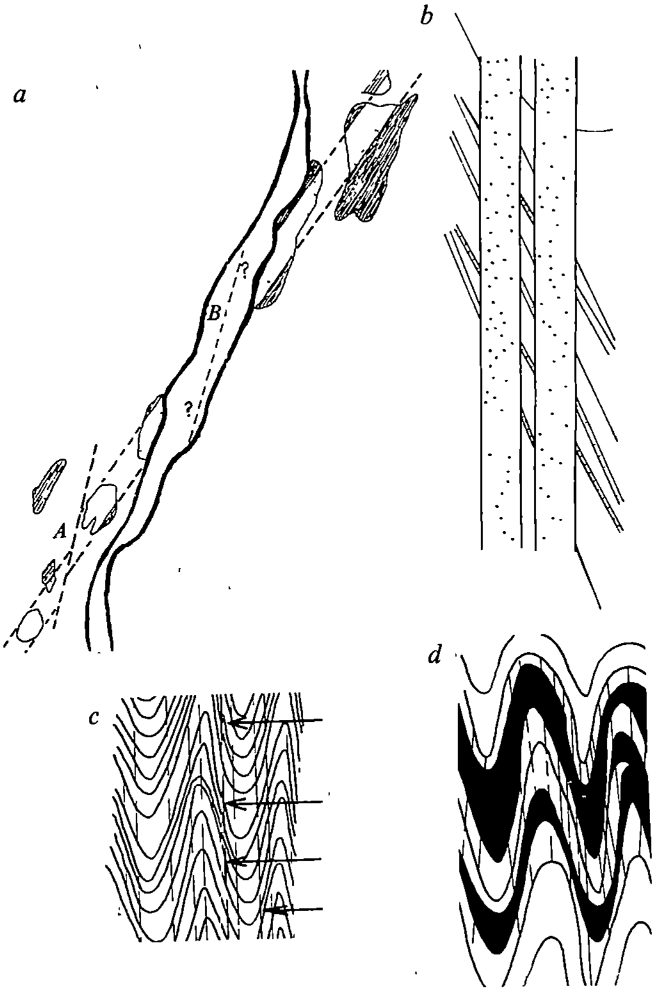

Fig. 1 The Poggendorff illusion in geological contexts; the illusory perceptual data are more likely to mislead when they favour an investigator's geological hypothesis than when they do not. *a*, 'Sinistral Poggendorff' offset of stippled layer across data gap misinterpreted as a fault, an interpretation reasonable at *A*, but not at *B*; *b*, illusory displacements, continuations and rotations of linear elements across two adjacent data gaps suggest dilation effects; *c*, illusory step-like displacements of cleavage, especially at locations arrowed; *d*, apparent offsets of continuous cleavage traces across dark bands.

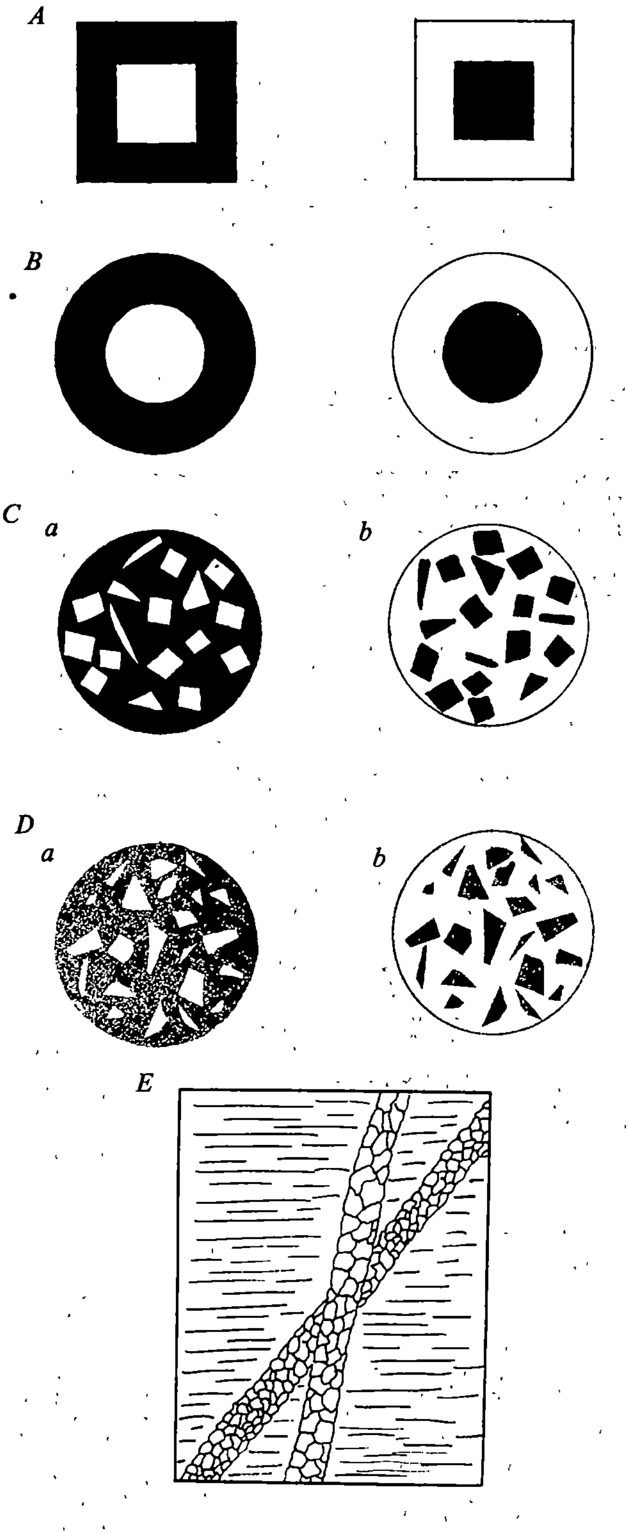

Fig. 2 *A* and *B*, The Helmholtz irradiation illusion in which a light area on a darker background appears larger than an equal dark area on white; however, in *C*, estimates of the percentage area occupied by grains in *a* and *b* are usually equal when both are presented together; but when presented separately the black grains (on the line-bounded background) are judged to cover a larger area than the white grains (on a contrast-bounded background); *D*, the grains in *a* and *b* again, in spite of the lower brightness contrast than in *C*, seem to cover the same area, but the dark grains are judged to cover a greater area when judgments are made separately. Actual area in *c*: 25%; *d*, 20.5%. *E*, 'Sinistral' Poggendorff offset of the older vein in *E* was misremembered as dextral by 23% of geologists.

Although this may be expected to cause an overestimation bias in area estimations of lighter grains, or areas, within a darker matrix, this is not necessarily the case. Twenty-eight geologists (with 2–5 yr experience) individually gave unaided absolute estimates of the total areas occupied by grains in eight 5-cm diameter items (9–23 grains in each). Two of the samples (17 and 23 grains) were presented deliberately both in white on black and black on white, with the grains evenly distributed. Contrary to predictions from the effect in the Helmholtz irradiation illusion, mean area estimates were larger (and not smaller) for black grains on a white background than for white on black. Overall mean values were respectively 29.4% and 25.4% ($0.025 > P > 0.01$, actual area 25%). Over this range of grain density the act of estimation may therefore involve other perceptual and cognitive processes which cause closure between multiple black elements and which thus counter the mechanisms used in seeing the standard irradiation illusion.

Monochromatic charts with black-on-white figure–background relationships should be misleading when total area estimations need to be made of a few large items; they do not accord so closely with estimates made without their aid as do the white-on-black scenes. The latter, in fact, are less likely to cause an underestimation bias for scenes of intermediate magnitude. Imagery-based techniques, such as mentally translating grains so that they cluster and fuse into a sector, do not promote greater accuracy of performance. Subjects stated that mental translation led to increased errors when the grains were small, widely separated, circular, or of uneven outline. Estimation through general impression, using 3–4-s delayed augmented feedback during 15 estimations of chromatic and monochromatic natural and diagrammatic samples, led to lower errors in other subjects after unaided estimates had stabilised (before–after comparison for 15 geologists (> 3 yr experience) and 2 non-geologists (one male, one female), ($0.025 > P > 0.01$)). The two female subjects tested had the highest initial errors but improved more than all the male subjects, eventually equalling male performance.

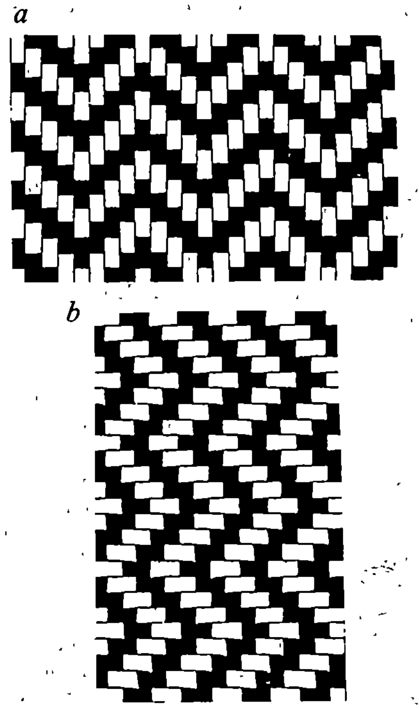

Fig. 3 *a*, The "illusion of the kindergarten patterns" is schematically similar to fracture cleavage associated with large offsets. The apparent fanning of the laths is entirely illusory; all are parallel-sided and aligned vertically. Decreases in brightness contrast between, say, lighter sandy layers and darker clay-rich layers, decreases the illusion. *b*, The same as *a* but at 90° to it.

If illusory data elements contradict common geological expectations, then the latter dominate over some of the psychological elements, during constructions in visual memory, but not necessarily over others. A total of 69 geologists with 2–5 yr experience observed a slide depicting two acutely intersecting but straight, undisplaced veins of equal thickness (Fig. 2*e*). The intended Poggendorff offset is sinistral. After viewing for 7 s they drew representations which were assessed by three neutral judges for unambiguity of age relationships and true continuity of the older (more gently inclined) vein across the younger (near vertical). Twenty subjects did unambiguously represent the older vein as displaced but 16 of them showed the displacement as dextral. Such a representation should be expected only if the younger vein grows at a high angle to its margin. Six geologically and psychologically inexperienced subjects reported seeing the "sinistral displacement" but four of these could not accurately remember data on age relationships (the latter was accurately recorded by 96% of the geologists).

Figure 3 shows the combined effect of the irradiation distortion and Poggendorff offset in the form of the "illusion of the kindergarten patterns"[5]. This is schematically similar to those instances of fracture cleavage in deformed rocks where the displacement along the cleavage is large in comparison to the thickness of the cleaved layer, and the brightness contrast of the rock lithologies is high. The 'fanning' of the cleavage is illusory: all the cleavage surfaces are straight, parallel and vertically in line. Similar problems may be created by geological analogues of the Zöllner and Fraser illusions (ref. 2 and Fig. 4). The tightly folded recumbent multilayer in Fig. 4*a*, for instance, seems to be penetrated by a convergent cleavage fan; that in Fig. 4*b* seems to be penetrated by divergent zones of thinning. In fact, the cleavage traces are parallel and in line (that is, 'axial planar'). Structures with these general appearances are quite common in orogenic belts, yet true axial planar cleavage is rarely reported. Its frequency of occurrence may have been underestimated. This emphasises the importance of the precise measurement of cleavage fan angles, in contrast to reliance on visual judgment and general verbal labels.

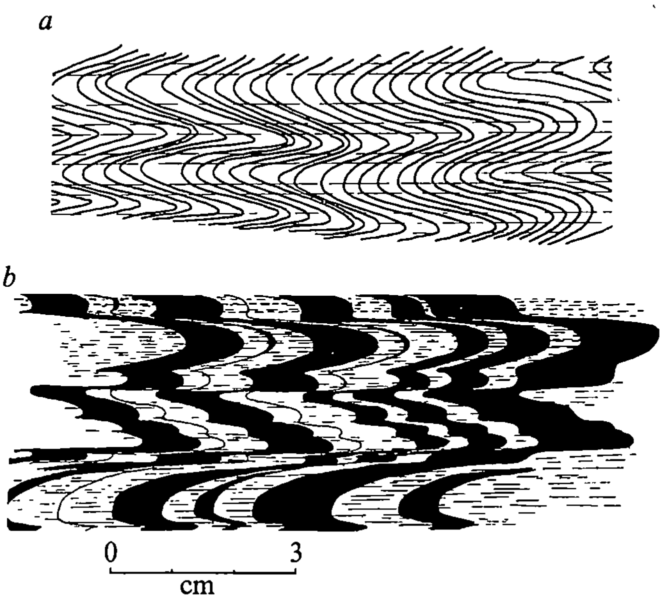

Fig. 4 Geological analogues of (*a*) the Zöllner illusion, and (*b*) the Fraser illusion. *a*, Recumbent multilayer folds seems to have an associated convergent cleavage. In fact, all the cleavage traces are parallel (true axial planar cleavage) Easily overestimated convergence angles are also seen in many outcrops of mesoscopic F_2 folds in the area of the Ballachulish "nappe", Argyllshire, Scotland. *b*, Based on a natural structure in Appin Quartzite Transition Group, Laroch Valley, Argyllshire. Six out of seven postgraduate structural geologists perceived the four major crenulation cleavage zones as fanning, and the finer, small scale cleavage traces as parallel sided. In fact, finer traces are fanning (divergently) and lower order zones are parallel sided.

In the vertical–horizontal illusion a vertical or slightly left-of-vertical line[6] appears longer than a horizontal line of the same length. Consequently, the amplitude–wavelength ratio of standstone ripples, or indeed any waveform, seems to be larger when the enveloping surface to the waves is horizontal, than when it is vertical. Low eccentricity ellipses, with horizontal long axes also appear closely circular when the difference between axes lengths is small (< 5%). Geological objects known as 'ooids' (Fig. 5*a*), which have circular outlines when undeformed, become elliptical after compaction and tectonic deformation. They are, however, rarely geometrically ideal shapes, and in some cross sections their interiors may be very irregular or even more elliptical than the peripheries. In the latter case this results in an illusory contraction of the ooid normal to the long axis of the interior ellipse—a variant of the Delboeuf illusion[7].

In most real geological situations, however, specific and nonspecific context effects do influence perceptual judgments. An important nonspecific effect is the continual necessity for separating out non-random fluctuations in shape and orientation from the inevitable random visual 'noise' inherent in geological (as opposed to geometrically ideal) shapes. Signal non-randomness in ooid geometry can go undetected when axes lengths differ by between 5% and 15% if geologists, through training, become accustomed to perceiving non-ideal forms and thus too easily accept natural shape irregularities as noise. Out of 54 professional and postgraduate structural geologists asked individually if the ooids in Fig. 5*a* needed analysing for evidence of deviations from circularity and of non-randomness in orientation, 36 replied that they did not (Fig. 5*c*). In fact, all the ooids are elliptical (Fig. 5*b*) and there is a preferred orientation of long axes in the horizontal. This fabric would not be eliminated no matter how high any subsequent strain and so their analysis is necessary. Sixteen non-geologists asked the same question all replied that they did think the ooids required analysis (confidence levels $\geqslant 3$). This would be explicable if the non-geologists were comparing the stimuli with more ideally shaped, memorised prototypes.

The practical way to aid decisions in these circumstances is for the observer to experiment with himself by judging the axial ratios of those ooids which to him seem closest to a unit axial ratio (however irregular their peripheries) and then checking the judgment by measurement. Errors of up to 15° commonly also occur in the location of the long axes of ooids when axial ratios are below 1.3:1. If two possible 'long axes' are constructed at the limits of the zone of location uncertainty, the length of the bisector of these axes is a better measure than that of one located intuitively.

On the basis of inappropriate constancy scaling interpretations of illusions[1], the upper half ('further away') portion of a vertical line should appear longer than the lower half. In addition, subjects can be expected to locate mid-points too high up along a vertically oriented dimension. Some evidence for the presence of such an effect, in a geological context, arose during an investigation[8] in which professional geologists located inflection points too high up on the limbs of moderate and high limb dip folds. Bisections were made within zones ranging from < 0.5 cm to 3 cm in length. In order to test both for range effects and also for possible psychological hindrances in the use of an additional way-up determination technique (Fig. 6), 30 final-year undergraduate geologists were requested to locate a number of mid-points between parallel lines separated by 3 cm and 6 cm. They were to judge the mid-height point. The parallel lines could be horizontal, inclined (45°) to the left, inclined to the right or vertical. Each of the 30 subjects provided 2–10 observations for each of the 8 conditions. No bias was found for the oblique or vertical cases, but in both width conditions, there was a small but very consistent tendency to locate mid-points too high up between horizontal lines (mean error 1.6%, $0.01 > P > 0.001$; all other conditions showed mean non-constant location errors of < 1%).

In an experiment examining the detection of asymmetry

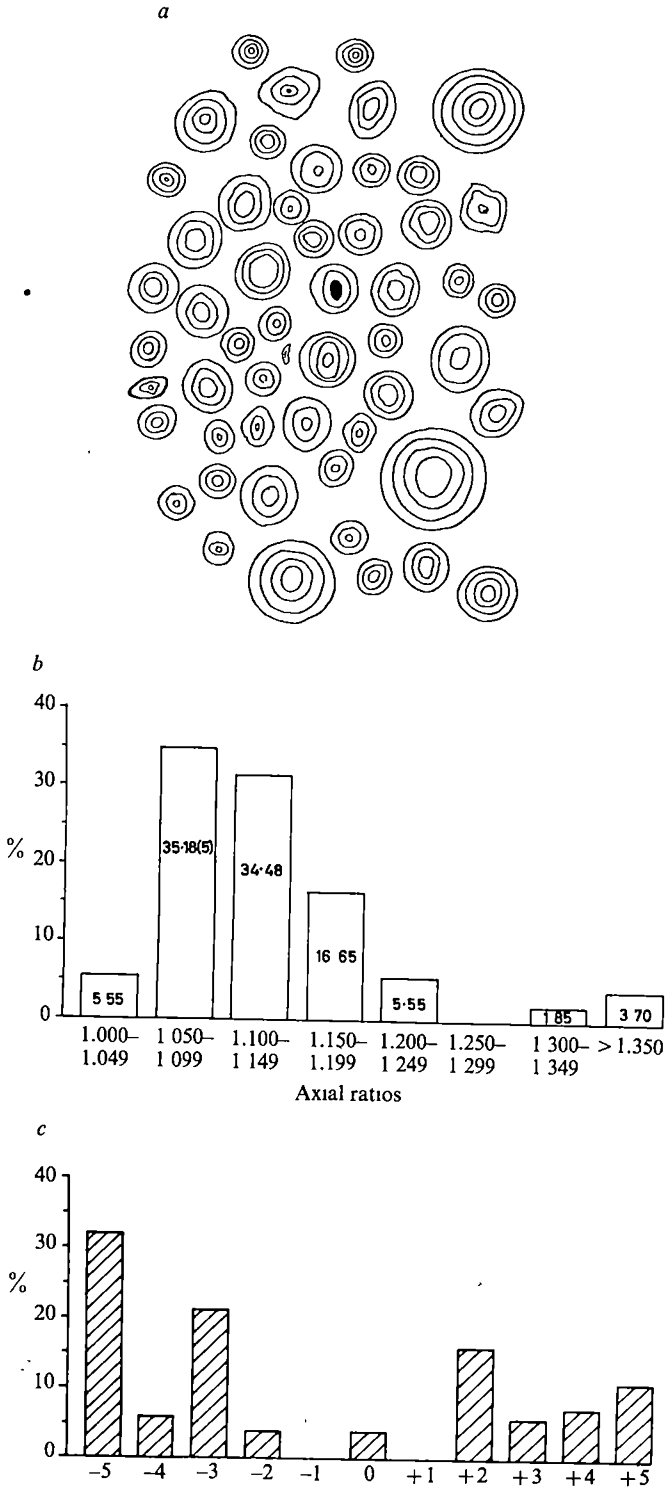

Fig. 5 *a*, In reflection of the vertical–horizontal and Delboeuf illusions, slightly elliptical ooids appear more closely circular than really they are. *b*, Frequency histogram of ooids' axial ratios, none of the ooids in *a*, are circular (54 ooids, mean axial ratio 1 15, range 1.025–3.45). *c*, Decisions of 54 geologists as to whether or not to analyse the ooids in *a* for evidence of inherited non-random deviation from a circular outline (−5 to +5, increasing levels in confidence of decision: −5, "definitely would not analyse"; +5, "definitely would analyse").

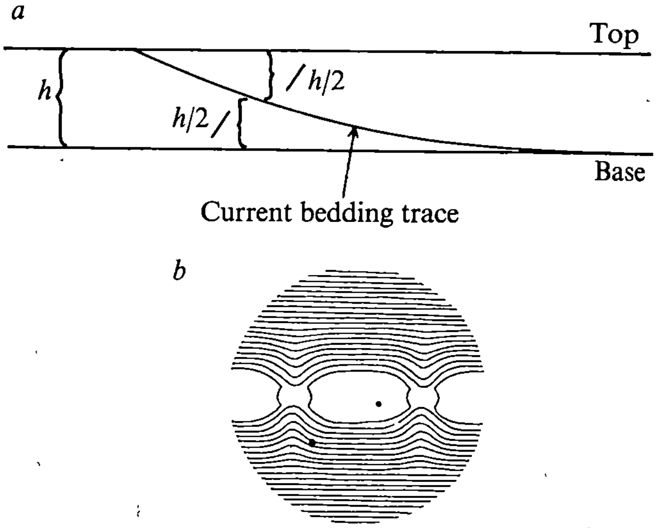

Fig. 6 *a*, 'Mid-point' method of way-up determination in areas where younging evidence is sparse and current bedding strongly flattened, demonstrated on an unambiguous example. Where mid-height surface intercepts current bedding trace, the longer segment is in the older half of the bed. Locations of mid-points by eye in horizontally positioned units tend to be too high up, leading to incorrect inferences of younging direction. *b*, One of the boudinaged layer stimuli: if deflections have less penetration above a boudinaged layer than beneath, this asymmetry is less likely to be detected than if the converse is true

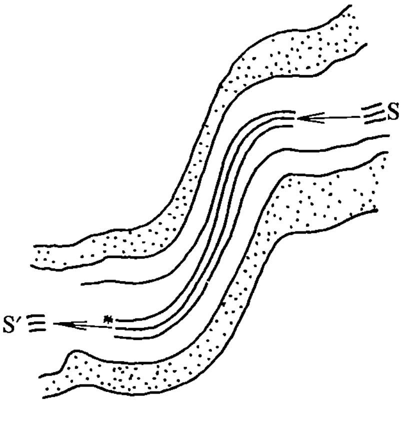
in boudinaged layers (Fig. 6*b*), similar results were obtained when 10 non-geologists and 3 postgraduate geologists assessed whether the zones of deflection around boudinaged layers (the waves dying out on both sides of the broken layer in Fig. 6*b*) had the same or different distances of penetration (stimulus visual angle 12°). Each subject provided two observations for each of four width conditions (same, 10, 20 and 50% difference) and four orientation conditions (horizontal, left and right oblique, vertical) in tachistoscopic presentation. The mean accurate decision time for the horizontal cases was 4.8 s, but for both oblique and vertical cases was 4.6 s. When, as in Fig. 6*b*, the upper zone of the horizontal condition was 10% narrower than the lower, 31% of the responses were erroneous; when the two were equal, 27% were erroneous. But when the lower half was the narrower, errors were reduced to 11.5%. This also indicates that when waves with progressive amplitude changes, cross the vertical dimensions to be compared, misjudgments of the length differences become exaggerated. The processes causing this may include differences in the implicit use of cues to upward as compared with downward perspective changes.

Provided that these perceptual difficulties are considered, it is possible for the geologist to use the mid-point location as an aid to way-up determinations. When current beds are strongly flattened it becomes more difficult to differentiate between their asymptotic bases and truncated tops. The way-up can, however, be determined by locating the mid-point between

Fig. 7 During lengthy visual tracking of layers in air-photographs and outcrops eye movements occasionally "jump tracks" and continue along adjacent layers. During visual tracing of the layer *S*, starting at top right, eye movements may continue at bottom left along *S′*. Correct line is asterisked.



the flanking bedding traces. Where this mid-height surface intersects the current bedding trace it divides it into two unequal segments, and the longer segment is in the older half of the bed (Fig. 6). I have validated this technique on flattened current beds in the Moine and Dalradian quartzites of the Loch Dochard region of Argyllshire, Scotland. If, however, the flanking bedding traces are horizontal then the mid-point between them should be located by measurement.

If illusions are conceived in terms of inappropriate visual induction processes, then they are difficult to compensate for because the false hypotheses on which they are perceived are in other circumstances correct, useful, and also out of conscious control[1]. Hypotheses, some of which can be brought into awareness, are also generated during visual search[9] and visual pursuit. In Fig. 7 a common assumption is that the three-layer batch at top right continues at bottom left. On the basis of this incorrect hypothesis the observer's eye movements shift from S to S'. When a wave of this geometry was present in a longer pursuit task, it caused shifts in eye movements, to adjacent layers, in 9 out of 29 undergraduate geologists. Visual pursuit needs to be done accurately during the interpretation of air-photographs and also during the observation of complex refolding relationships in outcrop. In the latter circumstances, pursuit lapses can lead, for instance, to 'mushroom' interference patterns[10] (contorted, but closed outcrop patterns) being missed when present, or spuriously inferred when absent. Because of difficulties in the visual pursuit of schistosity through the zone of thinning, crenulation cleavage often seems to involve actual limb displacements in items where no such displacements exist. Observers' eye movements (saccades) shift from their intended course, especially when the track is hypothesised to be more predictable than really it is. To avoid these shifts it is useful either to look along the track at a low viewing angle or deliberately to concentrate on the minutiae of any irregularities. The latter technique reduces saccade distance through eliminating the hypothesis that the track is highly predictable.

Man-made e.l.f./v.l.f. emissions and the radiation belts

K. Bullough, A. R. L. Tatnall & M. Denby

Department of Physics, University of Sheffield, Sheffield S3 7RH, UK

Morphological studies of e.l.f./v.l.f. emissions on the Ariel III and IV satellites indicate that man-made electromagnetic emissions, namely power-line harmonics generated in the industrialised regions of North America and, also, v.l.f. transmissions at 17.8 kHz (NAA) and 16.0 kHz (GBR) in the longitude sector which encompasses the South Atlantic Anomaly, are responsible, at least in part, for the formation of the electron slot ($2<L<3$) between the inner and outer radiation belts in the magnetosphere.

A PRELIMINARY study by Lefeuvre and Bullough[1] of v.l.f. emissions at 3.2 ± 0.5 kHz and 9.6 ± 0.5 kHz recorded on the Ariel III satellite (altitude $\sim$500 km, orbital inclination 80°) revealed the existence of a permanent zone of v.l.f. emission occurring over the USA and its geomagnetically conjugate region in the Southern Hemisphere. These Ariel III studies have since been extended and now confirm the importance of this longitude sector for wave-particle phenomena at low L shells ($2<L<3$). This American zone of e.l.f./v.l.f. emission is shown most clearly on the maps of percentage occurrence (Figs 1 and 2) for quiet magnetic periods ($K_p \leq 2+$). To obtain Figs 1 and 2, a count was made of the number of observations (typically 25–40) in each $10^{\circ}\times 2^{\circ}$ longitude–latitude sector and the percentage of such occasions for which the signal intensity exceeded $10^{-11}\ \gamma^2\ \mathrm{Hz}^{-1}$ FSE found. (FSE: free space equivalent, thus $10^{-11}\ \gamma^2\ \mathrm{Hz}^{-1}\ \mathrm{FSE} \equiv 4.8\times10^{-15}\ \mathrm{W\ m^{-2}\ Hz^{-1}}$ for a circularly polarised wave.) The orbit of Ariel III was such that full local time coverage was obtained in each 80-d period analysed. Little importance can be attached to the very localised maximum at 5°E, 56°N which occurred in the quiet period following a magnetic storm and close to a ground station at Winkfield, UK where observations were limited by tape recorder read out.

In Fig. 1 the 20% contour of occurrence is centred rather accurately on the North American continent (shown dashed) with a corresponding conjugate region in the south. The 60% contour in the Northern Hemisphere mapped geomagnetically into the opposite hemisphere shows isomorphism in the two conjugate regions. There is a pronounced maximum in occurrence (>60%) on lower L-shells ($2<L<3$). A closer examination of the contours of occurrence over North America (Fig. 2) shows that it is possible to attribute the source of the emissions to a combination of power-line harmonics and thunderstorm noise. The two major centres of thunderstorm occurrence (Colorado Mountains and the south-eastern USA) are four times more active in the first period (1967 May, June, July) than in the second (August, September, October). In the latter period the 60% contour is situated above the most highly industrialised region of the USA and south-eastern Canada. In the earlier period its extension to the west and south could be attributed to the greater thunderstorm activity. Electrical power consumption in Canada is concentrated in the south of Ontario and Quebec. Available statistics do not enable us to display it on the map. Measurements by D. Morgan (private communication) in a comparable industrialised area in the UK yielded magnetic field strengths at the ground of about $10^{-11}\ \gamma^2\ \mathrm{Hz}^{-1}$ for the 3.2 ± 0.5 kHz channel. This is the same as the baseline we have used for Figs 1 and 2. For typical high thunderstorm activity the mean thunderstorm noise level, measured overhead on the Ariel IV satellite without wave amplification, is also $\sim 10^{-11}\ \gamma^2\ \mathrm{Hz}^{-1}$ FSE. A preliminary examination of 500–1,000

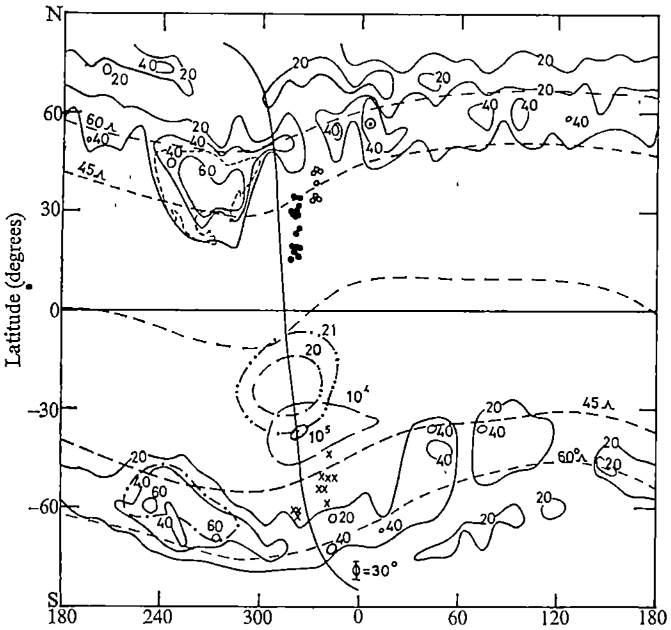

Fig. 1 Percentage occurrence of emissions with intensity $>4.8\times10^{-15}$ W m^{-2} Hz^{-1} at 3.2 kHz; 1967 May 5–July 24, $K_p \leq 2+$. — • — •, 60% contour (Northern Hemisphere) mapped into Southern Hemisphere (magnetic conjugate). – • • – • • –, Brazilian magnetic anomaly [magnetic field at 600 km ($\times10^{-6}$ T)]. – – –, South Atlantic anomaly [omni-directional electron flux >0.5 MeV cm^{-2} s^{-1} at 200 km (Vette, 1967)]. ●, 1967 May 16–23; ○, 1967 June 7–8 inclusive [GBR (code)]; ×, 1971 December 12–1972 March 1 [NAA (FSK)].

Hz e.l.f. data from Ariel IV (1972 March 20–June 22) indicates a small maximum in occurrence for signals $>10^{-11}$ γ^2 Hz^{-1} FSE (but none for signals greater than 10^{-8} γ^2 Hz^{-1} FSE) of 85–90% compared with an average of 65% around the world (at $L = 3$). Amplification at e.l.f. is much less than at v.l.f. (see below) and the signal could correspond to unamplified power-line harmonics. Thus the amplified emissions may be band limited in agreement with the rather limited observations from OVl-14 (ref. 2).

Dependence on geomagnetic activity

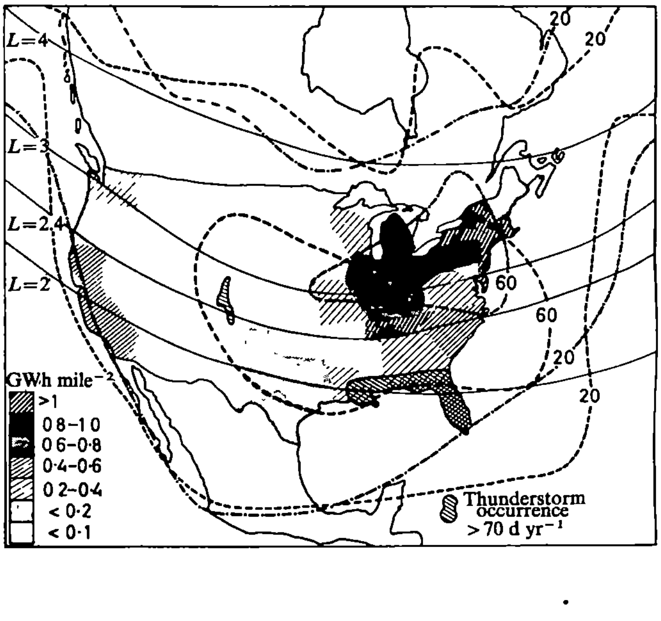
A detailed analysis of all passes over the zone maximum (240–300°E, 30–45°N) for both quiet and disturbed periods revealed a wide range in signal intensity (~50 dB) which reflects the variation in magnetic disturbance ($K_p = 0+$ to 9o) in this period. All measured intensities lay above the receiver threshold and a 10–20-dB reduction in the weakest signals from night to day could be ascribed to D-region absorption of a signal transmitted from the ground; this signal level being that obtained in the absence of amplification during quiet periods. Because of this wide range in signal intensity it was not possible to identify either a diurnal or weekly variation in signal intensity which could be attributed to the expected variations (≤ 3 dB) in power consumption. It is clear that wave amplification (two-hop whistler signal for a source in the USA) occurs very frequently. We have not yet analysed the one-hop whistler signal for this period. An analysis similar to that of Fig. 1 but for disturbed periods ($K_p \geq 3$o), shows the percentage occurrence rising to 100% over the eastern USA and its conjugate region. During these disturbed periods there is a tendency for the evening activity to lag behind that of the morning—as for higher latitude events[3].

GBR (16 kHz) and NAA (17.8 kHz) wave amplification

Further evidence of the importance of man-made v.l.f. emissions in the electron slot has been found in a study of the GBR (Rugby, 16 kHz) and NAA (Maine, 17.8 kHz) wavefields above the ionosphere. Amplification of the NAA signal at 17.8 kHz is commonplace whereas that of the GBR signal is rare. The phenomenon is strongly localised in the invariant longitude sector which includes the South Atlantic magnetic anomaly. This is shown very clearly in Fig. 3 where Ariel III daytime (SZA < 90°) GBR signal intensities measured in the azimuthal sector 225–255°E of N in the period 1967 May 12–August 1 are compared with those observed in the sector 105–135°E of N. Two types of signal, frequency shift keying (FSK) and specially coded, are plotted. The coded signal consists of pure continuous wave transmitted in a 90-s ON, 30-s OFF sequence. It can be seen that only the coded signals in the azimuth-range sector extending over the North Atlantic exhibit amplification. The observations were made using a minimum reading circuit[4], therefore transient amplification events in each observing period of 28 s are excluded. The FSK signal intensities lie close to those expected for propagation in the earth–ionosphere wave-guide with partial transmission through the ionosphere. The most strongly amplified (>10 dB) signals are plotted on the map (N. Atlantic) in Fig. 1. There are two groups; that to the immediate east of the anomaly are events observed at dawn in the period May 16–23 inclusive when the local time and solar zenith angle were ~0600 and ~85° respectively with little magnetic activity ($K_p \simeq 2-$, $\leq 3+$). Further east is a group occurring on June 7 and 8 at local time and zenith angles of ~1600 and ~55° respectively. These observations were preceded by a violent change in the AE index of 1100γ at 0000–0200 UT on June 6. Surprisingly, in none of these GBR events was there evidence of wave amplification in the wavefield observed over the South Atlantic.

The locations of the most intense amplification (>10 dB) events observed for the NAA wavefield in the period 1971 12, December–March 1 are shown in Fig. 1. These all lie in the Southern Hemisphere, slightly to the east of the anomaly, corresponding to amplification of the one-hop whistler mode. The NAA signal throughout this period was almost entirely FSK and was recorded, as for the Ariel III GBR observations, using a minimum reading circuit. An interesting feature of the NAA and GBR one-hop whistler signals, which were observed simultaneously on Ariel IV, was that the GBR signal (FSK) was never amplified in the presence of the more intense NAA signal, however, natural whistlers, at frequencies of 3.2 and 9.6 kHz, did exhibit simultaneous amplification for ~50% of these large amplification events. Apart from a few substorms

Fig. 2 Percentage occurrence of emissions with intensity $>4.8\times10^{-15}$ W m^{-2} Hz^{-1} at 3.2 kHz, annual electric power consumption (in GWh mile^{-2}) and thunderstorm occurrence for the USA $K_p \leq 2+$. – – – – – –, 1967 Summer (May, June, July). – • – • – • – •, 1967 Autumn (August, September, October). Relative thunderstorm occurrence: summer/autumn = 4 (see text).



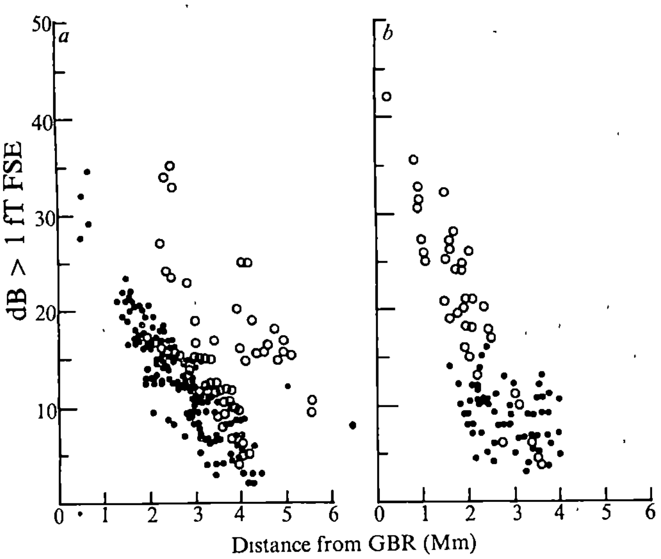


Fig. 3 Daytime amplification of the GBR 16-kHz coded signal over the North Atlantic 1967 May 12–August 1; all K_p; SZA⩽90°. ●, FSK signals; ○, coded (CW) signals. *a*, Azimuthal sector 225–255°E of N; *b*, Azimuthal sector 105–135°E of N

the NAA signal amplification was associated, as for the GBR wavefield, with solar illumination of the ionosphere at dawn. Further studies of the NAA wavefield by D. J. Davies (personal communication) support this conclusion.

Discussion

From the v.l.f. studies reported above, it is clear that man-made transmissions, particularly the power-line harmonics giving rise to the prominent zone of e.l.f./v.l.f. emission above North America, have an important role in the formation of the electron slot in the magnetosphere. Dungey[5] was the first to suggest that v.l.f. signals generated on the surface of the Earth might modify the energetic particle population in the magnetosphere by pitch angle diffusion into the loss cone and various authors (see ref. 6) have studied wave particle interaction in the electron slot region. Amplification of the signals in this sector make them much more effective in causing pitch angle diffusion. More direct evidence for wave amplification at mains harmonics, up to 6 kHz, has been found[7] from ground-based observations in Antarctica. They were able to identify a Canadian aluminium smelting plant as a possible source of some of the signals observed. The signal intensity of the band-limited noise observed on OVI-14 at the magnetic equator lay between 0.03 and 1 m $\gamma\text{Hz}^{-1/2}$ and occurred in the recovery phase of a magnetic storm ($D_{ST} = -120\gamma$). It was sufficient to account for the observed lifetimes of medium and higher energy electrons in the slot. Once the energetic electron population has fallen below the critical flux level indicated by the theory of Kennel and Petschek[8], then precipitation by a self-generated emission becomes impossible and a wave source is required. Lyons, Thorne and Kennel[9] have proposed that the electron slot is formed by high order gyroresonant interaction with plasmaspheric e.l.f. hiss, propagating to lower L shells from just within the plasmapause boundary where it is generated. More detailed correlative studies between wave and particle observations are required to ascertain the relative importance of e.l.f. hiss and power line harmonics (first-order cyclotron resonance). The Ariel III and IV evidence for a strong localisation in v.l.f., but not e.l.f. amplification, over the eastern USA suggests that the latter are more important. Theoretical calculations of energetic electron diffusion by the e.l.f. plasmaspheric hiss and power line harmonics indicate that the latter (in first-order resonance) could make an important contribution to diffusion at larger pitch angles where it was found[9] necessary to invoke higher order resonances for the e.l.f. hiss (Matthews, personal communication). There are also ground-based observations of band-limited hiss (centred on 5 kHz) which occurs during and after great magnetic disturbances at these invariant latitudes[10].

A recent study[11] of the precipitation of energetic electrons from the slot shows that peaked energy spectra, as well as the more normal exponential energy spectra of such electrons, may occur. This peak in the energy spectrum moves to higher energies with decreasing L in such a way that it could be attributed to a first-order cyclotron interaction at a single wave frequency over the range of L sampled. This, of course, is what we might expect to observe for the NAA and/or GBR signal. For the daytime model magnetosphere of Alexander[12] the parallel electron energies for first-order cyclotron resonance at the equator vary from 1 MeV at $L = 1.8$ to 6 keV at $L = 3.0$. Imhof *et al.*[11] ascribe the majority of their peaks to first-order resonance at 10 kHz and below (based on the model magnetosphere used) however, lack of data on the actual cold plasma distribution at the time of observation as well as the possibility of a wave–particle interaction at a distance from the equator, make it possible that a higher frequency was involved. The parallel energy, E_R, of the resonant electron is given by

$$E_R = E_c \frac{\omega_H}{\omega}\left(1-\frac{\omega}{\omega_H}\right)^3$$

where $E_c = B^2/2\mu_0 N$ is the magnetic energy per particle, $\omega_H = \frac{eB}{m}$ is the electron gyrofrequency (rad s^{-1}), $\omega = 2\pi f$, B is the local magnetic field, N the local electron density, e the electronic charge, m the electron mass and f the wave frequency (SI units). E_R is clearly very dependent on the value of B.

It has been known for some time (see refs 13–16) that the wave–particle interaction for a ground-based transmitter is a strong function of the duration of the transmitter pulse which causes phase-bunching of the electrons. The preferential amplification of the long duration coded GBR signal, in what is probably the two-hop whistler mode, provides a good example of this. The localisation of the GBR and NAA amplification, slightly to the east of the anomaly, comes from the increase in loss cone and pitch angle anisotropy[6] of electrons drifting eastwards through the anomaly. Also in this region field aligned structure will help by ducting the whistler wave along the same path as the interacting electrons. The maximum at dawn may be attributed to the decrease in E_c corresponding to an increase in electron density, N, as the cold plasma flows up the field lines from the ionosphere. Thus E_R is decreased and lower energy electrons, which are normally more numerous, drift eastwards into a region where cyclotron resonance becomes possible.

In conclusion, the power line harmonics and other man-made transmissions may, by first-order resonance with the energetic electrons, make a significant contribution to the electron slot between the radiation belts. Thunderstorms over North America also produce e.l.f./v.l.f. wavefields of significant intensity.

Protein-folding dynamics

Martin Karplus & David L. Weaver*

Department of Chemistry, Harvard University, Cambridge, Massachusetts 02138

In a discussion of the dynamics of protein folding two limiting models (random-search nucleation and chain propagation, diffusion–collision) are considered. It is suggested that the latter may have the dominant role in many proteins.

THE problem of the folding of a globular protein to its native structure has two parts[1]. The first is the static aspect concerned with the elements in the amino acid sequence that provide the information; the second deals with the dynamics of the folding process itself. Clearly, the answer to the first part of the problem is involved in the second (in particular, the stabilities of intermediate structures may be important in selecting the folding paths) and conversely, it is possible, though less likely, that the second affects the first (that is, that the nature of the folding process results in a non-equilibrium structure). Available data indicate that proteins *in vitro* can fold up to their native structure in times from tenths of seconds to minutes in the absence of S–S bridges[2]; formation of S–S bridges coupled to refolding tends to take longer. This is to be contrasted with the long times required to find the native conformation in a random search of all possible structures (for example, in the simplest model, such a random search would take on the order of 10^{50} yr for a protein consisting of 100 amino acids). Thus, protein folding must make use of more sophisticated search procedures, which, in one way or another, divide a protein molecule into parts such that the information contained in the sequence of each one can be used independently. The simplest solution would be that a protein consisting of 100 amino acids is composed of ten or so approximately equal parts, each of which finds its own unique stable form, and that these parts then come together to form the complete native structure. But it seems from studies of peptides in solution[3–8], as well as approximate energy calculations[9], that most sequences short enough to be searched through rapidly do not have a folded structure that is sufficiently stable. Thus, alternatives to this simple idea must be examined. Two possible limiting mechanisms for globular protein folding are discussed further below; they are referred to as the random-search nucleation and chain-propagation model and the diffusion–collision model. The latter mechanism is suggested to be more important than the former, though the folding of any particular protein may involve some elements of both limits.

Random-search nucleation and chain propagation

The model utilises a random-search nucleation step as the start of the folding process followed by chain propagation to obtain the native structure. The basic elements of such a mechanism are that first, a portion of the protein is small enough for a random search and yet stable enough to serve as a nucleation unit, and second, that once this unit has the native structure, it makes possible a sequential, essentially independent folding of subsequent amino acids. Such a mechanism was outlined by Wetlaufer[10], and earlier by Levinthal[11,12]. The process in its simplest version can be formulated by analogy with the treatment of helical dimer formation involving complementary oligonucleotides[13,14] or helix formation in a polypeptide with only a single nucleation site[15,16]. Tsong *et al.*[17,18] have provided a kinetic model for such sequential protein folding and given kinetic data[19,20] related to it. The chain-propagation steps are assumed to be analogous to the addition of units in helix formation in polypeptides and, therefore, very fast (that is, of the order of 10^{-6}–10^{-8} s). Concerning the nucleation step, it is more difficult to make a general statement, although a random search of the conformational alternatives of a minimal nucleus composed of approximately fifteen amino acids would require of the order of milliseconds.

Diffusion–collision

An alternative limiting possibility, the diffusion–collision model, considers the protein molecule to be divided into several parts (microdomains), each short enough for all conformational alternatives to be searched through rapidly. This condition implies that the native secondary structure of each such microdomain, though accessible by random events, is not stable. Consequently, several (two or more) of them have to diffuse together and collide in order to coalesce into a structural entity with the native conformation.

Anfinsen[21] has discussed the possibility that portions of a protein chain can "flicker" in and out of their native format and serve as nucleation centres coalescing through non-covalent interactions to give the native protein structure; this statement is suggestive of the diffusion–collision model.

To examine the factors determining the kinetics of the model, we consider an example involving two microdomains; this could represent a protein fragment composed of only two parts, or more generally, a portion of an entire protein. Each of the microdomains can be described as being in equilibrium between the native secondary structure and the unfolded random-coil structure, which includes the rest of the available conformational space. If the microdomains formed helices in the native state (as in myoglobin) the helix, random-coil transition would be involved. We assume here that coalescence can occur only if both the partners have the native structure when they collide and that the secondary structural transitions are fast relative to other processes. If the two connected units are regarded as diffusing together from a finite distance to form a stabilised entity with the native conformation, an order of magnitude for the time τ required for the coalescence can be obtained from the radial diffusion behaviour of spherical units. The result is (details will be given elsewhere)

$$\tau \simeq \frac{1}{\beta}\left(\frac{l\Delta V}{DA}\right) \tag{1}$$

where ΔV is the volume of the finite diffusion space (the space between two concentric spherical shells); A is the target surface area (the area of the inner shell) whose radius is determined by the sizes of the peptide units; D is the diffusion coefficient and l is a characteristic length (the average of the inner and outer shell radii, the latter being determined by the maximum distance of separation of the two units which are part of the same protein chain). The quantity β accounts for the fact that only a fraction of the microdomains have the native secondary structure when they collide. In a detailed theory, the various parameters involved (that is, ΔV, A, l) would have a direct physical significance, but in this heuristic discussion they are phenomenological in character and only order of magnitude values can be given. With $D \sim 1 \times 10^{-6}$ cm^2 s^{-1}, a value appropriate for spherical particles with the dimensions of protein fragments, and with the outer shell radius twice the inner one and equal to 2×10^{-7} cm (20 Å), equation (1) yields $\tau\sim\beta^{-1}[10^{-7}\text{–}10^{-8}]$s. To evaluate β, an equilibrium model can be used for simplicity; that is, $\beta=K_1K_2/(1+K_1)(1+K_2)$ where K_1 and K_2 are the (native)/(random coil) equilibrium constants for the two separated units. This expression ignores the possibility that β could vary as the partners approach and that details of the kinetics might modify the equilibrium result. From the above formulae for τ and β, it follows that for values of K_1 and K_2 equal to 10^{-3}–10^{-4}, orders of magnitude equal to the estimated equilibrium constant for helix nucleation in helix–coil transitions[22] and the native–random coil equilibrium in protein fragments[3–8,23], the folding time for a pair of units is of the order of 0.01 and 10 s. If several units have to come together at one time to form a stable entity and each one has a K_i value less than 10^{-3}, the folding time would be inordinately long. Consequently, a stepwise folding by this mechanism seems most likely; for example, two units coalesce to form a slightly more stable entity which in turn collides with a third entity, and so on. In this way the rate of the process would increase as the folding advanced, as expected for a cooperative transition.

Variation of τ with temperature is expected due to both D and β. The Einstein–Stokes expression for D approximately doubles in size between 10 °C and 40 °C. The dependence of β on temperature is difficult to estimate since it is determined by a balance between enthalpic and entropic (for example, hydrophobic) terms. Some temperature variation has been observed in the renaturation rate of acidified staphylococcal nuclease[24]. The results are not, however, sufficiently detailed to relate to the model discussed here.

Several refinements would have to be introduced into the model to make calculations of more than order-of-magnitude validity. These include a more detailed consideration of the size, shape and connections of the colliding segments, the possibility of the existence of an activation barrier to coalescence, the requirement for rotational as well as translational motion to obtain the correct position for a stable interaction, and the consideration of diffusion in the presence of a folding/unfolding process with the same time scale. Most of these effects are expected to increase the time required, though changes by several orders of magnitude seem unlikely except for the significant activation barrier.

Implications of the models

Two limiting mechanisms that could be involved in the folding of proteins to their native structure have been discussed briefly and their dynamics considered. The true folding process of a real protein may well involve elements of both extremes. Some amino acids would undoubtedly take up the native format in a sequential, rather fast (μs) manner whether the primary process were a random-search nucleation or a diffusion–collision step or a combination of the two. It seems, however, that folding an entire protein of 100 or more amino acids by a single random-search nucleation plus chain-propagation mechanism is not feasible. The difficulty is that rapid propagation after nucleation requires that the laying down of each successive amino acid or small group of amino acids be essentially independent of the conformation of the rest of the unfolded molecule. Although this may be a good approximation for helix formation, it seems unlikely for the complicated structure of globular proteins. If each propagation step requires a search through a significant fraction of the conformations of the uncoiled portion of the protein chain, the basic folding problem, albeit in a slightly reduced form, remains unsolved after nucleation. It has been noted in analyses of structural data that many larger proteins are composed of domains, each of which could fold almost independently[6]. Since these domains are composed of 50–150 amino acids, they are too large to serve as primary nucleation centres; instead they each raise the same folding problem as the entire molecule.

In contrast to the difficulties that are found with the random-search chain-propagation model, available structural and other data suggest that the diffusion–collision model can serve as the basis for a mechanism of protein folding. Several recent studies have shown that globular proteins have about one-third of their residues involved in chain-reversal turns[25–27]. Since each turn is normally composed of four residues (by the criteria used in the analyses), this result implies that a protein is on average composed of segments eight to ten residues between turns. Thus, it seems natural to suggest that these segments form the primary diffusing units in the diffusion–collision mechanism. The entire folding process would, as described above, involve a series of such diffusion–collision steps. These might have to follow a unique order to yield the native structure (single correct pathway); alternatively, different sequences of diffusion–collision steps might be possible. Further, particularly in the larger proteins, there may be several regions (the domains) that are individually fixed in their native structure by a set of diffusion–collision steps and finally come together to form the completed native protein molecule.

The diffusion–collision mechanism would be most effective if the individual segments (the diffusing units or microdomains) were relatively unlikely to bend significantly; that is, that they can be regarded as statistically rigid rods in the diffusion process so as to minimise entanglement problems. Empirical correlations tend to support this view[25–27], as does the model calculation of Levitt and Warshel[28]. Some regions which have a very well defined secondary structure (for example, α helices) could support more residues per segment; significant deviations from the average of eight to ten residues do occur, although a detailed correlation with the folding mechanism has not been made.

The motion emphasised here is essentially diffusive, and the attractive forces that stabilise the coalesced microdomains are short range; that is, until two groups are sufficiently close to prevent water molecules from being between them, no hydrophobic attraction can exist. Moreover, any directing forces provided by the connecting elements are likely to be damped by hydrodynamic effects. Once the segments have diffused together, the balance between hydrophobic attraction and van der Waals' repulsion will determine whether or not coalescence can occur in a given collision. This requires that segments have the correct secondary structure (including the side-chain orientation)[29]; otherwise a significant repulsive barrier would be expected. Consequently, the parameter β, which determines the fraction of the time that the correct secondary structure exists, has a fundamental role in the effective time constant of the diffusion–collision mechanism (equation (1)). It would be very useful to have experimental measurements or theoretical estimates of β for protein fragments that are likely candidates for the microdomains involved in the diffusion–collision process. These might be pairs ofhelices, pairs of peptide chain segments that can form a β sheet, or an α-helix plus β-sheet structure (ref. 30 and references therein); in the present context, a β sheet is regarded as an element of tertiary structure because it is formed by the coming together of two elements, each with the appropriate extended secondary structure. Such fragments might be made available for study either by cleavage of the native protein or by direct synthesis. Comparisons can be made also with the available equilibrium constants for the (native)/(random coil) transition of complete proteins[31]. Kinetic measurements for the renaturation of fragment-type systems are important as well; some data are available for the *Staphylococcus* nuclease peptides[32]. Possible model systems include glucagon (which has a random coil structure in dilute solution, but at high concentration forms a trimer composed mainly of α helices)[6–8], and the polypeptides that form β-sheet networks[33].

Incorrectly folded intermediates have been suggested on the basis of a kinetic analysis by Ikai and Tanford[34]. Creighton[35] has trapped intermediates with incorrect disulphide bonds in his study of the folding of the basic pancreatic trypsin inhibitor; both the correct and incorrect early intermediates (one disulphide bond) seem to be correlated with stabilising secondary structural elements of the type mentioned above[25–27,30]. Such incorrect folding might be expected if the diffusion–collision mechanism has an important role; for example, segments that are not together in the native structure could collide and form intermediates which are relatively unstable because of improper non-bonded contacts.

Two theoretical attempts[28,36] to fold a protein have been made as a means of investigating the static part of the problem. One of these, by Ptitsyn and Rashin[36], considered myoglobin as composed of stable helices and, on the basis of a simple model for hydrophobic interactions between the helices, compared different paths to the most likely folded structure, a rough approximation to the native conformation. This type of static analysis is certainly compatible with the diffusion–collision mechanism; in a corresponding kinetic model, the helix–coil equilibria of the different helices would have to be taken into account. Levitt and Warshel[28] have tried to obtain the native structure of the basic pancreatic trypsin inhibitor by energy minimisation. They began with a simplified model of the extended polypeptide chain that can bend easily at only a few amino acids. The protein is thereby divided into segments that simplify the folding process as in the diffusion–collision mechanism. An important additional element in their calculation is that the assumed balance between attractive and repulsive forces is such that the colliding segments do not need to have the correct secondary structure for coalescence to occur. If this were valid for the actual folding process, the kinetic behaviour would be significantly different from that described above, since the parameter β would not appear in equation (1). There would result a rapid diffusion step leading to an approximate structure, followed by a slower process involving local readjustments to the native structure. Most likely, the situation in proteins is intermediate, with some probability of coalescence even when the colliding segments have an only approximately correct secondary structure.

Many of the data used in published discussions of protein folding are obtained in studies of unfolding[2]. This raises the question of whether the pathways for the two processes are the same. Since diffusion of polypeptide segments over the distances involved requires less than a microsecond, it is hard to account for the observed unfolding times, which are of the order of seconds, by assuming a simple reversal of the folding process. Consequently, it seems necessary to introduce a slow random event (for example, nucleation of open regions) in the unfolding pathway that is different from that in folding. An alternative possibility, which has not been considered in detail here, is that both processes are limited by a high activation barrier involving the same intermediates.

The analysis given here shows that the information required for a complete description of the dynamics of protein folding is not yet available. We hope, however, that our discussion of different limiting mechanisms will stimulate others to perform the experiments necessary to clarify the processes involved.

Helpful discussions with Drs S. C. Harrison and J. R. Knowles are gratefully acknowledged. This work was supported in part by grants from the US National Science Foundation and the National Institutes of Health.

Mechanism localisation and control of restriction cleavage of phage T4 and λ chromosomes *in vivo*

K. Dharmalingam & Edward B. Goldberg

Department of Molecular Biology and Microbiology, Tufts University School of Medicine, 136 Harrison Avenue, Boston, Massachusetts 02111

The primary action of restriction endonuclease, cleaving infecting DNA, has been demonstrated in vivo. *This primary cleavage is followed rapidly by hydrolysis of the cleaved DNA at its newly exposed termini. Infecting viruses can inactivate cytoplasmic and membrane restriction endonucleases to prevent cleavage of unmodified DNA replicas.*

THE utility of restriction endonucleases as a tool in biological research and their potential in genetic engineering have aroused much interest in these enzymes[1,2]. Considerable information exists on the mechanism of action of restriction enzymes *in vitro*[3-5]. Much less is known about their function within cells. Recognition *in vitro* is somewhat ambiguous[6] and in fact some chromosomes which are cleaved by isolated restriction endonucleases *in vitro* are not restricted by bacteria containing these endonucleases *in vivo*[7,8]. Restriction endonucleases normally recognise a specific short nucleotide sequence in double-stranded DNA. There are two major classes of purified restriction endonucleases, defined as specific (class II) and nonspecific (class I), depending on their cleavage specificity *in vitro*[2]. Class II enzymes cleave the DNA at the restriction site by opposite or staggered nicks[9-13]. This distinction can be reduced by altering incubation conditions[6]. In addition, single-stranded DNA can be cleaved[14] in certain conditions. Class I enzymes can cleave at any place up to a few hundred nucleotides away from the recognition site. We wonder which of these variations reflect the variety of mechanisms of action of these enzymes within the

Table 1 Restriction and breakdown of T4 glu$^-$ DNA and T4 2$^-$ DNA in various hosts

E. coli strain	*rgl*	exo V	exo I	T4 phage	Plating efficiency	% TCA-soluble DNA
K	−	+	+	glu$^-$	1	3
K	−	+	+	2$^-$	1×10^{-4}	40
B	+	+	+	glu$^-$	1×10^{-5}	42
B	+	+	+	2$^-$	5×10^{-6}	48
W3110	+	−	+	glu$^-$	2×10^{-4}	8
W3110	+	−	+	2$^-$	0.7	8
JC7623	+	−	−	glu$^-$	2×10^{-4}	5
JC7623	+	−	−	2$^-$	1	6

Standard phage techniques were those of Adams[31] and other techniques and strains used were described by Silverstein and Goldberg[29,30]. DNA breakdown is determined as the TCA-soluble fraction of DNA. Glu$^-$ phage were T4αgt^{57}βgt^{14} grown on *E. coli* K *rgl*$^-$, 2$^-$ were T4 am N51 grown on *E. coli* B. The data given are not corrected for absorption which was 85–90% for both 2$^-$ and glu$^-$ phage.

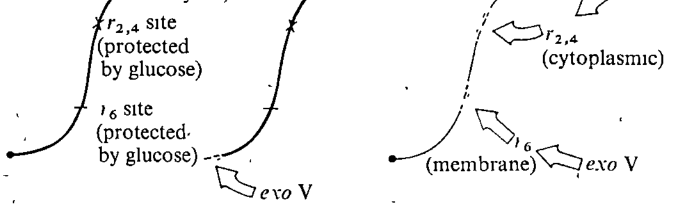
cell and which are merely artefacts of the *in vitro* environment.

Recognition sites in the DNA may be modified specifically (for example, methylation of *E. coli* DNA and λ DNA[15,16] or glucosylation of T-even DNA[17-19]), rendering the DNA insensitive to the appropriate restriction enzyme. *In vitro*, the action of restriction enzyme is usually studied by observing the cleavage of an intact viral chromosome into large fragments. For example, phage λ DNA is cleaved *in vitro* at five sites by fi$^+$ R-factor-coded restriction endonuclease (endo R. *Eco*RI[20]). *In vivo*, the cleavage by restriction endonucleases is followed by extensive hydrolysis by nonspecific nucleases[21-25], resulting finally in acid-soluble fragments[12,26]. We call this hydrolysis DNA breakdown, to distinguish it from the initial cleavage. Breakdown of unmodified λ DNA in *E. coli* K depends on the function of the bacterial *rec* BC locus. Growth of unmodified phage is restricted in *rec* BC$^-$ hosts even though DNA breakdown does not occur[27]. In considering the possible biological mechanism of action of restriction enzymes in the cell, we were surprised that large DNA fragments have never been demonstrated *in vivo* as primary products of restriction endonuclease cleavage. In this report we try to clarify the relationship between the initial cleavage by restriction endonucleases and the subsequent breakdown of the cleaved fragments by exonuclease V (exo V is specified genetically by *rec* BC)[28] *in vivo*. Using *rec* BC$^-$ bacteria, we were able to prevent degradation of the fragments cleaved from the unmodified T4 or λ phage chromosome by the cellular restriction endocucleases. Therefore we were able to demonstrate that these large fragments are intermediates in the restriction process *in vivo*, as postulated after *in vitro* experiments. We were also able to show that different restriction endonucleases which are thought to be localised in the cytoplasm or in the membrane can be inactivated in different ways by the infecting phage.

Role of cleavage and breakdown in restriction of T4

A phage T4 amber mutant in gene 2 produces particles of normal appearance in non-permissive Su$^-$ hosts. Though they adsorb and eject DNA normally, they do not produce progeny on Su$^-$ or Su$^+$ bacteria unless the bacteria lack *exo* V[29,30]. Table 1 compares the restriction (plating efficiency) of phage particles defective in gene 2 (2$^-$) and non-glucosylated (glu$^-$) phage and the breakdown (% of trichloroacetic acid (TCA)-soluble DNA) of their DNA after infection. In the presence of exo V both 2$^-$ and glu$^-$ infecting chromosomes are broken down, but in the absence of exo V they are not. In the presence of *rgl* (the restriction systems for non-glucosylated T-even phages) growth of 2$^-$ phage is not restricted, whereas growth of glu$^-$ phage is. In *rgl*$^-$ hosts, with or without exo V, glu$^-$ DNA is not broken down nor are glu$^-$ phages restricted.

Fig. 1 A model for the mechanism of restriction of 2$^-$ and glu$^-$ T4 phage by endonucleolytic cleavage and exonucleolytic breakdown of DNA. Thick line, glucosylated DNA; thin line, non-glucosylated DNA.



These findings can be explained by the model illustrated in Fig. 1. T4 gene 2 specifies a protein (P2) which seems to protect the end(s) of the entering phage genome from exo V. Modification of the DNA by glucosylation protects the entering genome from the *rgl* endonucleases. In the absence of P2, exo V would digest the entering DNA exonucleolytically. This action would thus be directly responsible for both the breakdown of part of the genome and the consequent restriction of the phage. The presence of P2 on the unmodified genome could protect the natural termini from exo V, but could not protect newly exposed ends created by endonucleolytic action of the *rgl* systems. Thus, as Table 1 shows, restriction of T4 glu$^-$ phage would be a direct result of cleavage of the genome by the *rgl* systems, whereas breakdown would be a secondary result of exo V action on the newly formed unprotected ends.

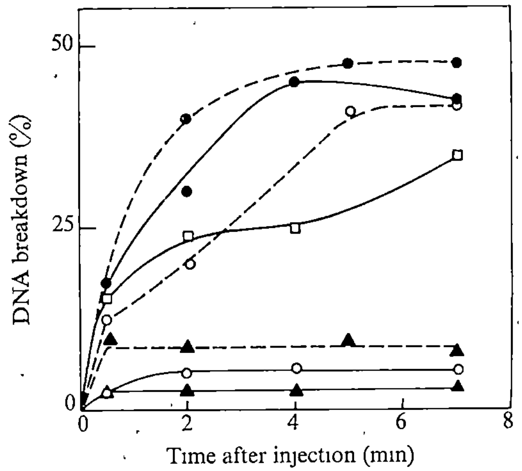


Fig. 2 Kinetics of breakdown of T4 glu$^-$ DNA and T4 2. Su$^-$ DNA in various hosts Experimental details are as described in Table 1. ●—●, glu$^-$ T4 in *rgl*$^+$ exo V$^+$ exo I$^+$ (B); ▲—▲, glu$^-$ T4 in *rgl*$^-$ exo V$^+$ exo I$^+$ (K *rgl*$^-$); ○—○, glu$^-$ T4 in *rgl*$^+$ exo V$^-$ exo I$^-$ (JC7623); □—□, glu$^-$ T4 in *rgl*$^+$ exo V$^+$ exo I$^-$ (W3110 sbcB); ●- - -●, T4 2 Su$^-$ in *rgl*$^+$ exo V$^+$ exo I$^+$ (B); ▲- - -▲, T4 2.Su$^-$ in *rgl*$^+$ exo V$^-$ exo I$^-$ (JC 7623); ○- -○, T4 2.Su$^-$ in *rgl*$^+$ exo V$^+$ exo I$^-$ (W3110 sbcB).

According to this model, it should be possible to demonstrate *in vivo* the initial cleavage products of unmodified DNA by infection of cells lacking exo V. To demonstrate such fragments we had first to determine the proper strains and appropriate time after infection to extract the DNA. Figure 2 shows that when exo V cannot digest the DNA, there is little acid-soluble material produced up to 7 min. This is the case even up to 25 min (unpublished). In cases where breakdown occurs it is usually complete by 5 min after infection. When

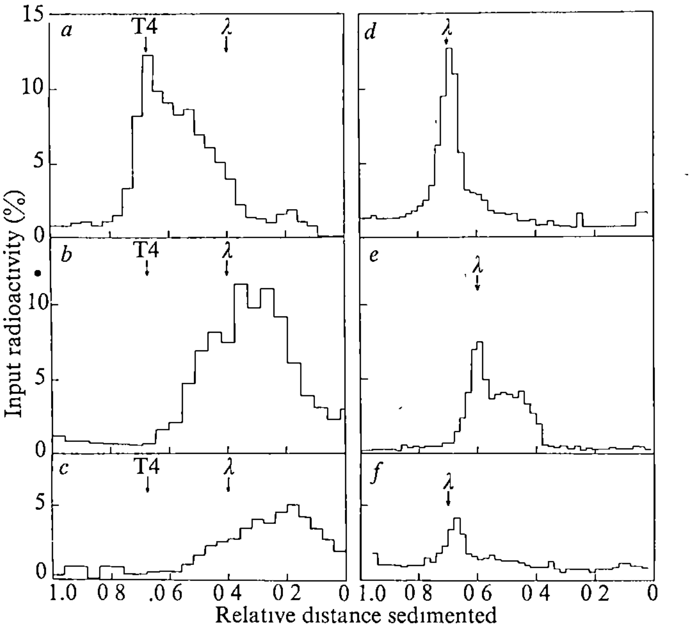

Fig. 3 Demonstration of primary cleavage products of *rgl* and r_K restriction *in vivo* *a*, *b* and *c*: T4, *rgl* restriction. Cells (5×10^8 per ml) were infected at 37 °C with two or three ^{32}P-glu$^-$ T4 phage each. After 5 min aeration at 37 °C cells were lysed and 0.2-ml samples were layered on to 4.5 ml 5%–20% alkaline sucrose gradients[32]. Marker phage (^{3}H-λ) was added to the infected cell lysate after addition of sarkosyl The DNA was sedimented for 100 min at 147,000*g* at 20 °C, fractionated by dripping on to Whatman scintillation pads, and washed with cold TCA. The 5% cold TCA removed acid-soluble nucleotides and therefore some of the graphs show less than 100% recovery. The calculated position[33] of T4 DNA shown in each graph was checked experimentally on several occasions. *a*, *rgl*$^-$ exo V$^+$ exo I$^+$ (K rgl$^-$); *b*, *rgl*$^+$ exo V$^-$ exo I$^-$ (JC 7623); *c*, *rgl*$^+$ exo V$^+$ exo I$^+$ (B). *d*, *e* and *f*: λ, r_K restriction. Cells (5×10^8 per ml in 0 01 M Tris buffer, *p*H 7.4, 0.001M $MgSO_4$) were infected with two or three ^{32}P-λC_{I857}· C_{600} r_K^- m_K^- per cell. Cells and phage were prepared as described before[34]. After 5 min of aeration at 37 °C cells were lysed and analysed in alkaline gradients as described above except they were run at 192,000*g* for 120 min. Adsorption of λ was 85–90% at 5 min after infection for all cells. *d*, r_K^- m_K^- exo V$^+$ (C600); *e*, r_K^+ m_K^+ exo V$^-$ (JC 7623); *f*, r_K^+ m_K^+ exo V$^+$ (QL).

exo V digests DNA in the absence of exo I, the production of acid-soluble fragments is delayed to some extent (Fig. 2). Thus the presence of exo I makes, at most, a transient difference in acid solubility and does not affect cleavage by *rgl*.

The products of cleavage and subsequent breakdown were analysed by sucrose gradient centrifugation (Figs 3 and 4). In the absence of exo V the *rgl* systems cut each DNA strand in only a few places and there is but little breakdown of DNA to small acid-soluble or insoluble fragments (Fig. 3*b*). DNA strands from non-glucosylated T4, are intact after infection of a host which contains exo V but lacks the *rgl* systems (Fig. 3*a*). Hosts with both exo V and *rgl* systems yield DNA strands which are much shorter on the average than in exo V$^-$ *rgl*$^+$ hosts, and much of the DNA is lost when the filters are washed with TCA since it is TCA-soluble (Fig. 3*c*). Neutral gradients give results consistent with this interpretation (data not shown), since on *rgl*$^+$ exo V$^-$ hosts the entering DNA is cleaved and sediments as a few peaks, the amplitude of which is greatly reduced in *rgl*$^+$ exo V$^+$ hosts. Thus we have been able to demonstrate the *in vivo rgl* cleavage products of unmodified T4 genomes. This cleavage prevents T4 growth even in the absence of breakdown by exo V (Table 1).

The model in Fig. 1 predicts a very different result for the degradation of the 2$^-$ genome. If restriction is a direct result of exonucleolytic attack, the large DNA fragments should get progressively shorter, and the small single-stranded excised pieces should be produced directly without intermediate sized fragments. Figure 4 shows the time course of degradation of parental 2$^-$ DNA in *rgl*$^+$ exo V$^+$ and *rgl*$^+$ exo V$^-$ hosts. The DNA molecules are gradually shortened, and the excised single-stranded fragments are converted directly to small acid-soluble or insoluble pieces in exo V$^+$ cells. This is consistent with the action *in vitro* of exo V, which degrades double-stranded DNA directly into single-stranded fragments one to several hundred nucleotides long[35]. Since 2$^-$ DNA is fully glucosylated it is not cleaved by the *rgl* system. Figure 4 shows a small amount of short acid-insoluble oligonucleotides sedimenting between 0 and 15% from the top of the gradient. The amount of this material is roughly constant from 1 to 4 min after infection while the total amount of breakdown products as measured by acid solubility rises rapidly (30%, 40%, 45% and 48% in 1, 2, 3 and 4 min, respectively). Thus it seems that exo V, *in vivo*, hydrolyses DNA into oligonucleotides up to 500–600 units long (remaining at the top of the gradients), which may well be the initial products of degradation. These are then further degraded to acid-soluble material by exo V, as has been shown *in vitro*[35]. This secondary degradation to mononucleotides may be aided by exo I which can rapidly hydrolyse short single-stranded DNA fragments of glucosylated as well as non-glucosylated DNA to mononucleotides. This idea is consistent with our findings (Fig. 2) that in exo V$^+$ exo I$^-$ cells, the breakdown of glu$^-$ and 2$^-$ DNA is slower than in exo V$^+$ exo I$^+$ strains. The final ratio of acid-soluble to insoluble

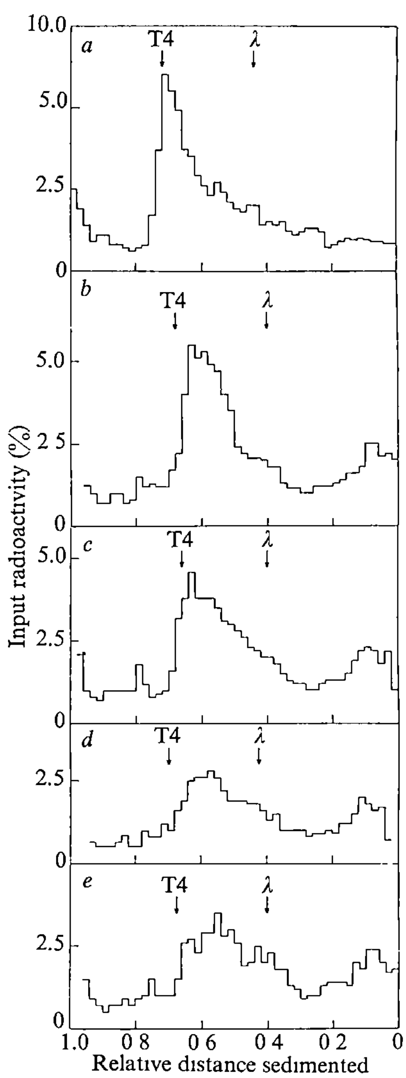

Fig. 4 Kinetics of digestion of T4 2$^-$ DNA *in vivo*. Experimental details were as described in Fig. 3. Aliquots of infected cells were lysed at the appropriate times and 0.2-ml samples were layered on the alkaline sucrose gradients *a*, exo V$^-$ exo I$^-$ (JC 7623) cells lysed 5 min after infection. *b*, *c*, *d*, and *e*, exo V$^+$ exo I$^+$ (B) cells lysed 1, 2, 3 and 4 min, respectively, after infection

material may be due in part to reincorporation of acid-soluble products into acid-insoluble material.

Simmon and Lederberg[27] showed that breakdown of unmodified λ DNA *in vivo* is aided by exo V in restricting hosts, and is independent of other nucleases, like exo I. Based on our data on glu^- T4 restriction, our model (Fig. 1) explains the mechanism of restriction of T4 *in vivo* independently of exo V. According to this model, unmodified λ should be restricted even in exo V^- hosts. Restriction of growth of unmodified λ has already been shown[27]. In restricting exo V^+ cells, at low multiplicities of infection, unmodified λ DNA is broken down to acid-soluble nucleotides (Fig. 3*f*). Only about 10% of the DNA sediments along with the marker DNA, and no high molecular weight intermediates are found in these conditions. Analysis of restriction products in similar conditions in a restricting exo V^- host is shown in Fig. 3*e*. About 75–80% of the λ strands are cut into large fragments of 0.4–0.9 the size of λ. This agrees with the *in vitro* results[9,12] first shown by Meselson and Yuan. The rest of the DNA strands cosediment with whole λ marker strands. Only about 5% of the DNA is degraded to acid-soluble fragments. This indicates that the absence of large intermediates in exo V^+ cells is due to the secondary action of exo V. The efficiency of restriction is more or less the same in restricting hosts whether or not exo V is present.

Localisation of r_6 and $r_{2,4}$

Revel[36] showed that the *rgl* function is controlled by two genes: r_6 which restricts all glu^- T-even phages, and $r_{2,4}$ which restricts only glu^- T2 and T4. Fukasawa[22] proposed that the *rgl* system is a membrane function since modified (glu^+) parental DNA could escape restriction in an rgl^+ UDPG pyrophosphorylase$^-$ host allowing the unmodified (glu^-) progeny DNA to replicate and mature. Fleischman and Richardson[37], however, on the basis of *in vitro* experiments showed that *rgl* acts on replicating DNA. Though their data seem to support a cytoplasmic site for $r_{2,4}$, they point out it may nevertheless be membrane bound. Hewlett and Mathews[38] reinforced the proposal of Fukasawa by showing that superinfecting glu^- T6 is not restricted after T4 *imm*$^-$ primary infection. (The *imm*$^-$ mutation prevents exclusion and breakdown of superinfecting T4 chromosomes). They suggest that the mere attachment of the primary phage inhibits *rgl* functions since the successful passage of the superinfecting glu^- T6 does not depend on primary phage protein synthesis. Silverstein and Goldberg[30] found that successful superinfection of glu^- T4, in contrast to glu^- T6, requires protein synthesis by the primary phage. They suggested that, although r_6 may indeed be localised in the membrane, as Hewlett and Mathews[38] concluded, $r_{2,4}$ is probably cytoplasmic, as suggested by the experiments of Fleischman and Richardson[37]. On the basis of these experiments and those reported below, we suggest that r_6 is a membrane function whereas $r_{2,4}$ is probably cytoplasmic.

Table 2 shows that superinfecting glu^- DNA is broken down in $r_{2,4}{}^+$ cells only when expression of the primary infecting phage is prevented. Expression was prevented either by addition of chloramphenicol before primary infection, or by using heavily ultraviolet-irradiated primary infecting phage, which cannot express many genetic functions after infection (for

Table 2 Localisation of restriction functions $r_{2,4}$ and r_6

Bacterial strains	Chloramphenicol	Primary phage	Superinfecting phage	% DNA breakdown of superinfecting phage

		T4*imm*$^-$	T6glu^-	3
	−	UV.T4	T4glu^-	35
		UV.T4	T6glu^-	9

The log phase cultures were collected and resuspended at a cell density of 5×10^8 cells per ml in broth and three T4 *imm*2 phage were added per bacterium After 5 min two or three ^{32}P-glu^- T4 were added per bacterium. Chloramphenicol was added (100 μg ml^{-1}) when required 3 min before addition of primary phage. Adsorption and DNA breakdown were assayed 5 min after addition of superinfecting phage Wild-type T4 phage (10^{11} per ml) were irradiated in washing fluid[29] for 10 min to a survival of <0.001% These UV T4, killed cells at an efficiency of 90% of unirradiated phage. UV T4 particles were used for primary infection at a multiplicity of 4–5 ^{32}P-T6αgt^{am10am16} grown on K *rgl*$^-$ Su^- were used for superinfection experiments.

example, immunity to superinfection, T4-induced endonuclease[39] and anti-exo V, Table 2). Superinfecting glu$^-$ T6 DNA, however, is protected from breakdown in r_6^+ (with or without $r_{2,4}$) cells by the primary infecting phage, even when expression of the primary phage is prevented by chloramphenicol or ultraviolet irradiation.

Controls of restriction systems

The breakdown of superinfecting glu$^-$ DNA by exo V in an $r_{2,4}^+$ exo V$^+$ cell, in the absence of primary phage expression, implies previous cleavage of the superinfecting DNA by an *rgl* enzyme (Fig. 1). The lack of breakdown of the superinfecting glu$^-$DNA in an $r_{2,4}^+$ exo V$^+$ cell, after expression of the primary phage, is to be expected (whether or not the *rgl* system is working) as the result of the expression of an exo V inactivating activity by the primary infecting phage[40,41]. We have shown that the glu$^-$ superinfecting DNA is not cleaved in $r_{2,4}^+$ cells[42]. Therefore the primary infecting phage must code for an anti-$r_{2,4}$ activity which inactivates $r_{2,4}$ after infection. Thus, the reason that unmodified progeny T-even DNA can replicate from a modified parental template and mature in $r_6^+r_{2,4}^+$ hosts (where unmodified parental DNA is normally restricted) is because the early interaction of the infecting phage particle with the host surface inactivates r_6, and subsequent expression of the unrestricted parental genomes leads to a protein which prevents $r_{2,4}$ action on the unmodified progeny DNA.

It is interesting in this respect that unmodified λ is also not restricted by the cytoplasmic r_K in the presence of the sbcA mutation[27]. It would be interesting to know if the sbcA mutation leads to inactivation of r_K or possibly whether it prevents the action of r_K on the unmodified λ chromosome.

There is a series of proteins produced by the phage which protects its DNA at various stages of infection (see refs 43 and 44). The phage coat itself is a group of proteins protecting the DNA during transfer from one host to another. The gene 2 protein of T4 protects the DNA from exo V when entering the host. We predict that analogous proteins will be found on other double-stranded linear DNA containing phage possibly gene 2 of phage T7)[44], especially since many of them also make a protein which inactivates exo V (refs 40 and 41). We also think that a protein attached to the DNA terminus may have other functions in morphogenesis, injection and expression, similar to the "pilot" protein of single-stranded DNA phage[45]. T4 phage also codes for an activity which blocks $r_{2,4}$ restriction endonuclease[42]. The presence of 20–25% of intact λ strands after infection of r_K^+ exo V$^-$ cells at a multiplicity of 2–3 may reflect unadsorbed and unrejected DNA, but it may also reflect protection of some late entering chromosome from r_K by an anti r_K-activity synthesised from the large cleavage fragments of the first genome which entered.

The restriction–modification system seems to serve as a defence and speciation mechanism which can alter the genetic effectiveness of entering DNA which it thereby defines as foreign[46-48]. Restriction cleavage of the DNA will prevent the phage production but not necessarily expression of much of its genome. Subsequently, breakdown prevents, in addition, most gene expression[29] but still makes possible rescue of many genetic loci[23,49]. We are currently investigating the expression of the cleavage products of phage DNA *in vivo*.

Ariel V sky survey observations of X rays from the globular cluster candidates 3U2131+11 and MXO513–40

THE high energy (2–18 keV) detector system of the Ariel V X-ray sky survey experiment (SSE) has observed the faint, high galactic latitude X-ray sources 3U2131+11 and MXO513−40 on a number of separate occasions over a period of a year (January–December 1975) and the results are reported here. These sources have previously been observed by OSO-7 (and 3U2131+11 also by Uhuru), and the globular clusters NGC 7078 and NGC 1851 respectively, were proposed as identifications[1,2]. Variability of the timescales of days to months was also observed[2].

The SSE instrument and data analysis are described elsewhere (ref. 3 and G. Villa *et al.*, unpublished). The 90% confidence error box for the source location is determined from combining the individual positional measurements by calculating the product of the probabilities of the source having been found at any given point during a single scan[4,5].

Figures 1 and 2 show the error boxes for 3U2131+11 and

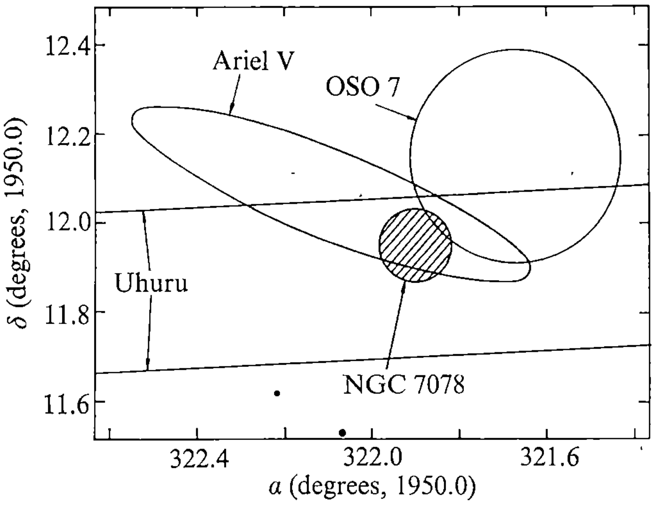

Fig. 1 Positional error boxes for the X-ray source 3U2131+11 associated with NGC 7078, from Ariel V, OSO-7 and Uhuru

MXO513−40 from the Ariel V sky survey, together with those from OSO-7 (ref. 2, and from Uhuru[1], for 3U2131+11). The Ariel V error boxes reduce the uncertainty in the locations of the sources and support the previous identifications[1,2] of 3U2131+11 = NGC 7078 and MXO513−40 = NGC 1851. The centroids of our 90% confidence error boxes have celestial coordinates (α, δ, 1950.0) and areas as follows

3U2131+11: (322.10°, 12.07°), 0.15 degree^2

MXO513−40: (78.19°, −40.13°), 0.066 degree^2

Figures 3 and 4 show, for the two X-ray sources, the intensities observed by Ariel V. Each data point consists of a summation of observations over a period of 1–2 d. Clark *et al.*[2] have reported variability of factors $\sim$2 and $\sim$5 for 3U2131+11 and MXO513−40 respectively, on timescales of days to months. For 3U2131+11 the intensities measured by Ariel V (Fig. 3) are consistent with a constant value of $\sim$2 Ariel V counts s^{-1} (2–18 keV). They are also consistent with the variability $\sim$2 reported from OSO-7 (ref. 2), but it seems unlikely, from Fig. 2, that the variability greatly exceeds this level, as all 9 statistically significant intensity measurements ($\gtrsim 3\sigma$) from Ariel V are within a factor 2 of each other.

The Ariel V observations of MXO513−40 show intensity variations of a factor $\sim$6 over periods of $\sim$10 d, consistent with the OSO-7 data[2]. The range of intensities recorded was $\sim$1–7 Ariel V count s^{-1} (1 Ariel V count $\simeq$ 2.7 Uhuru counts, 1 OSO-7 counts $\simeq$ 15 Uhuru counts[6,7] for a spectrum like that of the Crab Nebula). Of particular interest is a set of six observations centred on 17 February 1975 (MJD42460) covering a period of $\sim$20 d (see Fig. 4). These observations suggest flare-like behaviour, the source intensity increasing from < 1 to $\sim$6 Ariel V counts s^{-1} in 12 d and then falling back to the original level on a similar timescale. Combining the two 'flares' with the Ariel V data at $\sim$MJD42460 and 42605, with a similar emission peak from OSO-7 at $\sim$MJD41700 (see Fig. 4), reveals a possible periodicity in flaring of (160±20) d (or sub-multiple of this period).

Being highly evolved, globular clusters appear ideal sites for capture binary systems or massive central black holes. Both have been used in explaining the globular cluster X-ray sources, the emission being assumed to result from appreciable matter accretion (see refs 8–11). In each case the X-ray emission should arise close to the centre of the cluster, and our results are consistent with such a location. For MXO513−40, our X-ray error boxes do not favour identification with any particular optical object in NGC 1851, of those that have been suggested[12,13], though it may be significant that both the Ariel V and OSO-7 error boxes lie to the same side of the cluster centre. Therefore it is necessary to obtain a still more precise location for the X-ray source.

Finally, we note that none of the theories so far put forward explicitly accounts for the variability on timescales of days and longer, observed by Ariel V and OSO-7. Thus it is important to monitor the X-ray emission and search for correlated variability in the candidate optical counterparts. X-ray spectral data will also be useful in testing the theories for the emission[6,11].

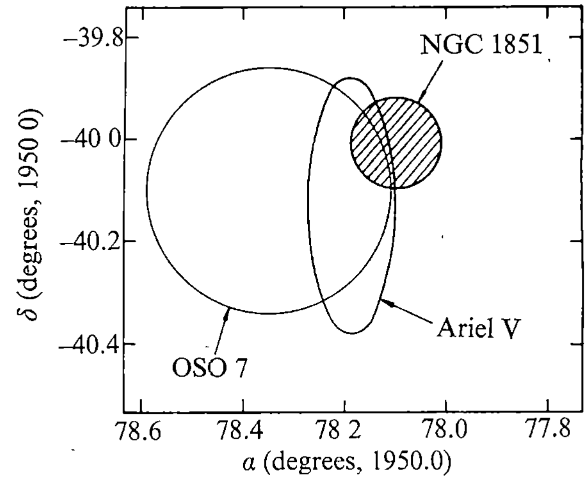

Fig. 2 Positional error boxes for the X-ray source MXO513−40 associated with NGC 1851, from Ariel V and OSO-7.

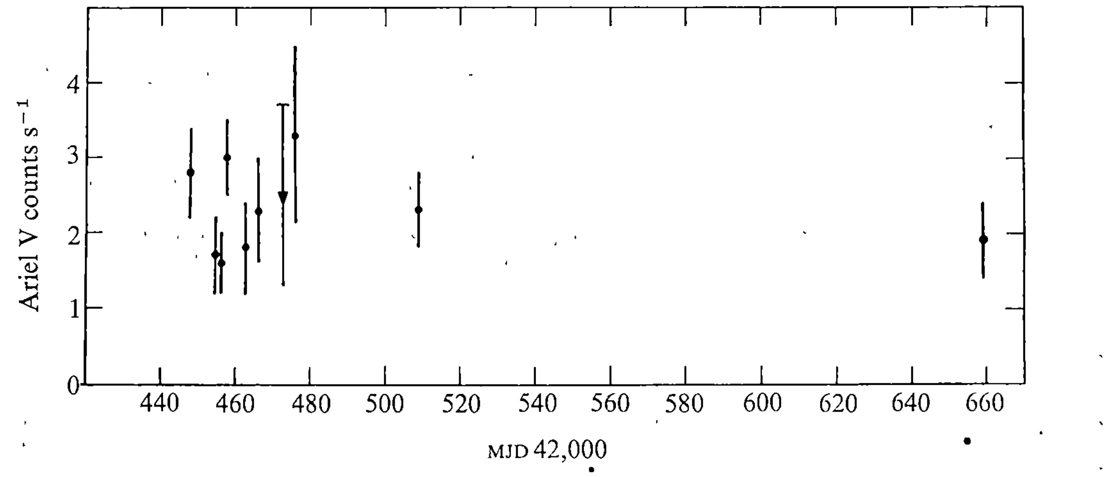

Fig. 3 Ariel V observations of intensity against time for 3U2131+11. Error bars are $\pm 1\sigma$

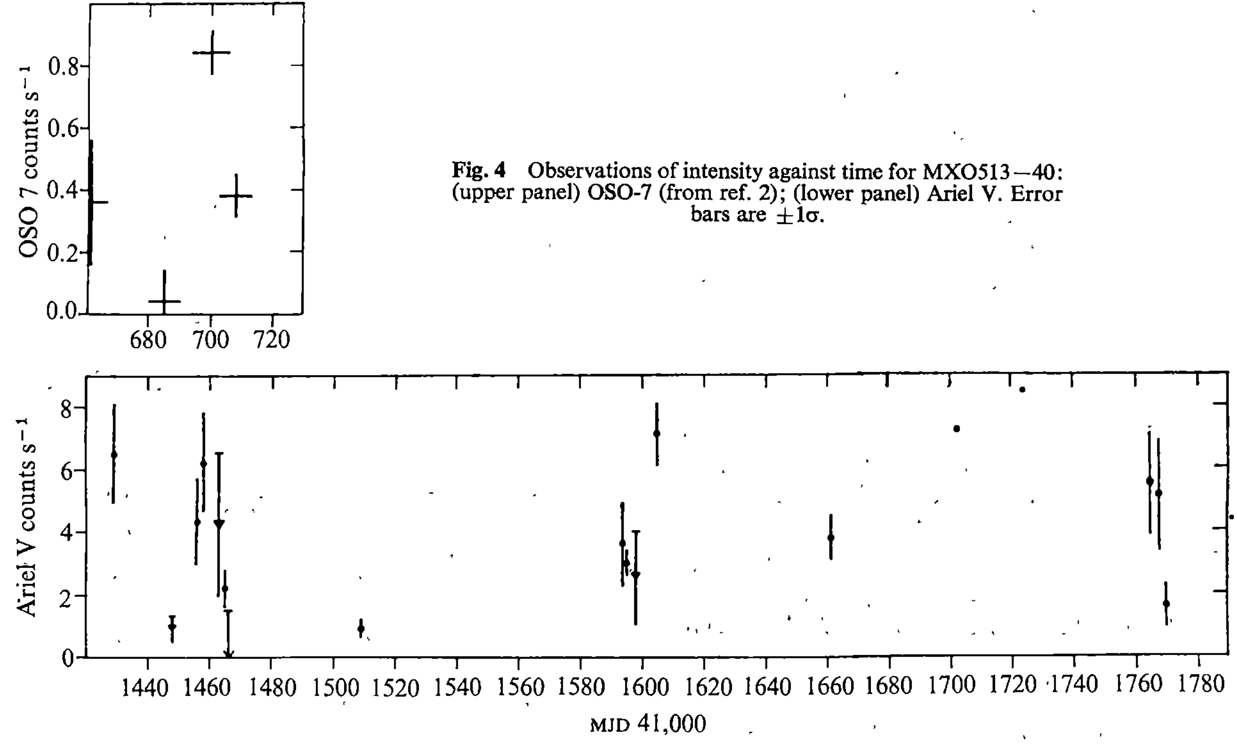

Fig. 4 Observations of intensity against time for MXO513−40: (upper panel) OSO-7 (from ref. 2); (lower panel) Ariel V. Error bars are $\pm 1\sigma$.

We gratefully acknowledge the use of data analysis computer programs written by Dr C. G. Page and M. G. Watson. The Ariel V project is supported by the SRC who also provided a research associateship for J.P.P.

Note added in proof[8]: Jones and Forman have recently reported[14] an Uhuru observation of an X-ray burst from the vicinity of MXO513−40. We note that the peak intensity of MXO513−40 observed by Ariel V could be supplied by about two such bursts per orbit.

New galactic population class

GALACTIC γ rays have been shown to come from regions where H_2 is dense, and where also 'population I' objects are predominantly found. The existence of such regions can be interpreted using the density-wave model of spiral galaxies, and leads us to propose here a change in the Baade classification scheme: 'population I' now to include all the objects associated with the H_2 clouds, and a new class, 'population 0', to refer to the regions, relatively richer in atomic hydrogen, which lie further from the galactic centre.

Satellite observations[1] imply that γ-ray emission is highly non-uniform in the Galaxy, and that its emissivity distribution peaks about halfway between the Sun and the galactic centre[2–4]. Analysis of the final SAS-2 data places this peak emissivity in the region between 5 and 6 kpc from the galactic centre[5]. The γ-ray emissivity distribution bears a strong similarity to the distribution of molecular clouds in the Galaxy[6] which also peaks in the 5–6-kpc region[7,8]. This similarity, coupled with the lack of enough gas in atomic form (H I) to explain the γ-ray measurements led to the supposition that H_2 is far more abundant in the inner Galaxy than H I, and that H_2 has the major role in producing galactic γ rays[6,8,9]. In fact a γ-ray emissivity which scales like the more uniform H I distribution cannot explain the observations. Recent studies indicate that the volume averaged density of H_2 is ~ 2–3 molecules cm^{-3} in the 5–6-kpc region and drops off dramatically at <4 kpc and in the outer Galaxy, so that at 10 kpc at least half of the interstellar gas is probably in atomic form[9]. There is a negligible amount of H_2 in the outer regions of the Galaxy[7,8]. A deduction of the implied cosmic-ray distribution from the γ-ray observations shows that the cosmic rays increase (relative to the local intensity) by a factor of ~2 (ref. 9) or slightly more[5] at a maximum coincident with the maximum in the gas density, in the 5–6-kpc region, and that the cosmic rays drop off rather rapidly in the outer Galaxy[9,10]. The cosmic-ray distribution deduced using the γ-ray observations in conjunction with the deduced variation of total gas (H I+H_2) in the Galaxy is, within experimental error, identical to the distribution of supernova remnants[11] and pulsars (refs 12 and 13, and J. Sieradakis, personal communication). The similarity of the deduced cosmic-ray distribution and the distribution of super nova remnants provides our strongest evidence to date that the observed cosmic-ray nucleons, which make up 99% of cosmic rays, originate in galactic supernovae, in either the explosion or the resulting pulsars[14].

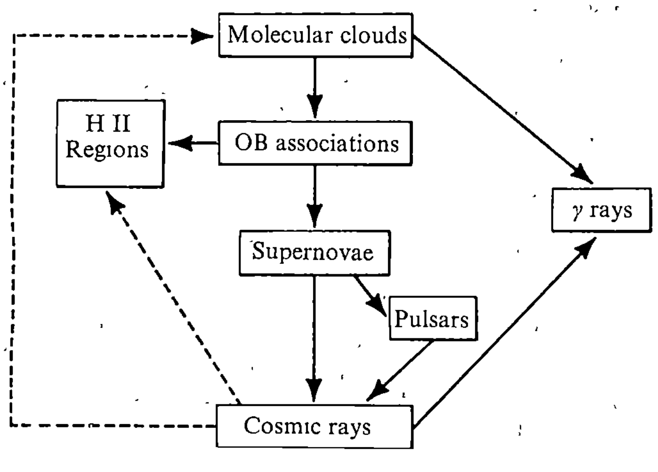
On the large scale, therefore, there appears to be an excellent correlation between several important constituents of the Galaxy in terms of their distributions as a function of galactocentric distance. These constituents are molecular clouds, H II regions (ionised hydrogen), cosmic rays, γ rays, supernova remnants and pulsars. All of these constituents of the Galaxy seem to be densest in the 5–6-kpc region and seem to drop off sharply inside of 4 kpc and in the outer Galaxy. They all can be associated with the formation and evolution of the population I stars in the Galaxy and are known to have a population I distribution[15,16]. They are associated with the formation and destruction of hot young O and B stars in the Galaxy, which delineate the arms in other spiral galaxies. That the correlation of these components is natural can best be seen in Fig. 1. The gravitational collapse of molecular clouds is expected to lead to the formation of OB associations containing the massive, hot, short lived O and B stars whose ultraviolet radiation causes the formation of zones of ionised gas around them (H II regions). The massive O and B stars, after a few million years, terminate their existence as supernovae, which in turn leads to the generation of cosmic rays. It has also been suggested that supernova explosions can trigger the formation of new OB associations 'in a feedback effect' (ref. 17, and H. B. Ogelman and S. P. Maran, unpublished). The compound effect of cosmic rays and molecular clouds being enhanced in the same region of the Galaxy then leads to an even stronger enhancement of the γ-ray emissivity in this region. In addition, an increase in the flux of subrelativistic cosmic rays may help lead to an increase in the amount of ionised gas in the region ~5 kpc, as indicated in recent surveys (ref. 18 and F. J. Lockman, personal communication).

Whereas all of the above components of the galaxy have correlated large scale galactic distributions, 21-cm radio observations of H I indicate a relatively constant overall density distribution of atomic hydrogen between 4 and 14 kpc from the galactic centre with no evidence for a significant enhancement in the 5–6-kpc region[8,19]. This implies that the H_2 distribution is much more sensitive to the compression effects expected in density-wave models of galactic structure than the more diffuse H I with the ratio H_2/H I having a radial galactic dependence somewhat similar to that of H II/H I as discussed by Shu[20].

There is a large variation in structural details among spiral galaxies. This range of detail, from those with long thin well developed arms and high surface brightness (van den Bergh type I) to those with only a bare hint of arm structure (van den Bergh type V) has been incorporated into the general framework of density wave theory by Roberts *et al.*[21]. The galaxies with well developed arms and high surface brightness with an implied star formation rate are found to satisfy the condition $(W_\perp/a) > 1$ where $W_\perp$ is the velocity component of baxic rotation normal to the spiral arms and a is the effective acoustic speed of the interstellar gas. In the inner regions of galaxies, there can exist zones of strong nonlinear compression where $(W_\perp/a) > 1$ and in the outer regions, zones of weak linear compression where $(W_\perp/a) < 1$. Burton[22] has estimated that the interface between these two zones in our Galaxy occurs at a galactocentric radius $R \sim 10$ kpc.

Figure 2 shows the smoothed radial distribution of mean surface densities of the atomic and molecular components of interstellar gas in our Galaxy based on the recent data of Burton *et al.*[8], where the H_2 density is normalised according to the methods of Stecker *et al.*[9] and using a scale height of ~65 pc for the molecular cloud distribution (based on the larger sample given in ref. 7). Also shown are the regions of weak and strong compression. It can be seen that the transition region near 10 kpc is one in which the total surface density is roughly constant but where larger and larger amounts of gas are converted from H I to H_2 as R decreases.

Fig. 1 Relationship between various 'population I' galactic components.



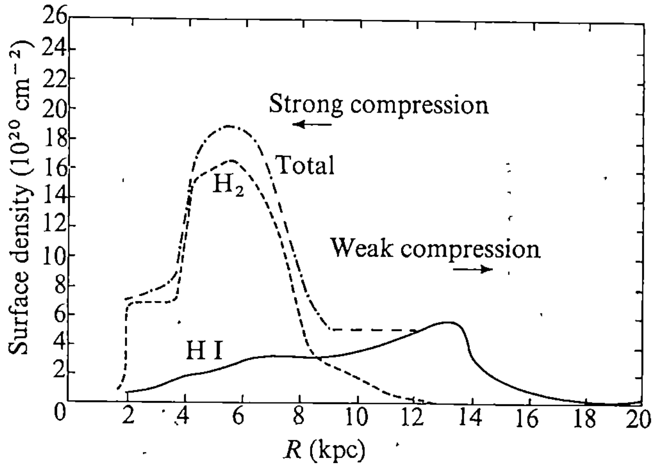


Fig. 2 Surface density distribution of H I, H_2 and total gas as a function of galactocentric radius (see refs 8, 9). The H_2 data are slightly different than those given in ref. 7, but can be considered qualitatively the same for the purpose of the present discussion. The graph illustrates the general separation of H I and H_2 components in the Galaxy and the correlation of these components with the weak compression and strong compression regions of the galactic disk respectively.

These recent observational and theoretical developments (and see also ref. 22) prompt me to suggest the following changes in the Baade[23] classification scheme for galactic objects: first, the classification 'population II', which consists of old disk stars ('high velocity stars'), nuclear bulge stars, halo stars and globular cluster stars stays the same.

Second, the classification 'population I' should be expanded to include all galactic objects narrowly confined in the galactic plane and associated with the formation of population I stars. Thus the set of galactic objects of population I will include molecular clouds, OB associations, H II regions, dark nebulae, dust, supernovae, and even associated radiation fields such as infrared, synchrotron and π^0-decay γ radiation from molecular clouds. This population is expected to predominate in regions of the galaxy where $(W_\perp/a) > 1$ (strong compression)[8,21,22].

Third, I define a new class, 'population 0', consisting of the more diffuse atomic hydrogen which is now considered not to have a primary role in star formation. (In the case of some of the denser H I clouds there may be some blurring of definition.) This population will be important in regions where $(W_\perp/a) < 1$ (weak compression). The main distinction between populations 0 and I stems from the effect of compression with the higher compression regions caused by the nonlinear density waves. These effects result in the marked differences in distribution and dynamics between the two populations. For instance, the population 0 component will have a scale height perpendicular to the galactic plane $\geq$ 110 pc, and a galactocentric radius of maximum surface density of 12–13 kpc. For population I objects these figures would be ~40–70 pc and 5–6 kpc respectively.

It is found that in late-type spiral galaxies it is characteristic for the neutral hydrogen density to peak well outside the visible radius of the galaxy[24]. The above classification, with population 0 removed from a primary role in the star formation process, naturally accommodates this hitherto somewhat mysterious fact.

Volcanic triggering of glaciation

AN instantaneous glaciation model for the formation of the large Pleistocene ice sheets has been proposed by Flohn[1] and by Ives *et al*[2]. It depends on the sudden buildup of a permanent snow cover over sub-Arctic upland plateaux including Baffin Island, Ungava, Labrador and Keewatin, Melville Peninsula, and the Finnmark Plateau and upland Sweden. The crucial event in this sudden snow buildup is the survival of snow over a large area for a single summer which then results in a series of feedback reactions leading to the establishment of permanent snowfields and, subsequently, icefields. I suggest here that such a survival could have resulted from one or several closely spaced massive volcanic ash eruptions.

Barry *et al.*[3] have stated that the climatic change needed to initiate the buildup of large permanent sub-Arctic snowfields may be quite small, but no quantitative estimates have been made of the conditions which could result in the large-scale survival of snow for a single summer. The most likely of these conditions would be a greater than normal winter snow accumulation followed by a cold, cloudy (or hazy), snowy summer, with a dearth of warm storms and a greatly decreased input of solar radiation. Volcanic eruptions over the past several centuries for which climatic data are available have enhanced these conditions, as is evidenced first, by a decrease in solar radiation which in latitudes 30–50° varies from 20 to 30% (refs 4 and 5); second, a decrease in the daylength of effective summer insolation[6]; third, a decline in mid-latitude yearly temperatures of 0.5–1.8 °C and in summer temperatures of up to 2–3 °C, (these declines lasting from 3 to 7 yr, and 10–15 yr at the higher latitudes)[5-7]; and fourth, a possible increase in precipitation (many of the coldest and wettest summers in Europe, North America and Japan have followed volcanic eruptions[6,8]) resulting from increased stratospheric dust of micron and sub-micron size which could descend into the troposphere and serve as freezing nuclei[9].

The effects of volcanism on temperature would be at least twice as great at the higher latitudes judging by temperature data supplied by Schell[10]. Volcanism would also lead to fewer warm storms over the sub-Arctic, which would mean less snow pack ablation[7,11], and to a higher frequency and intensity of summer snow storms with a resulting increase in albedo.

Such climatic effects came to maxima during the two largest volcanic eruptions since AD 1500—in 1815 and 1835. The eruptions respectively had Dust Veil Indexes of 3,000 and 4,000, total volume of tephra of 100–300 km^3 and 50–150 km^3 and volumes of atmospheric dust production of around 15 km^3 and 12 km^3 (ref 6). These eruptions were considerably less intense than some of the large Pleistocene eruptions, one of which[12] had a rhyolytic pumice and ash production of more than 900 km^3. The maximum yearly mid-latitude temperature decline in the first several years following the 1815 and 1835 eruptions was around 1.0 to 1.7 °C, and the maximum decline in summer temperatures was 2.2–2.3 °C. The temperature depression following a massive eruption of around 900 km^3 would depend on the total atmospheric ash production from the eruption and could be at least three times those averages in mid-latitudes and at least six times in sub-Arctic regions. There is also the possibility that a massive eruption north of the equatorial region at the right time of year would block almost all direct solar radiation during the entire summer in the sub-Arctic.

Considering the possible climatic effects of volcanism, I suggest that a massive tephra eruption (that is, 300–900 km^3 or larger) could have produced sufficient atmospheric dust to promote the summer survival of the snow pack on sub-Arctic plateaux. Survival would be especially likely if there were large eruptions two or more years running. Once such a survival of summer snow had occurred, it could have led to the autocatalytic growth of permanent snowfields as outlined by Flohn[1] with the following modifications: first, as a result of the original ash eruption or eruptions, the feedback process would be reinforced, leading to a greater probability of snowfield survival in the second and subsequent summers, since the lowered temperatures and decreased solar radiation would occur for at least several summers, especially at the higher latitudes; second, increased albedo and lower temperatures could result from an increase in the area of sea ice (such as occurred after the 1912 Katmai eruption[13]), which would augment the increased land albedo resulting from the survival of summer snow. Flohn[1] has indicated that the high surface albedo of a snowfield that has survived a single summer would prevent its early destruction and has outlined some steps by which a 15-m tall forest on the Ungava plateau could be covered by snow within 22 yr after a summer in which the upland snow did not melt.

If a sub-Arctic snow pack survived into early or mid-summer as a result of a massive ash eruption, then there is a possibility that the thermal condition of the land surface could contribute to further snow survival. An example[14] of this sort of feedback mechanism is the anomalous summer of 1968 during which cold sodden ground and an increased level of snow survival in parts of northern Eurasia in the early summer led to the formation of a stationary upper cold trough over north-eastern Europe and north-western Siberia. The trough persisted with the aid of thicker sea ice to the north, and it contributed to the survival of the snow pack in some areas until late June or early July and to the occurrence of early snowfalls from late July to late August. Flohn[1] has suggested that such a superimposed cold low resulting from the large-scale survival of summer snow would force the upper air to curve cyclonically and thus increase snowfall.

There is evidence of an increased area of permanent snow on the sub-Arctic plateau during the recent Little Ice Age[2,3,14,15] and during a previous neoglacial phase around 2,400 yr BP (ref. 16). It is not possible to estimate the relative importance of volcanism in those increases, though both periods were characterised by significant increase of volcanic activity[17]. Whatever the total increased area of snowfield, it was not sufficient to trigger the formation of a large ice sheet, and as a consequence both periods could be considered "abortive glaciations" in the sense of Flohn[1] and Ives *et al.*[2]. Had a massive eruption occurred during these phases of increased volcanism and glaciation, then it is quite conceivable that an increase in the area of permanent snow cover might have occurred to the point at which the albedo increased and temperature fell sufficiently to permit the snowfields to survive. If that occurred, then large, mid-latitude ice sheets may have subsequently formed.

For the volcanic triggering proposed here to operate, the Earth must be in the proper stage of its glacial–interglacial cycle, that is, a genuine interglacial must be occurring so that there is sufficient heat in the oceans to energise the transport of large volumes of water over the sub-polar plateaux[18].

If a massive ash eruption occurs when the Earth is experiencing a major ice-sheet advance, then it would have little climatic impact, nor, according to Adam's model[18], would a large eruption have much impact in the early stages of glacial retreat. If, however, a large ash eruption occurred after a massive retreat of the mid-latitude ice sheets, then sufficient cooling over upland plateaux could result in year-round snow cover. If so, then a major glacial readvance could occur, always assuming that sufficient heat had been stored in the oceans to transfer enough water to the snowfields.

The possibility that large Pleistocene ice sheets were initially triggered by massive volcanic eruptions is not contradicted by the geological record. There is an apparent correlation between major phases of global ice advance and ash eruptions in New Zealand, Japan and southern South America over the past 42,000 yr (ref. 17). A compilation of further information on volcanism from these areas and from North America and Europe, which I have recently made, supports this conclusion. The much higher rate of explosive volcanism throughout the Pleistocene has already been suggested as an indication of a possible link between volcanism and glaciation[19,20].

Changes in V_P/V_S before the Tokachi-oki earthquake of May 16, 1968 off NE Japan

THE detection of premonitory variations in the ratio of compressional to shear wave velocities is one of the most promising tools for earthquake prediction[1,2]. Changes in V_P/V_S for some moderate sized earthquakes ($M \simeq$ 5–6) located on Japanese islands have been found[3,4], and for shallow, small to moderate sized earthquakes ($M < 7$) located on continents. For large submarine earthquakes ($M \simeq 8$), however, velocity changes have not previously been reported.

The Tokachi-oki earthquake of May 16, 1968 ($M = 7.9$; focal depth 0 km) occurred near the junction of the Japan Trench and Kurile-Kamchatka Trench. Although earlier work[3] had shown no changes in seismic velocities (nor for the Sanriku-oki earthquake ($M = 7.5$) of 1960, also in the same area), I have carefully reanalysed arrival times before these two earthquakes and found significant variations in V_P/V_S. So far as I know, this is the first time that a change in V_P/V_S before and after a great submarine earthquake ($M \simeq 8$) has been detected.

The events that occurred in the focal zone of the Tokachi-oki earthquake (May 16, 1968) during 1951–74 were selected from the Seismological Bulletin of the Japan Meteorological Agency for analysis. The 1968 Tokachi-oki epicentre and after-shock area, together with the stations used for this analysis are shown in Fig. 1. The swarm earthquakes of 1952 (maximum $M = 6.5$) and the Sanriku-oki earthquake of 1960 are also included. Three station combinations, such as Hachinohe(HAC)–Aomori(AOM), Miyako(MIY)–Akita(AKI) and Urakawa(URA)–Obihiro(OBI) were selected for the V_P/V_S calculations. The apparent ratio of compressional to shear velocities was calculated by

$$V_P/V_S = [t_S(A) - t_S(B)] \,/\, [t_P(A) - t_P(B)]$$

where t_P and t_S denote arrival time of P and S waves at the corresponding stations. The V_P/V_S ratio from each combination was selected with the restrictions that the source depth must be $\leq$ 40 km, and that $1.00 < V_P/V_S \leq 2.00$.

The results are illustrated in Fig. 2. Figure 3 shows a typical example of Δt_S against Δt_P for chosen periods of time for the HAC–AOM combination. Long range premonitory changes in V_P/V_S before the 1968 Tokachi-oki earthquake are clearly seen for the HAC–AOM and URA–OBI combinations, but less so for the MIY–AKI combination. These anomalies in V_P/V_S cannot be attributed to a biased distribution of events used for the analysis because there is no obvious difference in the geographical distribution of epicentres for the normal period and the anomalous one (see Fig. 4).

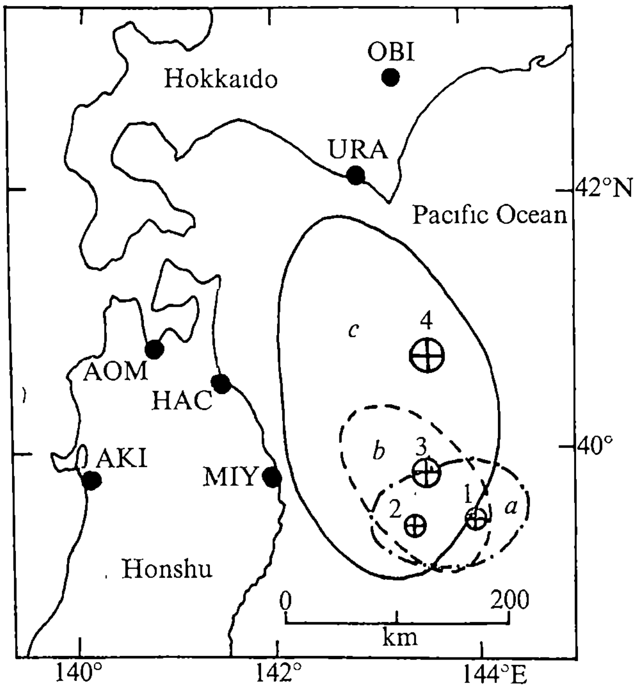

Fig. 1 Locations of the 1968 Tokachi-oki earthquake and siesmograph stations of the Japan Meterological Agency (●) Region *a*; area of the swarm earthquakes in October 1952 with the two largest events of magnitude 6.5 (refs 1, 2) Regions *b* and *c*; after-shock areas of the Sanriku-oki earthquake of March 21, 1960, with magnitude 7 5 (ref. 3), and the Tockachi-oki earthquake of May 16, 1968, with magnitude 7.9 (ref. 4), respectively.,

This long range variation was disturbed by the 1952 swarms and the 1960 Sanriku-oki earthquake. The change before the latter was especially pronounced. The 1968 earthquake occurred 4 yr after V_P/V_S returned to normal.

We may identify only the latter half of the precursory interval, the so-called recovery phase, as is seen in Fig. 2. Unfortunately, we cannot know the V_P/V_S ratios in the decreasing stage, because of the scarcity of data published by

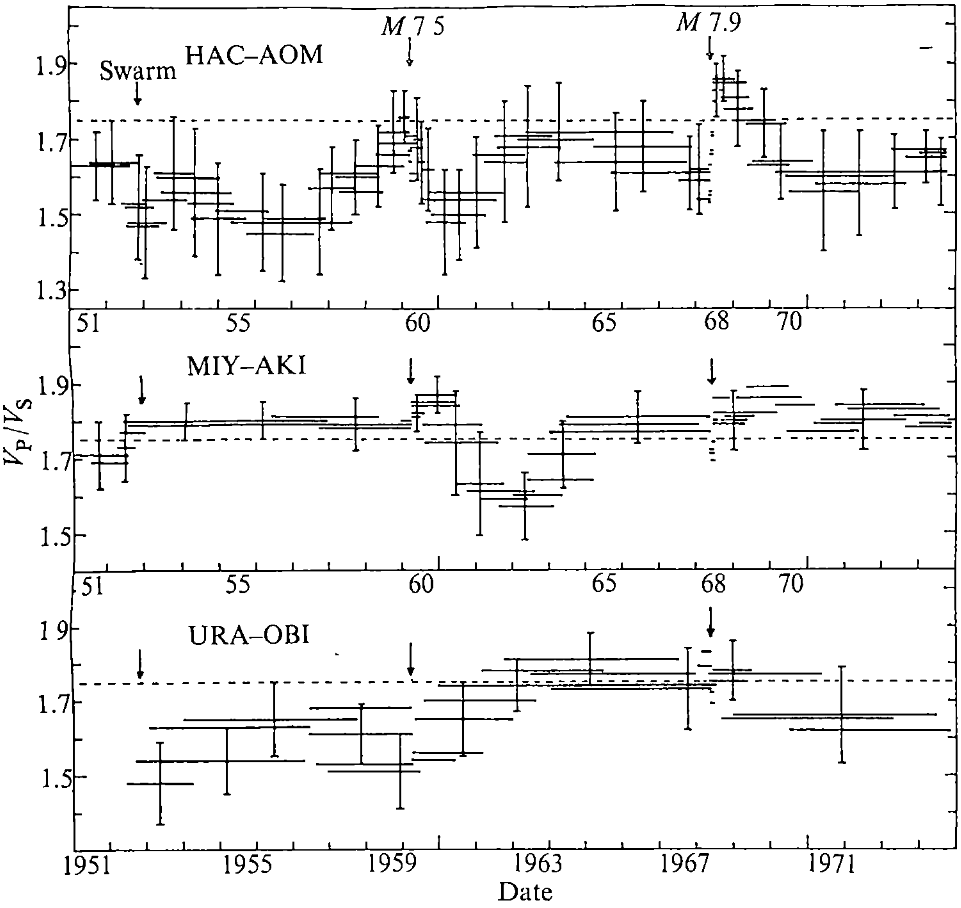

Fig. 2 The variation of V_P/V_S as a function of time before and after the Tokachi-oki earthquake of 1968, for the three station combinations. Horizontal bars show the means for a running time window of ten events stepped by two with its length indicating the time period covered by each window Vertical bars indicate the 90% confidence limits of the means of some representative windows.

the Japan Meteorological Agency before 1950. The latter half of the precursory interval before the 1968 Tokachi-oki earthquake, however, indicates that a 10–17% decrease in V_P/V_S had occurred, assuming a normal value of 1.75.

Whitcomb *et al.*[5] have proposed that the earthquake magnitude (M) and precursory anomaly time (t), deduced from V_P/V_S data, are related by

$$\log t = 0.68M - 1.31$$

where t is in days. From this, the precursory intervals are expected to be 17 yr for an $M = 7.5$ event and 32 yr for $M = 7.9$, respectively. Consequently this analysis is considered to cover almost the whole recovery period, although we cannot decide

Fig. 3 Plots of Δt_S as against Δt_P for three typical periods of time in HAC–AOM combination, each interval including ten events. *a*, Anomalously low stage, October 1, 1955– August 22, 1957, mean and 90% confidence limits V_P/V_S = 1.45±0 13. *b*, Normal stage, May 17, 1963–March 31, 1965, V_P/V_S = 1.72±0.13. *c*, Anomalously high stage, June 26, 1968–May 3, 1969; V_P/V_S = 1.85±0.06.

Experimental examination of the gravitational inverse square law

IN a previous paper[1] we pointed out that earlier data on the measurement of the gravitational constant suggest a systematic shift in the value with the separation of the masses. This laboratory has been examining this question for about a year, and the early data gave a discrepancy of 0.4%. New, intensive experiments have given 92 data points, with a resulting discrepancy of 0.37%.

Our experiment compares the gravitational constant at a mass separation of 29.9 cm with the value at a separation of 4.48 cm. To expedite this comparison the gravitational torque signals are kept about the same by using a much larger mass at the greater distance. Following the ingenious suggestion of Faller and Koldweyn (unpublished; see also ref. 2), we have used rings for the attracting mass because the field is very flat at the 'Helmholtz' point and thus the positional accuracy need not be very great. The far ring is made of centrifugally cast brass and has a mass of 57,580.83 g. The near ring is made of pure tantalum with a mass of 1,225.271 g. The far ring has an outside radius of 27.112 cm, an inside radius of 21.589 cm, a thickness of 7.633 cm, and the field maximum is located on the ring axis 17.415 cm from the face of the ring. The near ring has an outside radius of 4.5536 cm, an inside radius of 2.7513 cm, a thickness of 1.7765 cm, and the field maximum is located on the ring axis 2.6088 cm from the face of the ring.

Table 1 Error contributions to Δ_{thy}

Source	Error
Torsion pendulum assembly balance	0.00007
Big ring floor tilt	0.00005
Big ring–pendulum assembly interaction	0.00036
Small ring–pendulum assembly interaction	0.00004
Big ring mass, dimensions and position	0 00031
Small ring mass, dimensions and position	0.00012
Attracted ball sphericity	0.00001
Ring density inhomogeneity	0 0001
Total error	0.00051

The gravitational force was detected with a 48.6-cm Cavendish torsion balance suspended by a 0.002-inch tungsten fibre. The attracted ball, with a mass of 50 g, was made of tantalum and hung by two fibres 87 cm below the balance rod. This reduced the gravitational torques caused by the pendulum rod and counter balance ball. The pendulum hung in a vacuum of 1×10^{-7} mmHg and the vacuum chamber wall temperature was controlled to ±0.01 °C. Substantial effort went into mounting the apparatus to reduce vibrations (diffusion pumps vibrate badly) and the pendulum hung from a vibration damper suggested by Liebes. The position of the pendulum was detected by a beam of light which was split into a two-photodiode null detector.

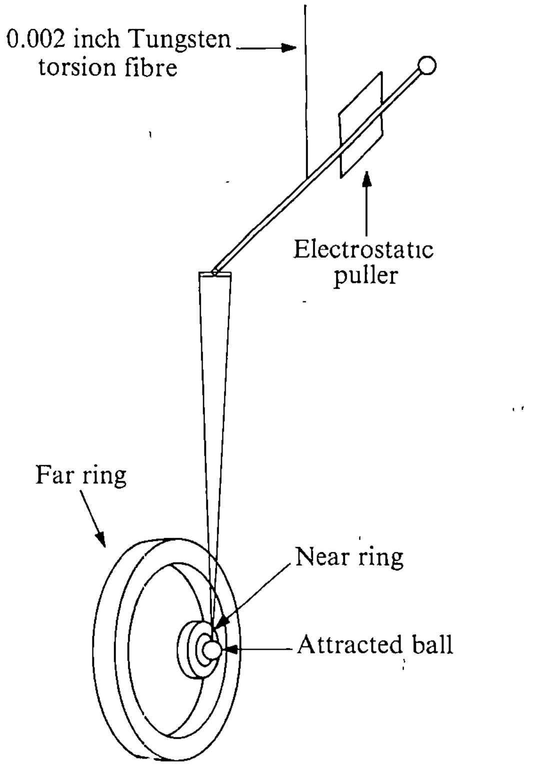

Fig. 1 Apparatus schematic illustrating the positions of the rings. The rings are used one at a time and alternately.

Another important aspect of the experiment was the use of an electrostatic puller to balance the torque of the rings. The experiment was operated in such a way that the attracted ball did not change its position appreciably. The balance voltage (squared) was the measured gravitational torque signal in the experiment; several voltages would be tried which gave an output just slightly off null and the correct null voltage would be interpolated from them.

The quantity measured in the experiment was

$$\Delta = \frac{\tau_{far} - \tau_{near}}{\tau_{near}} \tag{1}$$

where τ_{far} is the total torque produced by the far ring and τ_{near} is the total torque produced by the near ring. The Newtonian value of $\Delta(\Delta_{thy})$, was calculated by finding the torque produced by each ring on the attracted ball and each element of the pendulum assembly. Numerical integration over the rings was used to find

$$\Delta_{thy} = 0.03807 \pm 0.0005$$

where the error analysis is given in Table 1.

Table 2 Error contributions to Δ_{exp}

Standard deviation of the mean of the data	0.00015
Signal against voltage proportionality constant	0 00015
Contact potential	0.00028
Small ring torque	0.00027
Total error	0.00044

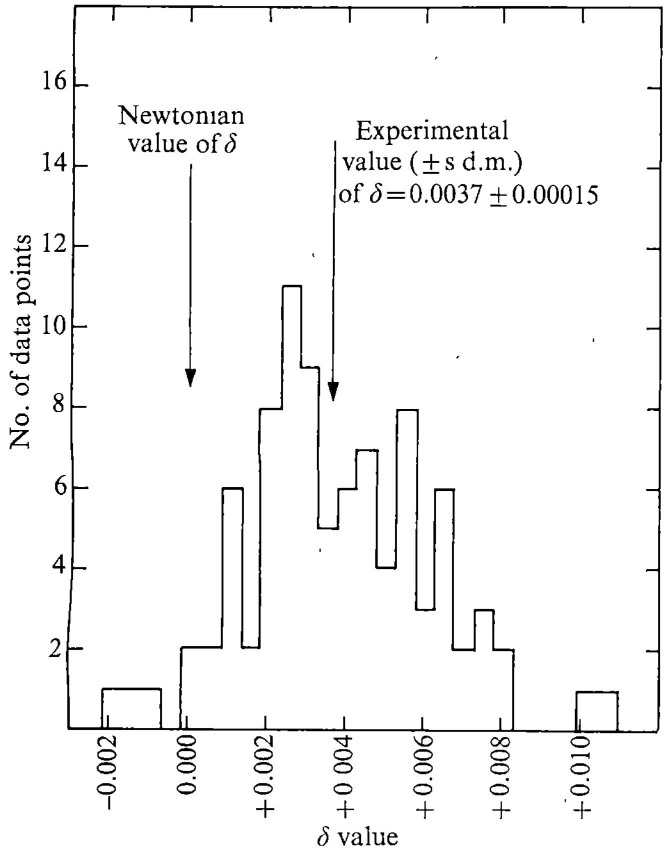

Fig. 2 Histogram of 92 δ values.

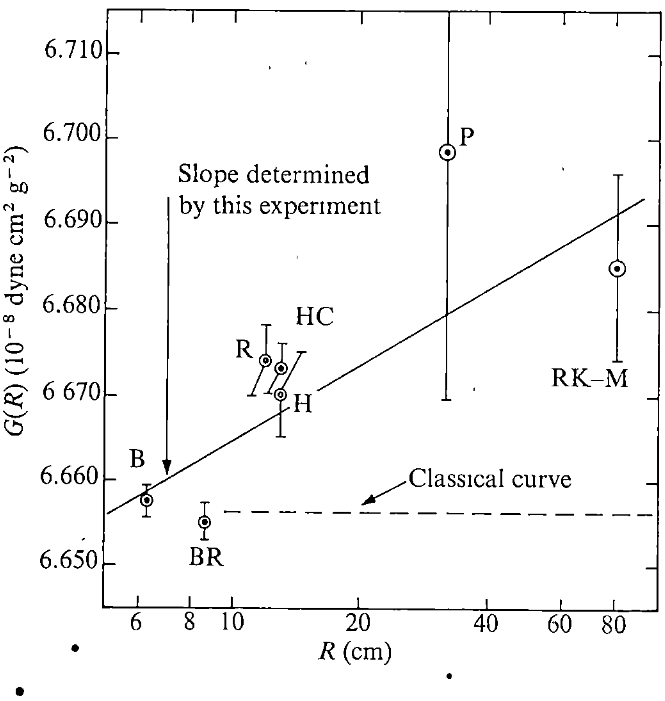
Δ_{exp} was found by directly measuring the torque difference $\tau_{far}-\tau_{near}$ by first putting one ring and then the other in position. This gave

$$\Delta_{exp} = 0.04174 \pm 0.0004$$

The discrepancy between the two results is

$$\delta = \Delta_{exp} - \Delta_{thy} = 0.0037 \pm 0.0007$$

Fig. 3 The slope of $G(R)$ given by this experiment compared with earlier data. B, ref. 3; BR, ref. 4; R, ref. 5; H, ref 6; HC, ref. 7; P, ref 8; RK–M, ref. 9.



The experimental values of δ are given in a histogram in Fig. 2.

A careful re-examination of the experiment indicates that there is no error present large enough to account for this value of δ. In particular, reversal of the rings showed, as theoretically expected, that there is no density inhomogeneity of the rings sufficient to explain this result.

The slope of $G(R)$ from this experiment is shown with G data from ref. 1 in Fig. 3. It will be seen that the two sets of data agree quite well and suggest that the gravitational force law should be modified at laboratory dimensions by

$$G(R) = G_0[1+(0.002)\ln R]$$

It should be remarked that while these results indicate an inverse square law failure at small distance, it is also clear that the experiment was carried out in the Earth's gravitational field and that we may, in fact, have a failure of the superposition principle.

I thank the many students who worked on this experiment, especially Orin Humpheries, Jim Stratton, Steve Katon, Jim Daffe, Don Ogden, and Paul Horn. I also thank John Lewis for weighing the rings, Professors R. Gibbs and E. Forsman for useful conversations, and Research Corporation for support.

Organic complexes of iron and aluminium in natural waters

IN natural waters throughout the world[1], iron concentrations are commonly several orders of magnitude greater than the equilibrium solubility of iron hydroxide[2]. Highly coloured waters (which have relatively high concentrations of organic matter) commonly have even greater iron concentrations. Two of the chemical species postulated to account for this phenomenon are: (1) fine colloidal particles of iron hydroxide (possibly associated with colloidal organic matter) and (2) dissolved complexes of iron with naturally occurring organic substances. While the existence of colloidal iron hydroxide in natural waters is widely accepted[3], there is little conclusive evidence for or against the existence of dissolved organic complexes of iron. We wish to present evidence which suggests that dissolved organic matter forms complexes not only with iron but also with aluminium, with competition between Fe and Al for available complexing sites determining the relative abundances of the two metals in natural waters.

Lamar[4] has shown that substantial amounts of iron and organic matter remain in solution after filtration through 0.01-μm (100-Å) membrane filters, indicating the possible presence of dissolved organic complexes of iron. Since particle diameters < 0.01 μm have, however, been reported for colloidal iron hydroxide[5], the results of filtration studies have thus far been inconclusive.

The frequently cited correlation between iron and organic matter concentrations[4] suggests another possible means of distinguishing between dissolved and colloidal iron. A direct

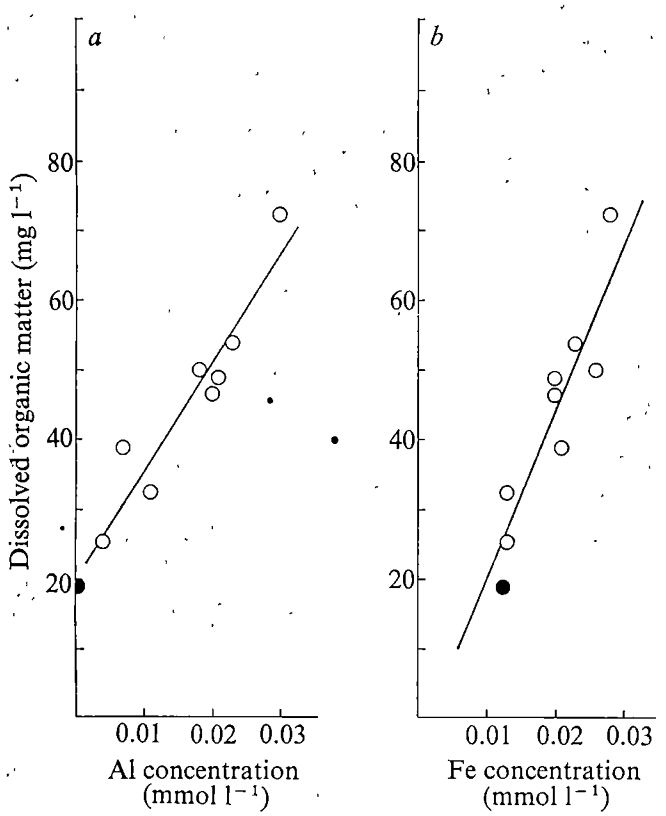

Fig. 1 Correlation between DOM (mg l^{-1}) and the concentrations of Al (*a*) and Fe (*b*) (mmol l^{-1}) for the Satilla River system (○) and for the world average river (●) The slope for Al is 1,547±222 (mg mmol^{-1}), intercept 20.1, and correlation coefficient 0.943. For Fe, these parameters are 2,378±472, −2.7, and 0.899.

correlation between iron and organic matter concentrations is more likely to result from the formation of dissolved organic complexes than from the random adsorption of colloidal iron hydroxide on the surface of colloidal organic particles. Consequently, since only a moderate correlation between iron and organic matter concentrations is usually observed in natural waters, it has generally been concluded that iron is present mainly in colloidal form. In fact, when we reported that a moderately good correlation exists between dissolved organic matter and the concentrations of iron and aluminium in the Satilla River system in the south-eastern USA, we attributed the observed scatter in the data to a lack of discrimination between dissolved and colloidal species[6].

There is, however, another reasonable explanation for the lack of a good correlation between iron and organic matter concentrations. Since it is unlikely that the organic matter in natural waters selectively complexes iron, a substantial fraction of the available complexing sites could be used to complex other metals. Natural abundances of the various metals and stability constants of the respective metal–organic matter complexes would determine the final distribution of complexed metals. For example, because of natural variations in the local relative abundances of Al and Fe in the Satilla River system, only moderate correlations are observed between dissolved organic matter (DOM) and the individual metal concentrations (Fig. 1). An excellent correlation between DOM and the sum of Al and Fe concentrations is, however, observed (Fig. 2), indicating that the total solubility of the two metals is determined by the complexing capacity of the DOM. For comparative purposes, data for the average concentrations of DOM (19.2 mg l^{-1})[7], Al (0.0004 mmol l^{-1})[8], and Fe (0.0120 mmol l^{-1})[1] in the rivers of the world are also plotted in Figs 1 and 2.

Beck *et al.*[6] have demonstrated that the bulk of dissolved organic matter in the Satilla River system closely resembles fulvic acid, an important fraction of soil organic matter which forms stable complexes with many metal ions, including Al and Fe. In low *p*H, low ionic strength waters such as the Satilla River, the stability constant for the Fe–fulvic acid complex is approximately two orders of magnitude larger than the stability constant for the Al–fulvic acid complex[9]. For Al to compete successfully with Fe for available complexing sites, Al would have to be much more abundant than Fe. In the Satilla River, analyses of exchangeable cations in the < 2 μm fraction of suspended clay minerals have shown that Al is the major metal cation and that the average Al/Fe molar ratio is > 270 (ref. 10). Thus, it is reasonable to assume that Al is present in sufficient excess to compete successfully with Fe for available complexing sites in the fulvic acid.

To calculate the molar DOM/(Al + Fe) ratio, it is necessary to estimate the molecular weight of the DOM. In a recent study, a number-average molecular weight ($\overline{Mn}$) of 1,269 was determined by vapour pressure osmometry for DOM which was isolated from the Satilla River[11]. This value is comparable with the $\overline{Mn}$ of 945 which has been reported for soil fulvic acids[9]. Assuming that the $\overline{Mn}$ of DOM in the present study falls somewhere between the experimentally determined values of 945 and 1,269, the calculated molar DOM/(Al + Fe) ratio would be between 0.8 and 1.1. Thus, metal–organic complexes of ~ 1:1 molar ratio such as those reportedly formed in metal–fulvic acid solutions[9] are also formed in the Satilla River.

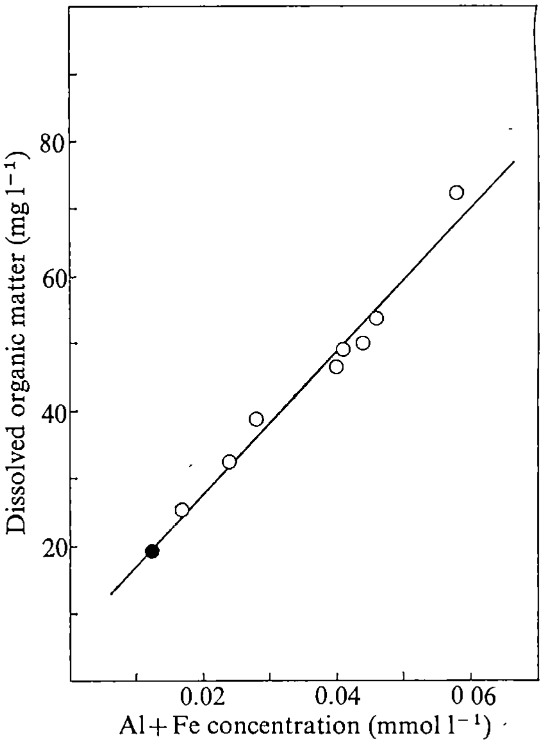

Fig. 2 Correlation between DOM (mg l^{-1}) and the sum of the concentrations of Al and Fe (mmol l^{-1}) for the Satilla River system (○) and for the world average river (●). The slope is 1,058±78 (mg mmol^{-1}), intercept 6.6, and correlation coefficient 0.984.

In Fig. 2, the calculated least squares line does not pass through the origin, possibly indicating that a small fraction of the available complexing sites are occupied by metals other than Al and Fe. Based on stability constants of metal–fulvic acid complexes[9], Ca is the only major cation which might be complexed to a significant extent. Although the Ca/(Al + Fe) ratio is ~ 1:1 in the Satilla River[6], a value of 30:1 is observed in the world average river[1]. Thus, in the world average river, a substantial fraction of the complexing sites may be occupied by Ca, leaving much of the total Al and Fe present as colloidal hydroxides. Thus, it is probably fortuitous that the ratios of DOM to Al, Fe and (Al + Fe) in the world average river are the same as those found in the Satilla River (see Figs 1 and 2). Only when actual data are available for other river systems will it be possible to determine whether the metal–organic interactions observed in the Satilla River are generally important in the transport of iron and aluminium in natural waters.

Shortening of growing season in the US corn belt

I ATTEMPT here to relate the gradual and oscillatory temperature drop in the Northern Hemisphere to a shortening of the length of the growing season in the US corn belt.

The Northern Hemisphere has cooled down during the past 30 yr (refs 1–3); Kukla and Kukla[2] have shown that the increase in the mean annual area of snow and ice over the Northern Hemisphere during the winter of 1971–72 was equivalent to one-sixth of the change necessary to bring back the full-ice conditions of the most recent ice age. Wahl and Bryson[3] reached a similar conclusion, and stated that in the past 30 yr the sea-surface temperatures measured at nine ship stations in the North Atlantic have decreased by an amount equivalent to one-sixth of the drop to minimum ice age temperatures of 17,000 yr ago. Similarly, the average length of the growing season at six climatological stations with the longest meteorological records in the US corn belt (see Fig. 1) have shortened by 14% (27 d) within the past 30 yr. Detailed study of corn belt data, however, indicates highly oscillatory year-to-year variations over the past 75–100 yr, indicating the need for caution in predicting trends.

The six climatological stations covered in Fig. 1 are located to the south and south-west of the Great Lakes. The prevailing winds are generally south-westerly during the growing season and there is great geographical variability of the observed parameters within the area. The microclimatology of some stations is affected by riverine or urban and industrial influences. For that reason I have not attempted to establish a representative average change in the growing season in the corn belt.

The growing season at Toledo (Fig. 1*a*) decreased by as much as 43 d during the last 30 yr, the largest decrease of the six stations. On the other hand, no change, or a slight increase, was observed at Peoria (Fig 1*d*), a site affected by both riverine and urban and industrial influences. Except for Peoria, the decrease in the length of the growing season at the remaining five sites varies between 22 and 39 d (Fig. 1)

The growing season is defined as the number of days between the last killing frost in the spring and the first in the autumn. It is important to realise, however, that though the length of the growing season is a significant factor, other climatic variables also impose significant limits on corn production. Thompson has stated[4] that the unusually high temperatures from 1930 to 1940, especially during the months of July and August, resulted in below average crop yields compared with those expected during normal weather. After 1940, although the length of the growing season in the corn belt was generally decreasing, both temperature and moisture were ideally distributed, and record corn yields were established. As the average growing season in the corn belt is now 165 d little further decrease can be tolerated as the minimum requirement for hybrid corn is 100–130 d. A more important factor is the ever present, large, year-to-year, oscillatory character of the growing season: for example, the abnormally early killing frosts in Iowa in 1875 (August 22), in 1950 (August 20), and in 1974 (September 5).

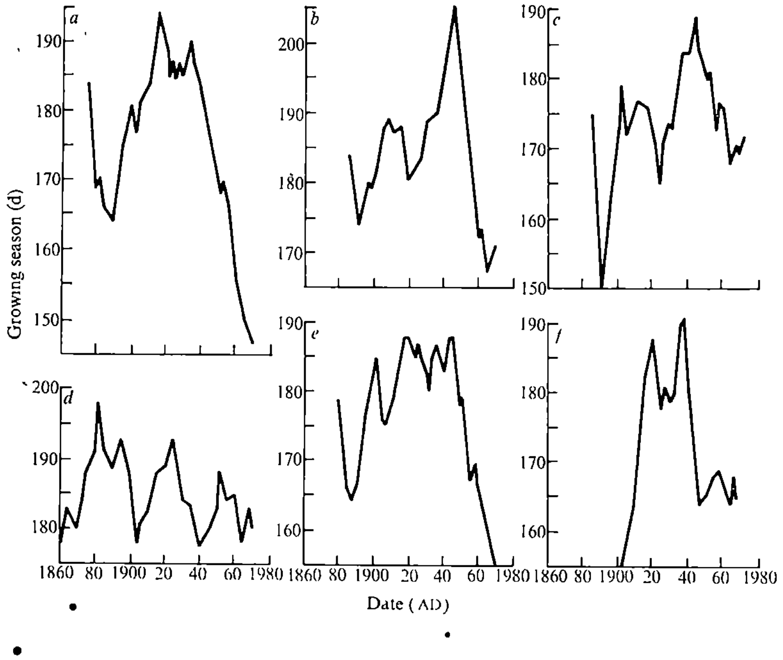

Fig. 1 11-yr running averages of the variations in the length of the growing season for six stations in the US corn belt: *a*, Toledo; *b*, Columbus; *c*, Des Moines; *d*, Peoria, *e*, Dubuque, *f*, Fort Wayne.

The variations in the length of the growing season seem to serve as a useful climatic index, directly related to the agricultural production areas and sensitively linked to the variations of the seasonal patterns.

I thank G. J. Kukla of Lamont-Doherty Geological Observatory for comments.

Entropy of vitreous ice

THE excess thermodynamic properties of vitreous solids over those of crystalline forms include contributions from two sources: first, the configurational changes that occur in the vitreous state[1]; and, second, lattice vibrations that are of a relatively low frequency and are thought to be relatively more anharmonic. We consider here the excess and the residual entropy of vitreous ice and discuss each in terms of the molecular processes and the structure.

There are at least two allotropic forms of vitreous ice[2], obtained by depositing vapours on a substrate maintained at 10 K in one case, and at 77 K in the other. The former has a density nearly 20% higher than the latter, and its oxygen pair correlation function obtained from X-ray diffraction shows an additional peak at 0.33 nm, corresponding to about 1.4 next near-neighbours[2]. It is also noteworthy that very thin deposits of amorphous films of ice on cold (< 173 K) thimbles of hygrometers[3]—a common and unwanted occurrence in meteorological experiments—may be yet another allotropic form. Only vitreous ice, obtained by depositing vapours on a substrate held at 77 K, with a 'glass transition temperature', T_g, of 135 K, is considered here.

The entropy, S, of vitreous, cubic and hexagonal ice is plotted against temperature in Fig. 1. The values were obtained from the known heat capacity of vitreous and cubic ice[4] at temperatures above 21 K, and from the calculated heat capacity below 21 K, assuming a constant Debye temperature. The entropy of hexagonal ice was obtained from the known heat capacity at temperatures above 2 K (refs 5–7). The excess entropy, S_{exc}, which is the difference between the measured values ($S_{vitreous}-S_{crystal}$), is also plotted against temperature in Fig. 1.

At high temperatures the vibrational heat capacity of solids approaches the classical limit, k, per degree of freedom. If the lattice vibrations were solely responsible for the difference between the entropies of the amorphous and crystalline solid, a plot of S_{exc} against temperature would resemble the Debye heat capacity curve; that is, it would show a rapid rise at low temperatures followed by an approach to an asymptotic value at a characteristic temperature, θ, given by, $\theta = h\nu/k$, of the frequencies, ν, that differ between the two solid forms.

The S_{exc} value of vitreous ice follows the Debye behaviour up to 85 K (Fig. 1). It shows a rapid rise in the range 5–40 K, followed by a nearly constant value of 1.2 J K^{-1} mol^{-1} in the range 55–85 K. Above 85 K, S_{exc} increases progressively with temperature and reaches a value of 2.1 J K^{-1} mol^{-1} at 135 K ($= T_g$), at which the spontaneous crystallisation to cubic ice occurs. The temperature dependence of S_{exc} in Fig. 1 is remarkably similar to that observed for vapour-deposited solid methanol, for selenium and other glasses[8] and for the disorder frozen-in state of crystals[9].

The initial increase in S_{exc} of 1.2 J K^{-1} mol^{-1} is partly attributable to the difference in the Debye frequencies and partly to the difference in the degree of anharmonicity of lattice vibrations. It is considerably smaller than the initial increase found for other amorphous solids[8,9] but seems reasonable in view of the fact that vitreous and hexagonal ice have nearly the same molar volume[2] and the same number of near neighbours at a distance of 0.276 nm.

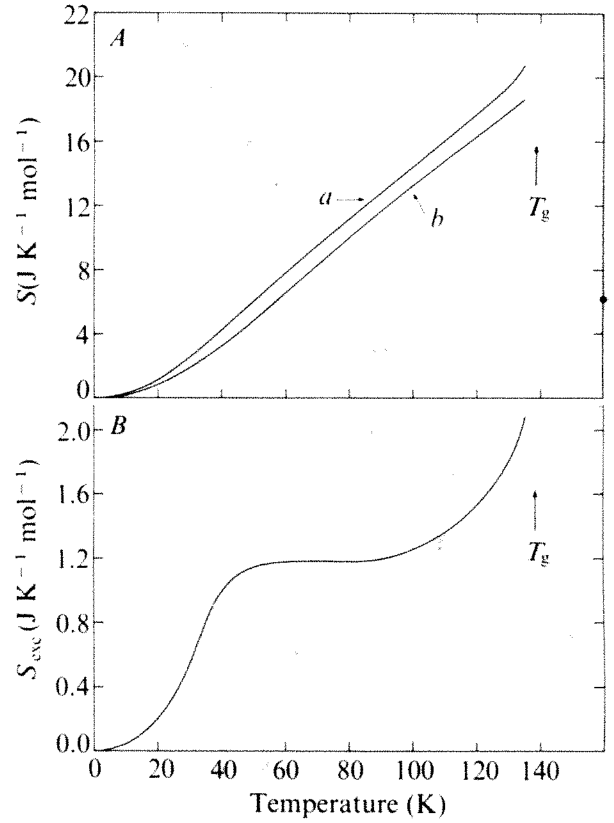

Fig. 1 *A*, Calorimetric entropy of vitreous (*a*), and cubic and hexagonal (*b*) ice plotted against temperature in the top half. Within the experimental error of 1%, the entropy of cubic and hexagonal ice are the same below 135 K. *B*, Excess entropy of vitreous ice over crystalline ice ($S_{vitreous}-S_{crystal}$) plotted against temperature. T_g, The 'glass transition temperature' at which spontaneous crystallisation to cubic ice also occurs.

The 75% increase in S_{exc} between 85 K and 135 K is no doubt attributable to the presence of configurational degrees of freedom, and indicates the onset of small-scale molecular rearrangements in vitreous ice. These may occur in some local regions surrounded by a rigid amorphous matrix, as in many molecular glasses[1], and would involve either or both of the rotational and translational motions of water molecules. These molecular motions would show up in a dielectric study as either a secondary relaxation[1] or a high value of the dielectric loss.

The residual entropy, S_{res}, of vitreous ice must, of course, have contributions from two types of disorder of water molecules; one, the positional and the other, the orientational. The contribution from the positional disorder can be readily inferred from a comparison with an analogous tetrahedrally-bonded structure. Since the continuous random network structure of vitreous ice[10] is similar to that of vitreous silica[11], the maximum value of this contribution is 5.8 J K^{-1} mol^{-1}, a value calculated for the latter from topological considerations[12]. The maximum contribution to S_{res} from orientational disorder is 3.4 J K^{-1} mol^{-1} ($= R\ln(3/2)$), as in hexagonal and cubic ice, but a realistic value would be less, for, in the vitreous state, the six orientations of a given water molecule would not be equally probable and consequently, each of the $(3/2)^N$ configurations would not have the same energy. The maximum theoretical value of S_{res}, anticipated for a fully H-bonded, fully (orientationally) disordered, vitreous ice is, therefore, 9.2 J K^{-1} mol^{-1}.

The calorimetric value of S_{res} of vitreous ice cannot be obtained from the Third Law of Thermodynamics as the course from vitreous ice to the equilibrium liquid state at 273 K involves two irreversible transformations: first, vitreous → cubic ice at 135 K, and, second, cubic → hexagonal ice in the range 160–210 K. Only the maximum value of calorimetric S_{res} can be obtained using the Clausius inequality principle. Thus: $dS > (dq/T)$, where dq is the heat evolved in the process at a temperature T. For the transformation, vitreous → cubic ice, $dq = -1.64 \text{ kJ mol}^{-1}$ at $T = 135$ K (ref. 4). Therefore, dS, which is the minimum entropy loss at the transformation, is $12.1 \text{ J K}^{-1} \text{mol}^{-1}$. The S_{res} can be written as

$$(S+S_{res})_{vitreous} - (S+S_{res})_{cubic} < 12.1 \text{ J K}^{-1} \text{mol}^{-1}$$

At 135 K, $S_{vitreous} = 20.8$, $S_{cubic} = 18.7$ and $(S_{res})_{cubic} = 3.4 \text{ J K}^{-1} \text{mol}^{-1}$. The maximum value of the calorimetric S_{res} is, therefore, $13.4 \text{ J K}^{-1} \text{mol}^{-1}$, which is consistent with the corresponding theoretical value of $9.2 \text{ J K}^{-1} \text{mol}^{-1}$.

The agreement between the maximum value of the theoretical and the calorimetric S_{res} is significant, although it does not indicate whether an increase in S_{res}, such as would occur if the vitreous ice were not completely H-bonded, is partly compensated for by a decrease in S_{res} attributable to the lack of complete orientational disorder. In the absence of the heat capacity data of liquid water between 135 and 230 K, this analysis seems to be the simplest and perhaps most appropriate.

I am indebted to Professor M. Goldstein, Yeshiva University, New York, for discussion.

Restricted pollen flow of two woodland herbs determined by neutron-activation analysis

THE movement of pollen is a critical event in the population genetics of wind-pollinated plants. Neighbourhood size and potential for genetic differentiation, for example, are significantly influenced by pollen flight distances[1,2]. The evolution of phenological and morphological mechanisms that enhance wind pollination is well studied[3,4], but the actual distance of pollen flight in natural populations is less clearly documented. Pollen movements have been estimated by using genetic markers in field plots[5], trapping pollen with artificial barriers[6], and catching radioisotope- and chemically-marked pollen of conifers[7–9]. I report the successful measurement of wind-dispersed pollen in natural populations of woodland herbs, using neutron-activation analysis of surface-treated pollen. Preliminary results suggest highly restricted pollen movement in these herbs.

Carex plantaginea Lam. and *Carex platyphylla* Carey (Cyperaceae) are common sedges in New York forests. These monoecious plants flower in early May. The florets are highly modified for wind pollination, although the different culm (stem) morphologies of the two species suggest that pollen flow might be relatively lower in *C. platyphylla*. Fertile culms elongate well before most other vernal herbs appear; thus, there are few herbaceous barriers to pollen flight.

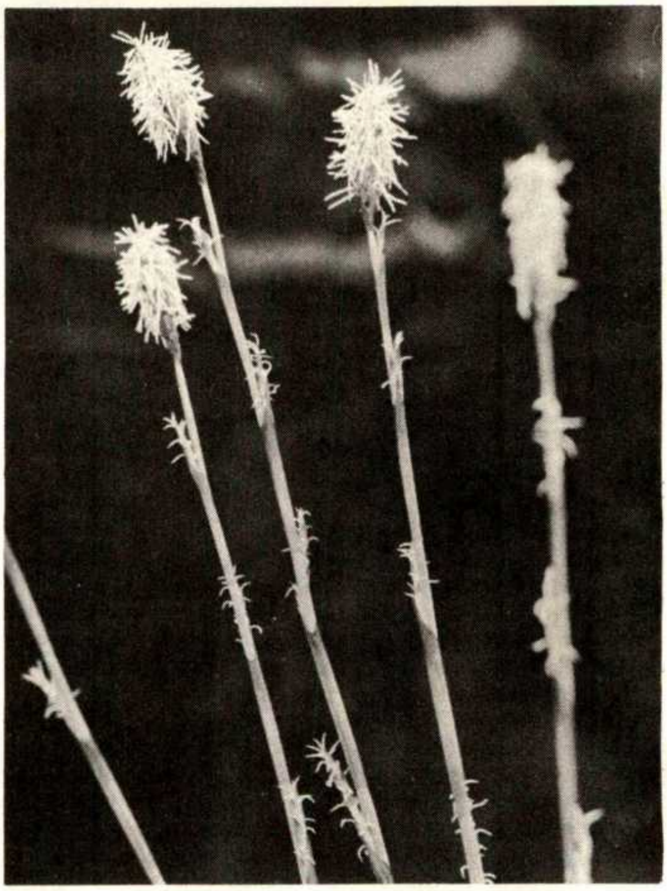

Fig. 1 Tops of fertile culms of *Carex plantaginea* during anthesis. Lateral pistillate spikelets have exserted stigmae a few days before and during opening of anthers from the terminal staminate spikelet. *Carex platyphylla* has a similar infloresceinse, but is shorter (~ 12 cm as against 20 cm for *C. plantaginea*), with lateral spikelets more clustered towards the apex, and erect foliose bracts subtending the lateral spikelets. (×0.39).

Pollen movements within a population of each species were estimated by marking pollen of selected plants with a normally absent element, samarium. After pollen dispersal, traces of samarium were searched for on stigmae of plants throughout an area uninterrupted by trees. A section of a local population of each sedge species was selected for study. These had similar densities, ~ 15 plants per m^2. Before exsertion of anthers, 15 μl (*C. platyphylla*) or 25 μl (*C. plantaginea*) of a samarium solution were applied with syringes to staminate spikelets of several central culms in each cluster. A 0.1 M solution of samarium oxide of natural isotopic abundance was prepared in hot dilute HNO_3 (ref. 10). This was buffered with 0.1 M EDTA, then the *p*H was raised to 5.7 with 1 M NaOH. For use on these species, a 0.15% solution of Tween 20 (polyoxyethylene [20] sorbitan monooleate) was added as a wetting agent.

The day after anthesis, pistillate spikelets from both inoculated plants and others in the cluster were collected into washed polyethylene vials. The wind speed was normal, $< 10 \text{ km h}^{-1}$, on days of pollen flight. Spikelets from three culms at each sample point were put in each vial, and a control series of vials was filled with *C. plantaginea* spikelets before any samarium was introduced into the population. Neutron-activation analysis of samples followed, to determine the amount and presence of samarium-labelled pollen at the various distances from the treated plants. For this analysis, the samples were bombarded with neutrons, causing unstable isotopes of samarium to be formed. The major activity comes from 47-h ^{153}Sm which β decays to ^{153}Eu, which in turn emits γ rays. The dominant emissions, 70 keV and 104 keV γ rays[11], were counted on a NaI scintillation detector. Data are summarised in Table 1.

These data record a rapid decrease of activity within short distances from samarium-treated spikelets. Ten readings from pistillate spikelets from the samarium-treated culms of *C. platyphylla* show great activity. Within 0.15 m from the inoculated culms, there is a greater than 30-fold decrease of activity. By 0.5 m from the treated spikelets, activity at some locations was halved again, and many locations recorded no activity above control levels. Beyond 1.0 m, only four readings showed activity above the control. No bias in directionality of pollen flow was seen in these data. (No samples from the central, inoculated *C. plantaginea* culms were available, as these particular culms failed to develop mature pistillate florets, a common occurrence in population of this species[13].)

The generally lower dispersal range of *C. platyphylla* pollen supports the hypothesis that the culm morphology of this species lowers pollen flow. This may be attributed in part to the lower height of the staminate spikelets on these culms. Dispersal distance varies inversely with height of pollen source[14]. Also, the subtending foliose bracts beneath *C. platyphylla* pistillate spikelets act as mechanical barriers to pollen.

Additional studies of pollen movement in these species might include flow rate throughout clusters of similar density, but containing tree trunks. Such clusters would be expected to have lower dispersal levels, as tree stands decrease pollen movement[15,16]. Also, information on congruence of movements of treated and untreated pollen, flow during high wind speeds, and correlation between pollen movement and actual gene flow are needed. Even if infrequent, long distance pollen flow could be important to genetic processes.

The wind dispersal pattern in this study is consistent with the leptokurtic pattern seen in studies using other methods. Similarly, highly restricted pollen flow is reported from many insect-pollinated populations[2]. The neutron-activation analysis results support evidence that herb populations may be quite isolated genetically from adjacent populations[17], and that local population differentiation over the range of a species may be frequently achieved[18–21]. The low pollen dispersal pattern of these *Carex* species superficially adapted for 'wide' pollen flow, highlights the need for care in postulating large neighbourhood size in their populations.

Table 1 Relative amount of samarium-treated pollen at distances from treated staminate spikelets

**A*, Total number of peaks counted.

†*B*, Number of peaks with activity > 1 s.d. above mean of the control series.

Samples were irradiated at the Cornell TRIGA MARK II reactor for 1 h with a neutron flux in the range of 7×10^{11} neutrons cm^{-2} s^{-1}. After 18-h decay, γ-spectrum analysis was done with a 3″ × 3″ NaI (Tl) well-counter (Baird-Atomic Model 810C) and a 256-channel pulse-height analyser (Technical Measurement Corp. Model CN-110). Scintillations were counted for 120–600 s. Counts were calculated from 40 channel widths, relativised for count time, and corrected for decay and background radiation[12].

The use of neutron-activation techniques for studies on genetic structure and processes in populations is recommended for its relative ease and accuracy[22,23]. This technique is also applicable to other ecological studies by field biologists, such as recording visitation patterns of nocturnal pollinators, feeding behaviour of nectar feeders, or occurrence of food exchanges between members of animal colonies.

I thank H. C. Aderhold and the Ward Laboratory of Nuclear Engineering, Cornell University for help in this study.

Inhibition of float formation in water hyacinth by gibberellic acid

THE water hyacinth (*Eichhornia crassipes*) is one of the most harmful weeds of tropical and subtropical waterways and lakes. Its reproductive potential is enormous and in favourable conditions it forms dense mats which may cover the surface of a body of water. Such prolific development can obstruct the drainage of farmlands, block hydroelectric installations in dams, hinder navigation and affect fisheries (reviewed in ref. 1). The leaves of free-floating water hyacinths are characterised by a bulbous swelling in a section of the petiole which provides buoyancy. These floats, however, do not develop when the plants are rooted in the soil of muddy shores. In those circumstances the petiole narrows gradually from its base to the leaf blade. We have found that the formation of floats can be inhibited by extremely low concentrations of gibberellic acid (GA_3) in the water. As a consequence of treatment the plants become unstable and partially sink below the surface of the water.

Water hyacinth plants were cultured *in vitro* in polyethylene trays (45 × 30 × 8 cm) on 1/5 strength Long Ashton medium composed of the following (mg per l of nutrient solution):

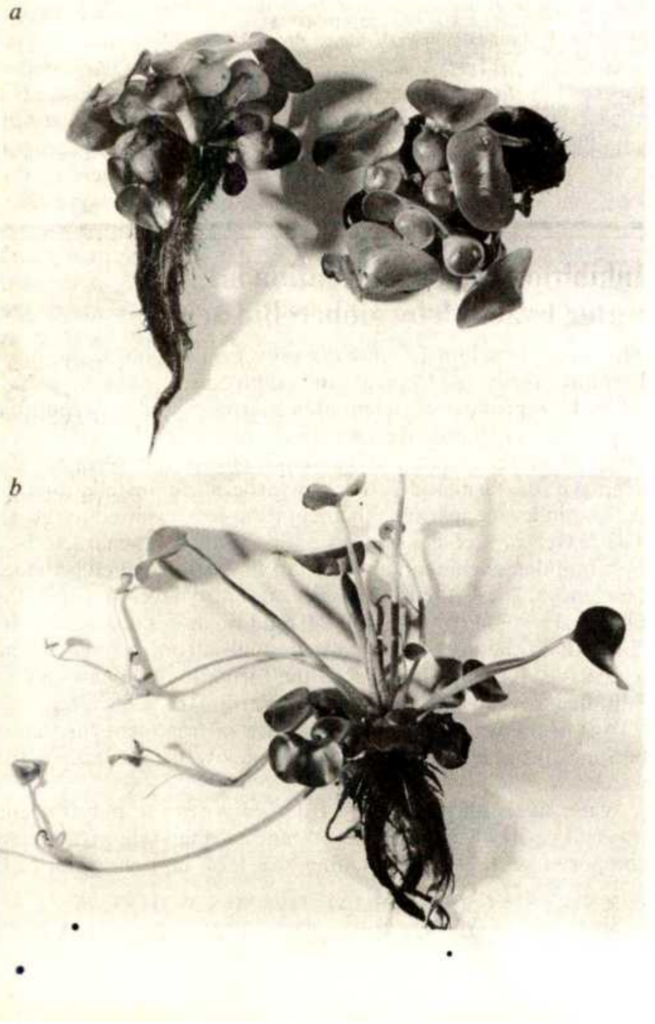
KNO_3, 81; $Ca(NO_3)_2.4H_2O$, 189; $MgSO_4.7H_2O$, 74; $NaH_2PO_4.H_2O$, 0.35; $MnSO_4.H_2O$, 0.35; $CuSO_4.5H_2O$, 0.05;

$ZnSO_4.7H_2O$, 0.06; H_3BO_3, 0.6; NaCl, 1.2;
$(NH_4)_6Mo_7O_{24}.4H_2O$, 0.02; $FeSO_4.7H_2O$, 5.6; EDTA, 5.8

adjusted to *p*H 7 with 1 N NaOH. The plants were exposed to continuous illumination (12,000 erg cm^{-2} s^{-1}) from white fluorescent tubes at 27±2 °C. Experiments were conducted in a greenhouse during the summer in reservoirs (100×100×60 cm) containing 20 cm of pot soil and filled up with tap water. The circumference of the floats and the length of the petioles were measured with a sliding gauge with Vernier scale (accuracy 0.1 mm). All experiments lasted 4 weeks. When the plants were cultured *in vitro* typical float leaves were formed (Fig. 1*a*). Increasing concentrations of GA_3, however, decreased the diameter of floats of newly formed leaves. As little as 0.03 p.p.m. of GA_3 (0.03 mg l^{-1}) in the nutrient medium suppressed the formation of float leaves (Fig. 1*b*). Even with 0.01 p.p.m. of GA_3 the floats were clearly smaller than those of controls. In Fig. 2 the quotient of petiole length and greatest circumference (*l*/*c*) is presented at different concentrations of GA_3. These values decrease markedly at concentrations of 0–0.03 p.p.m. At the highest concentration tested, 1.0 p.p.m., the value was very high because of the considerable increase in the length of the petiole. GA_3 also markedly inhibited vegetative multiplication of the plants and induced profuse flowering. 6-Benzyladenine (BA) counteracted the effect of GA_3. In the presence of BA the floats became slightly thicker than in the controls and plants with elongated leaves which had been cultivated on GA_3-containing medium reproduced floats quicker in the presence than in the absence of BA.

2-Chloroethyltrimethylammonium chloride (CCC), indol-3-yl-butyric acid (IBA), abscisic acid and the ethylene-releasing compound ethrel had no effect on float formation. Plants grown in the greenhouse in the presence of 0.03 p.p.m. of GA_3 produced only elongated leaves. These plants produced just a few daughter plants and eventually became submerged. The control reservoirs, on the other hand, were completely overgrown within 4 weeks. Preliminary spray tests in the greenhouse have shown promising results in the inhibition of float formation by GA_3.

Fig. 1 *a*, Water hyacinths after cultivation on 1/5 strength Long Ashton medium. Note the typical float leaves. *b*, As (*a*) but supplemented with 0.03 p.p.m. GA_3. Note the absence of floats in the newly formed leaves.



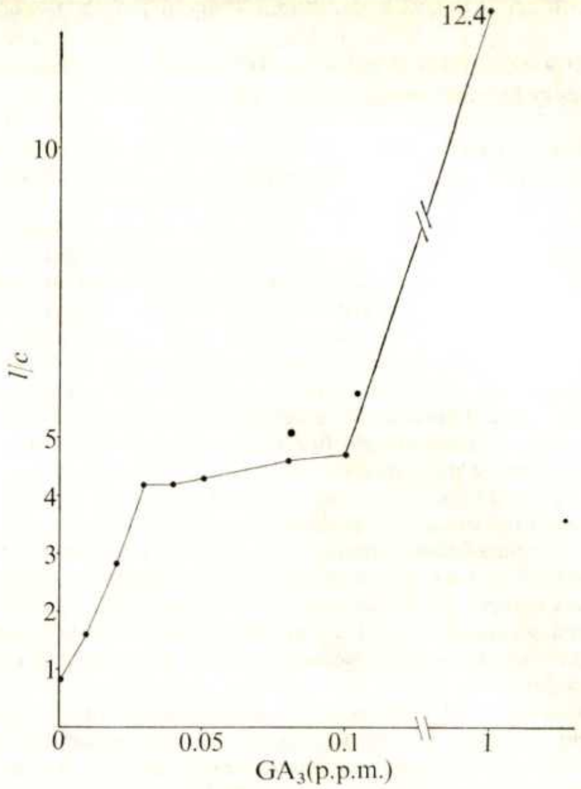


Fig. 2 Effect of various concentrations of GA_3 on float formation in water hyacinth, expressed as the quotient of length (*l*) and circumference at the greatest width (*c*) of the petiole.

In the wild, water hyacinths do not produce float leaves in crowded conditions or when rooted in the mud[2]. It has also been reported that a relatively high temperature and low light intensity (in the shade) promote elongation of the petiole[3]. Our results suggest that the external factors which influence float formation in water hyacinth act through endogenous gibberellins and perhaps cytokinins. The effective concentration of GA_3 (0.03 p.p.m.) was extremely low and as this hormone markedly inhibits vegetative growth it could perhaps be used to control the growth of water hyacinths in certain areas. It might be combined with biological means of control, such as *Neochetina eichhorniae* (water hyacinth beetle) or *Orthogalumna terebrantis* (water hyacinth mite). The very low concentrations of GA_3 that were effective would be economically feasible, and as GA_3 is a natural component of plants it should not endanger the environment.

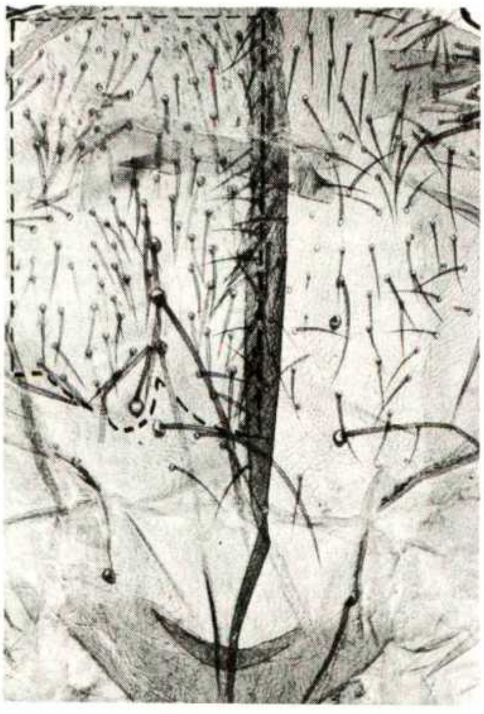
Morphogenetic mutants detected in mitotic recombination clones

GENETIC analysis has been used successfully for identifying the elements responsible for biological processes[1,2], and understanding the logic of their interactions. This approach has, however, been little used in the study of morphogenesis in multicellular organisms, chiefly because of a dearth of viable mutants and the difficulties of interpreting the altered primary gene function from the mutant phenotype. The existence of pleiotropy in particular makes this analysis difficult[3,4]. An alternative approach would be to study the effect of mutations on individual cell behaviour[5]. This approach depends on the well founded assumption that normal morphogenesis results from the ordered integration of discrete cell autonomous functions. This can be done in *Drosophila* in genetic mosaics, where the heterozygous, phenotypically wild-type individual is a carrier of clones of homozygous mutant cells. This approach has the advantage that morphogenetic mutants, even if they are lethal to the individual, can be detected, studied and interpreted directly at the cellular level.

Previous analysis in *Drosophila* has shown that about 90% of loci can mutate to a lethal condition[6,7]. Some 90% of these lethals are, however, viable in clones of epidermal cells and therefore amenable to clonal analysis[8]. Once the normal clonal parameters of a given developmental system are known[9–11], it is possible to detect mutants altering them. Here we describe a method of directly detecting and characterising morphogenetic mutants in clones produced by mitotic recombination. A similar approach has been used to detect cuticular differentiation mutants[12].

Morphogenetic mutants, induced in a chromosome arm carrying cell marker mutants, can be detected after mitotic recombination as morphological abnormalities associated with the cell marker phenotype. If the mitotic recombination event removes at the same time the *Minute* (*M*) allele in heterozygous M/M^+ growing cells, the resulting clones will be large[13] enough to be seen under the dissecting microscope. This procedure enables us to uncover mutants (1) in the chromosome arm of the *Minute*, (2) in heterozygous condition, (3) irrespective of whether they are lethal or present in a lethal-carrying chromosome and (4) as autonomous as well as partially nonautonomous cell mutations.

Fig. 1 *mwh jv* * $M(3)i^{55+}$ notum showing intercalary addition of chaetal elements.



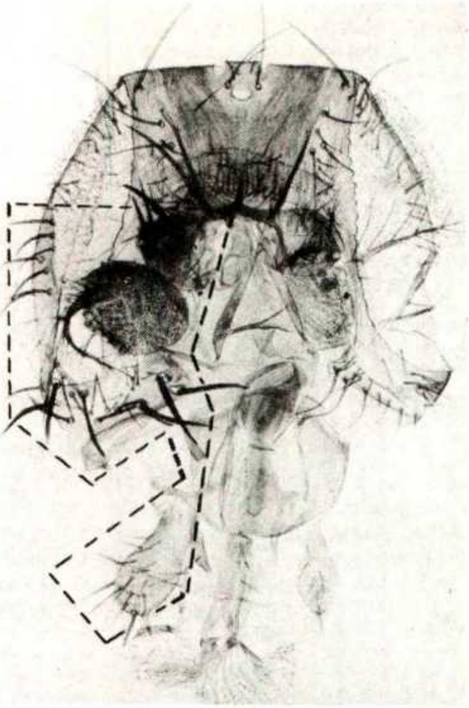


Fig. 2 *mwh jv* * $M(3)i^{55+}$ head showing cuticular elements about twice as large as wild type.

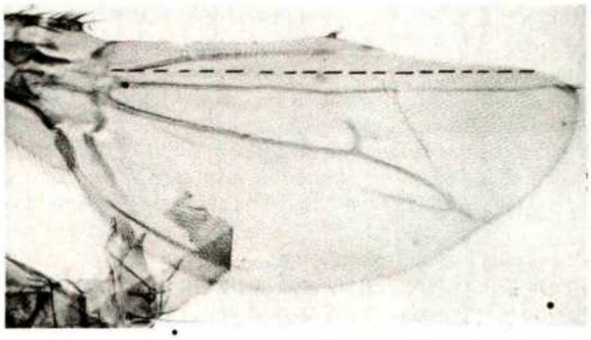
Thus, male gametes of the genotype *mwh jv*, mutations which mark the trichomes and chaetes respectively[14], were treated with ethylmethane sulphonate (EMS) (0.02 M)[15]. The treated males were crossed to balancer-carrying females (*TM1,sbd*/*TM3,e*^{11}) and the F_1 *mwh jv**/*TM1* and *mwh jv**/*TM3* females mass-crossed to $M(3)i^{55}$ *sbd*/*TM1* or to $M(3)i^{55}$ e^{11}/*TM3* males respectively. The F_2 progeny was irradiated with 500-r. X rays at 48–72 h after oviposition[16]. The emerged *mwh jv**/$M(3)i^{55}$ males were then scored under the dissecting microscope for morphological abnormalities, which could be anywhere in the body cuticle. Those males showing an abnormality were then crossed to balancer-carrying females, to ensure amplification of the treated chromosome, and then mounted on a slide and checked for the existence of *mwh jv* M^+ territories associated with the morphological abnormality. In positive cases the existence of a morphogenetic mutant was again verified in mitotic recombination clones in subsequent generations, mapped meiotically, separated from associated lethals by recombination, and maintained in balanced stocks for detailed study of its phenotype.

Out of 20 EMS-independent treatments, about 10,000 males of *mwh jv**/$M(3)i^{55}$ genotype were scored under the dissecting

Fig. 3 *mwh jv* * $M(3)i^{55+}$ wing lacking most of the anterior region. Some *mwh* cells remain.



microscope. Morphological abnormalities were detected in 95 individuals but progeny were obtained only from 68 of them. In 25 of the 68 individuals the malformation was associated with the *mwh jv* M^+ genotype, but in only 19 cases did the original malformation appear in subsequent generations. The association of the malformation with the clone of cell marker mutants indicated that it corresponds to a true mutation in the left arm of the third chromosome. Through further analysis we succeeded in assigning to each malformation a locus in that chromosome arm. All the isolated mutants have been shown to be lethal or closely linked to a lethal mutation. We tested the 19 mutants isolated for allelomorphism and found two pairs which did not complement. One of these pairs occurred in flies subjected to the same EMS treatment and can be attributed to the same mutational event and another pair corresponded to true alleles.

The different clonal phenotypes of these 18 mutants were classified as follows. A first group of five mutants lack entire regions of the adult cuticle, the surrounding territories being of more or less normal morphology (Fig. 3). They differ depending on the degree of autonomy of the lethal effect, extension of remnant *mwh jv* cells still present at the borders of the clone, and on the effect on the surrounding wild-type cells.

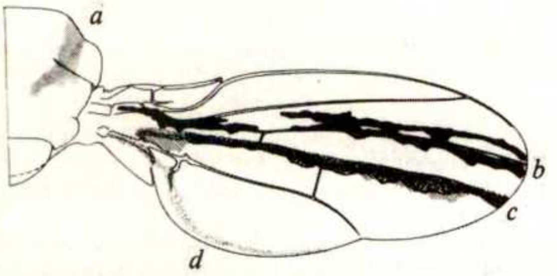


Fig. 4 *mwh* * $M(3)i^{55+}$ Diagram representing four elongated and split clones; *a*, *b* and *c* correspond to one mutant and *d* to another. Clone *c* runs along the antero-posterior compartment border in both dorsal and ventral surfaces of the wing.

A second group of nine mutants modifies the pattern of the clone in different ways. In two different alleles of the same locus the adult cuticular elements (trichomes and chaetae) are about twice as large as for the wild type (Fig. 2). Another mutant leads to the intercalary addition (2–3 times) of chaetae in an otherwise normally patterned tissue (Fig. 1). Two mutants lead to the formation of elongated and split clones, which are smaller than control ones of the same age (Fig. 4). Two mutants lead to the formation of outgrowths in the cuticular surface, one associated with whirls in the orientation of the trichomes and chaetae, and the other with thick and dark, poorly differentiated cuticle. A possible homoeotic mutant shows a transformation of the third joint of the antenna into tissue typical of the proboscis; clones in other regions of the body are of abnormal appearance.

A third group of five mutants shows different types of abnormality in the cuticle associated with chaetae and trichome pigmentation and/or morphology. They can be considered as mutations that affect the mechanisms of cuticular formation[12].

The mutant phenotypes described are suggestive of as many cell functions as can be discriminated by mutation. They possibly result from alterations in the mechanisms of growth and response to metamorphosis, cuticular differentiation, and in the control of sequential mitotic orientations, of the size of cuticular elements or of their distribution in patterns, and so on. From analysis of these and other mutants detected in this way we hope to infer the wild-type functions relevant to the genetic control of morphogenesis. These phenotypes examined at the cellular level, will also help to suggest molecular mechanisms underlying such cellular abnormalities. The efficiency of the reported method of detection of morphogenetic mutants is very high: about 1 such mutation for 500 flies scored. Using cell marker mutants[12] and *Minutes*[16] in other chromosome arms it will soon be possible to extend these studies to mutants over the entire *Drosophila* genome.

Stereotyped pattern of locomotion controlled by duration of previous tracking by a predatory insect

AMONG insects, an encounter with a particular stimulus[1–4] or the performance of a particular activity[5–7] may change the animal's later responsiveness to other stimuli or may prime the regular appearance of a stereotyped action pattern. Thus, various unrelated species display strictly predictable behavioural changes which depend not only on simultaneous events in the external environment as well as on general physiological variables, but also on well determined sensory or motor components of the subject's

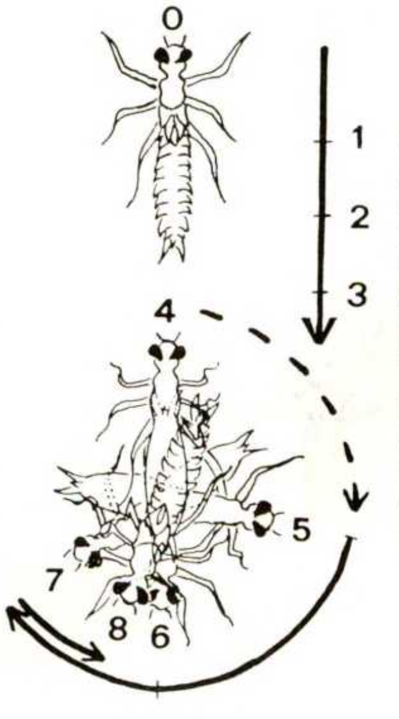

Fig. 1 The backing–turning pattern. After the disappearance of the prey stimulus, the larva (1) remains motionless (position 0); (2) it steps backwards repeatedly (solid arrow, positions 1–4); and finally (3) it turns repeatedly around its longitudinal body axis. The first pivoting movement is often accompanied by simultaneous backing (dashed arrow, position 5); thereafter, the insect turns clockwise and/or counterclockwise without changing its location (solid arrows, positions 6–8).

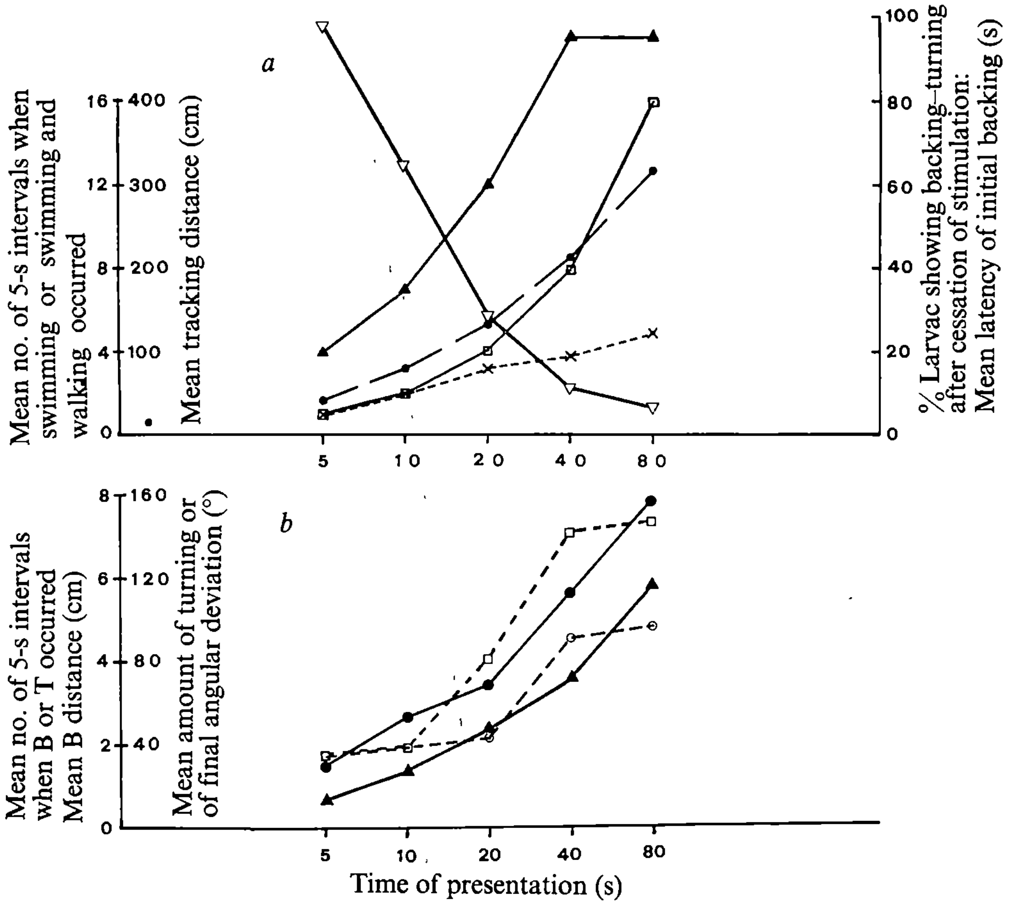

Fig. 2 *a*, Tracking time and tracking distance during presentation of the dummy for various times; percentage of larvae showing the backing–turning response within 3 min after removal of the dummy; and latency of initial backing response. B, Backing; T, turning; S, stimulation; ×, swimming time; ●, tracking distance; □, total tracking time corresponding to swimming and walking; ▲, backing–turning after stimulation; ▽, latency of initial backing. The increase in the number of individuals showing the backing–turning response and the decrease in the latency of the initial backing response are significant at the 0.01 and 0.001 levels, respectively. The relationship between the time of presentation and the percentage of individuals showing backing–turning corresponds to the equation $B\text{–}T = 0.517t^{1.564}$ (where t stands for time of presentation) $n = 100$ *b*, Number of backing–turning responses, backing distance and amount of angular turning within 3 min after removal of the dummy. ●, Backing–turning response; □, turning; ▲, backing distance; ○, final angular deviation corresponding to the change in the orientation of the insect's head and body resulting from the entire sequence of backing–turning movements. Except for the final angular deviation, the changes in the values of the different backing–turning parameters are all significant at the 0.001 level $n = 60$

antecedent behaviour. The study of these changes may aid the understanding of the nature of specific internal mechanisms which are influenced by previous behavioural states and which act in turn on the animal's subsequent behaviour. This may be of special interest in the study of highly elaborate action patterns, such as the figure-of-eight dance of the honey bee. In this example, the return of the bee from a given food source to the hive is followed by a precisely defined pattern of locomotion, in which the timing and orientation of certain parameters depend on specific aspects of the insect's outgoing flight[8]. A series of experiments analysed the reactions of the aquatic dragonfly larva *Aeschna cyanea* M. after a brief presentation of an artificial prey stimulus They revealed that the behaviour of the insect is influenced by the nature and former location of the stimulus, even after the latter has disappeared[9]. On the other hand, after a more extended presentation of a moving target—a stimulus which typically elicits prolonged tracking behaviour—the insect reliably carries out a strongly stereotyped pattern of locomotion, the form, control and function of which are described here.

Hungry subjects of the final larval stage were placed in a large experimental aquarium (70×70 cm) and presented with a spherical dummy prey (diameter, 3.5 mm) for 5–80 s. The dummy was introduced directly into the insect's visual field and then moved around the aquarium, its velocity being adapted to the subject's own tracking speed. At the end of the period of stimulation the dummy was removed quickly from the aquarium. The behaviour of the larvae during the presentation of the dummy as well as during the 3 preceding and 3 subsequent minutes was recorded by two cameras, one of them stationary, above the centre of the aquarium, the other fitted with a zoom lens and manipulated by the experimenter in front of the aquarium.

Presentations of the dummy during 5- and 10-s intervals elicited tracking with vigorous swimming movements; presentations of still longer duration elicited swimming movements followed by rapidly decelerating walking (and creeping) movements (Fig. 2*a*). After removal of the dummy, the insects tended to display a stereotyped pattern[10] which had not been observed before or during the presentation of the dummy. It consisted of three phases: (1) the larvae remained motionless and 'stared' in the direction in which the prey stimulus had just disappeared; then they carried out (2) a series of backing movements and finally (3) a number of turning or pivoting movements around the longitudinal axis of their body, without changing their location (Fig. 1).

The longer the preceding presentation of the dummy, the sooner the 'backing-turning' pattern appeared, and the greater (1) the percentage of larvae which showed this pattern (Fig. 2*a*), (2) the number of time units in which

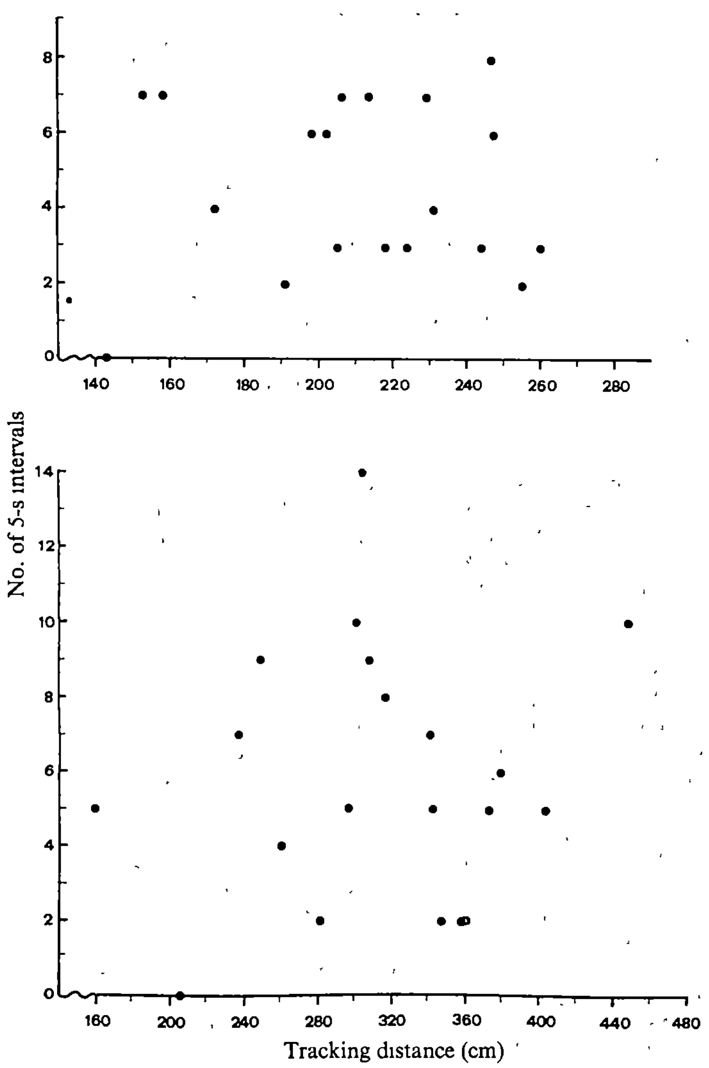

Fig. 3 Relationship between tracking distance during and number of backing-turning responses after presentation of the dummy for 40-(*a*) and 80-s intervals (*b*) The abscissa represents the tracking distance covered by individual larvae; the ordinate refers to the number of 5-s units for which a given individual displayed backing-turning responses during the first 3 min after removal of the dummy. For both experiments, the Spearman rank correlation test failed to show a significant relationship between the larvae's tracking distance and the number of backing-turning responses subsequently carried out. *a*, $r_s = 0.12$; *b*, $r_s = 0.0038$

backing and turning occurred, (3) the backing distance, (4) the amount of angular turning, and (5) the extent to which the animals had changed the orientation of their head and body as the outcome of the entire performance of the stereotyped response (either by turning repeatedly in the same direction, or by making clockwise as well as anticlockwise turning motions) (Fig. 2*b*).

During the two longest presentations of the target (40 and 80 s respectively), nearly all subjects followed the dummy until its removal and thus showed the same tracking time (Fig. 2*a*); the same individuals, however, differed considerably with respect to the distance they covered within 40-and 80-s intervals. Figure 3 shows that the correlation coefficient between the larvae's tracking distance and the number of their subsequent backing-turning responses tended towards zero. The intensity or persistence of the backing-turning response seemed therefore to depend on the time of the insects' tracking rather than on the distance they had covered.

Experiments in which the presentation of the dummy exceeded 80 s have demonstrated that after a time of presentation of 90 s or more the larvae cease to approach the prey and begin to back up and turn away from it, as if the dummy were no longer in their visual field. Thereafter, the insects might oscillate for several minutes between bouts of positive fixation, often combined with approach reactions, and short spells of negative backing-turning away from the dummy. Thus, the removal of the dummy eliminates the tracking command and therefore facilitates and synchronises the appearance of a whole sequence of backing-turning motions; it is, however, by no means a necessary condition for the release of that stereotyped pattern of locomotion.

Further experiments and observations involving the presentation of artificial as well as natural prey indicated that backing-turning occurred only during or after the presentation of a prey stimulus which had previously elicited an approach response. This stereotyped response seemed therefore to be a consequence of a specific activity, and not simply a result of the stimulus which had released this activity. Nevertheless, proprioceptive information resulting from predatory locomotion did not seem to have any influence on the occurrence of backing-turning. For instance, backing-turning movements occurred mainly after the pursuit had reached the stage of walking and creeping. Some insects, however, displayed (weak) backing-turning responses after the dummy had been presented for only a short time; in these cases, due to the brevity of presentation, the tracking responses took the form of swimming movements only. Furthermore, interpolated acts —such as striking and eating a real prey between repeated presentations of the dummy of short duration—did not reduce the cumulative after effect on backing-turning exerted by previous tracking movements. Finally, metabolic changes resulting from the energy consumption[8] during the tracking activity likewise seemed to have no influence on the occurrence of the stereotyped pattern of locomotion. Among other things, the priming effect of tracking depended on the insects' tracking time rather than on the tracking distance, the latter parameter being correlated with the larva's energy consumption. Thus, by analogy with Blest's[5] explanation of the priming effect which flying exerts on the stereotyped settling movements in hemileucine moths, the instigation of the backing-turning pattern may be explained by time-dependent central nervous after effects originating from the activation of those mechanisms which control tracking.

From a functional point of view one may consider that backing-turning has the following effects: (1) it stops any futile attempt on the part of the insect to catch a prey able to escape; (2) it reduces the probability that such a prey will be rediscovered after its momentary disappearance; (3) as direct observation of the larvae's hunting behaviour in the presence of living prey has shown, turning favours the detection of a new prey; (4) finally, the loss of contact with an escaping target reduces the insects' energy consumption as well as the danger that their tracking movements may attract their own enemies.

Modulation of B-cell interactions by T cells

INTERACTION between different lymphoid and non-lymphoid cells is a well established requirement for the development of the immune response *in vivo* and *in vitro*[1–3]. From this it follows that ultimately the regulation of the immune response must depend on the nature and frequency of such cell interactions.

Recently, in the process of examining suspensions of lymph node cells, stained with fluorescein isothiocyanate (FITC)-labelled rabbit anti-mouse immunoglobulin and obtained from mice partially depleted of T cells after treatment with anti-lymphocyte antiserum (ALS), a very high frequency of cell pairs was noticed, in contrast with control cell suspensions. We have followed up that observation and examined lymph node cell suspensions from control and ALS-treated CBA and C3H/Bi mice, and mice treated with ALS and reconstituted with thymocytes, in order to analyse the frequency, characteristics and kinetics of cell pairing. We found a higher frequency of pairs in the ALS-treated mice both in the cell suspensions stained with the FITC-labelled antiserum and in unstained suspensions prepared immediately after removal of the lymph nodes, washed twice, resuspended to a concentration of 1.2×10^9 per ml and examined in a haemocytometer chamber within 30 min of dissection (Table 1).

Whether counted in slides after staining with FITC-labelled immunoglobulin or counted in haemocytometer chambers after washing, the proportions of pairs found in ALS-treated suspensions were consistently higher (9.44%±2.02:6.92%±0.88) than in the respective controls (2.44%±1.02:1.31%±0.38). Moreover, the high frequency of pairs in the ALS-treated suspensions was counteracted by reconstitution with thymocytes (2.97%±0.34:3.25%±1.26).

In addition to the quantitative differences between the cell suspensions, qualitatively, the nature of the cell pairs examined also differed (Table 2). After ALS treatment, the increase in the numbers of pairs was due chiefly to homologous B-cell pairs (4.47%±0.95) and heterologous pairs (3.74%±1.83). Only a small proportion of pairs (1.07%±0.90) consisted of two unlabelled lymphoid cells, presumably T cells. Larger aggregates of cells, consisting chiefly of B cells, were also present in the smears of the ALS-treated lymph node cell suspensions, examination of these under phase contrast, revealed that, although some of the unlabelled cells were clearly lymphoid, some heterologous pairs consisted of one macrophage and one B cell. In the control cell suspensions most of the few existing pairs consisted of two unlabelled lymphoid cells (1.71±0.81). Reconstitution with thymocytes resulted in a low frequency of pairs, comparable with that observed in the controls, that is, most of the existing pairs (1.33±0.84) consisted of two unlabelled lymphoid cells.

Table 1 Percentage of cell pairs in lymph node suspensions of ALS-treated and control mice, and ALS-treated mice reconstituted with thymocytes

Treatment	No of mice	Pairs (%)	
		Slide	Haemocytometer
—	6	2.44±0.83	1.31±0.38
ALS*	12	9.44±2.02	6.92±0.88
ALS ± thymocytes†	4	2.97±0.34	3.25±1.26

Cells were examined unstained (haemocytometer) or after staining with an FITC-labelled antiserum (slide) The ALS-treated mice received 1.5 ml of ALS (Searle) at 2–3 months old, distributed in 3 subcutaneous injections of 0.5 ml given on alternate days before killing. This induced moderate decreases in the proportion of T cells (untreated: 72.8±8.14; ALS· 54.3±11.5) in the mesenteric and inguinal lymph node suspensions.

ALS-treated thymocyte-reconstituted mice received 1 ml or 0.5 ml ALS on day 0, on day 1 they received an intraperitoneal injection of 3.6×10^7 syngeneic thymocytes; and they were killed on day 2.

Cells examined in the haemocytemeter were adjusted to 1×10^6 ml^{-1} in MEM or medium 199.

Cells examined in microscope slides were stained with rabbit anti-mouse immunoglobulin and counted by the standard direct immunofluorescence technique. Minimum of 300 cells counted.

Mean ± s.d.

Finally the kinetics of pair formation in the control and ALS-treated populations was studied in Couette viscometer chambers where cells are allowed to collide in well controlled conditions of constant shear rate, viscosity and temperature (Table 3). Although some variation was observed between control and experimental groups, in individual experiments the ratios between the ALS-treated and control suspensions within each experiment were similar. The numbers of pairs in the partially T-cell depleted suspensions were always higher than in the controls (reflected by ratios > 1); at 7 min the pairs in both suspensions tended to disaggregate (reflected in the ratio nearest 1, 1.43) but at the later times, 21 and 28 min, reaggregation was observed at higher levels in the partially T-cell depleted suspensions. In conclusion, the present results indicate that partial T-cell depletion leads to an increase in the frequency of heterologous and B–B direct cell interactions, which can be reversed by reconstitution with thymocytes. It has been shown previously that both T and B lymphocytes release factors capable of diminishing the adhesion of the unlike cell type (B or T) *in vitro*[5]. This study is the first definitive indication that such factors must be operating *in vivo*. The increase in the numbers of direct B-cell interactions must occur as the consequence of a decrease in the concentration of T factor; whether the partial reduction in the numbers of T cells is sufficient to lead to that decrease or whether ALS has an additional inhibitory action on the release of the T-cell factor needs to be clarified. Whatever the exact mechanism, the effect was reversed by the *in vivo* administration of thymocytes.

The relevance of these observations to current theories of the mechanism of T-cell regulation of the immune response is obvious. They clearly offer an attractive cellular explanation of the finding of enhanced antibody production in partially T-cell depleted animals[6] (reviewed in ref. 7). If, in a partially T-cell depleted population of lymph node cells obtained in the absence of a deliberately administered antigen the chance of direct interactions between different cell classes increases so considerably, addition of antigens, especially thymus independ-

ent, will meet with the most favourable physical conditions for specific information to be passed economically between interacting cells. The requirement of cell aggregation for immunostimulation to occur has been demonstrated in other *in vitro* studies of cell interaction[8]. Moreover, we have now shown that administration of thymocytes reduces the number of B–B cell interactions. The most likely functional repercussion of such an effect *in vivo* would be suppressed or defective antibody production as a direct result of diminished B-cell activation. The suppressive effect of thymocytes administered to mice immunised with SSSIII has been elegantly demonstrated by the extensive work of Baker and his associates[9]. The question of how T cells exert a regulatory role of B-cell function has been the subject of much discussion. The mechanism we have now been able to visualise, strikes us as a simple and ingenious control device which could be operating in most experimental systems *in vivo* and *in vitro* in which helper versus suppressive effects have been described[10].

Effect of interferon on lymphocyte transformation and nuclear antigen production by Epstein–Barr virus

THE Epstein–Barr virus (EBV) can transform human and simian lymphocytes into blast cells which are then capable of indefinite growth *in vitro*[1–4], with 85–100% of the cell population expressing the EBV-induced nuclear antigen (EBNA). Biological[5–7] and molecular[8] evidence shows clearly that there are at least two types of EBV strains, one of which (P3HR-1 EBV) does not transform human lymphocytes[5,6] and seems to possess approximately 15% more DNA sequences than the highly transforming strain (B95-8 EBV)[8]. Furthermore, by infecting cells of the established EBV genome-negative BJA-B line[9] it was also possible to show that whereas B95-8 EBV induces only EBNA in these cells, P3HR-1 EBV induces both EBNA and early antigen (EA)[7]. Thus, by using cells of BJA-B line, it now seems possible to investigate further several known viral functions[10]. We report here the results of a study in which we found that lymphocyte transformation by B95-8 strain of EBV could not be prevented by interferon. As shown below, this finding is further supported by the observation that in spite of the presence of interferon in very high doses (that is, up to 10^4 U ml^{-1}), EBNA can still be produced in a fraction of the EBV-infected BJA-B cells.

It is already known that interferon may not only inhibit virus replication but also cell transformation by viruses[11–14]. Herpes viruses in general, however, seem to be relatively insensitive to the antiviral effect of interferon (see ref. 15 for review). The effect of interferon on cell transformation by EBV and other herpesviruses has not yet been described. Moreover, the effect of interferon on the expression of EBNA has not been investigated.

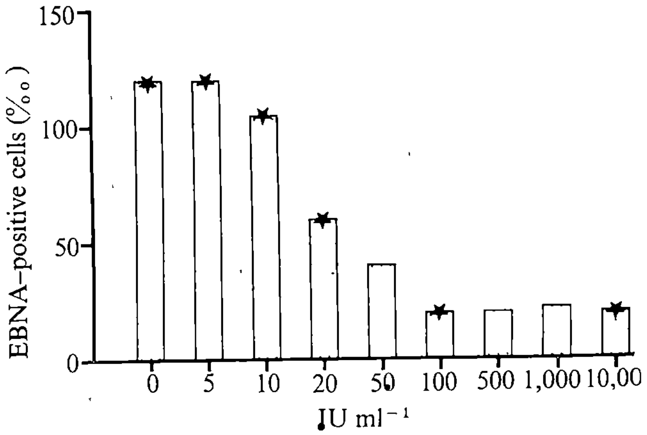

Fig. 1 Effect of interferon on EBNA production in BJA-B cells infected with B95–8 strain of EBV. Interferon was added to the culture medium 24 h before EBV infection. Interferon at these same concentrations was also added to the new medium used after infection, and the cells incubated for 72 h at 37 °C. Smears were prepared as described in Table 1. Whereas the results at 50, 500 and 1,000 IU are from single experiments, all others represent means from two separate experiments.

The experimental approach and the data on the effect of interferon on lymphocyte transformation are given in Table 1. Pretreatment of cells for 24–72 h with the interferon even at doses as high as 10^4 IU ml^{-1} did not inhibit lymphocyte transformation by EBV. No significant differences were observed in terms of time required for lymphocyte transformation by EBV (that is, development of a lymphoblastoid cell line · LCL) irrespective of the various interferon concentrations used. 85–97% cells from the transformed cultures contained EBNA when tested 3 weeks after infection. It is now well known that the presence of EBNA in the cells of a continuously growing lymphocyte culture is the best available evidence for EBV-induced transformation[5,10]. Several attempts to try to quantitate any effect of interferon on lymphocyte transformation by EBV were unsuccessful, since plating of EBV-infected CBL gave negative results in our hands (that is, EBV-infected CBL did not generally grow or stay viable for more than 5–7 d in semi-solid media, even in the presence of conditioning medium). We then decided to determine if CBL were sensitive to the anti-viral effect of interferon. Thus, using herpes simplex viruses we found that interferon can protect a large fraction of the cells against the cytocidal effect of these viruses (Table 2).

Fig. 2 Effect of interferon (●) on the kinetics of EBNA expression in EBV-infected BJA-B cells. ○, EBV alone. Cells were first cultured for 24 h in medium containing interferon (100 IU ml^{-1}) and infected as described in Table 1. The new culture medium added after EBV infection also contained interferon at this same concentration. Results represent means of two separate experiments

% EBNA-positive cells at 4 weeks	> 85	> 85	> 85	> 85

Lymphocyte transformation assays were carried out using human umbilical cord blood lymphocytes (CBL). CBL separation, culture, virus preparation and titration, EA and VCA (virus capsid antigen) staining procedures as well as tests for EBV specificity, were as described previously[5]. Two different preparations of human interferon, one concentrated and the other partially purified, containing 7.5×10^5 interferon units (IU) ml^{-1} (10^4 IU per mg protein) and 2.5×10^6 IU ml^{-1} (10^5 IU per mg protein) respectively, produced in Sendai virus-treated leukocytes, were supplied by Dr Kari Cantell (Central Public Health Laboratory, Helsinki). The procedures for interferon preparation, concentration and titration were as described previously[16]. The anti-viral activity of the interferon preparations was confirmed in our laboratory by a microassay system[17] on human embryo fibroblasts using Sindbis virus as challenger.

For EBNA induction in BJA-B, 10^6 cells were pelleted by a low speed centrifugation and the pellet resuspended in 0.5 ml of a virus dilution (known to be capable of inducing EBNA in about 12% of cells, collected 48 h after EBV infection). The cells were then gently dispersed and the mixture incubated for 1 h at 37 °C in a CO_2-humidified incubator. Growth medium (RPMI 1640 containing 10% foetal bovine serum and antibiotics)[9] was then added to bring the cell concentration to 10^5 cells ml^{-1} and this suspension was dispersed in culture tubes which were then kept at 37 °C for a desired period of incubation. The anti-complement immunofluorescence method[18] was used for EBNA staining but with the following modifications. JM reference serum[18] with anti-EBNA+VCA+EA antibody composition, diluted 1:5 in phosphate-buffered saline (PBS, *p*H 7.2) was used as common source of anti-EBNA antibody and complement; fresh JM serum in 0 2 ml aliquots was kept frozen at −90 °C until use. Smears with about 10^6 cells per coverslip were air dried at room temperature and fixed for 3 min in a 1:1 mixture of chilled (−20 °C) acetone–methanol and kept frozen at −20 °C until use. For EBNA reaction, fixed smears were incubated at room temperature for 45 min with fresh JM serum diluted to 1:5 in PBS, then washed twice with the latter and incubated for 45 min at room temperature with anti-human B_1C/B_1A FITC conjugate (Hyland Laboratories) at 1:20 dilution. The smears were subsequently washed (in PBS) three times, counterstained with Evans blue, washed three times and mounted on a slide in a 1:1 mixture of glycerol–PBS. Controls included (*a*) uninfected BJA-B cells, (*b*) EBV genome-positive Raji cells, (*c*) heat-inactivated (56 °C per 30 min) JM serum and (*d*) fresh EBV–0 serum, without detectable anti-EBV antibody, derived from a healthy EBV-seronegative donor.

*First, CBL of four different donors were used for these experiments. Interferon concentrations tested were 10^2, 10^3 and 10^4 IU ml^{-1}, respectively, and maintained by adding interferon to the new medium at every change. The EBV preparation used here had a transforming titre of $10^{5.5}$ $log_{10}TDC_{50}$ ml^{-1}. Infection was carried with 0.1 ml virus suspension per 10^6 CBL. The experiments were then repeated with CBL of two other donors with a new, partially purified interferon preparation (see above). At least two cultures (tubes and flasks) per donor were used in each of the above experiments.

†Transformation was confirmed by the criteria defined previously[5]. No transformation was observed in uninfected cultures, and the transforming activity was neutralised by pretreating the virus suspension with reference JM serum containing anti-EBV antibody. Serum from EBV-seronegative donor did not neutralise this transforming activity.

In preliminary experiments using BJA-B cells and CBL, we had found that in both cell types interferon had a similar inhibitory effect on the induction of EBNA by EBV. We therefore decided to quantify this effect only in the EBV genome negative BJA-B cell line. In BJA-B cells, the expression of EBNA could not be completely inhibited by interferon, even at doses as high as 10^4 U ml^{-1}. There was no detectable interferon effect (reduction in number of EBNA-positive cells) at 5 IU ml^{-1} but a considerable reduction was observed at doses over 10 IU ml^{-1}. Doses of 10^2–10^4 IU ml^{-1} gave similar results (Fig. 1). In preliminary experiments during the present study we found that in our experimental conditions the number of EBNA-positive BJA-B cells reached its maximum 40–48 h following EBV infection. Therefore, we investigated the effect of interferon on the appearance of EBNA up to 76 h after EBV infection. Figure 2 shows that a considerable reduction in the number of EBNA-positive cells was consistently detected in the presence of interferon in all the samples collected 20–72 h after EBV infection. Two other single experiments carried out using a more concentrated virus preparation (capable of inducing EBNA in about 20% of BJA-B cells), as well as interferon treatment of the cells beginning 1 week before EBV infection, also gave similar results. From these findings, it is difficult to understand why the anti-viral (EBNA) effect of interferon is effective only in a fraction of BJA-B cells. It is, however, possible that a subpopultaion of these cells is interferon resistant. In EBV-infected CBL cultures such a resistant cell population would outgrow the protected cells during the period (10–16 d) up to when the transformation is confirmed, and would thus explain the observed interferon resistance of CBL transformation by EBV. Note, however, that in other virus–cell systems interferon resistance in a fraction of virus populations[19] and/or a fraction of virus-infected cells[20] have been considered in the past as possible explanations for such a phenomenon.

Interestingly, it was previously found that interferon was unable to block the enhanced expression of EBV-induced antigens by hydrocortisone in EBV genome-carrying lymphoblastoid cell lines[21]. Note, however, that interferon has an inhibitory effect on cell transformation by other well known DNA viruses such as SV40 and adenoviruses[12–14]; this effect may, however, vary in degree according to the cell system and the virus used[12,13]. On the other hand, the effect of high interferon concentrations (10^4 IU ml^{-1}) on cell transformation as used in the present study was not tested against SV40 and adenoviruses[12,14]. Interestingly, the effect of interferon on EBNA production seems to be similar to its effect on T-antigen synthesis by SV40 and adenoviruses. In this respect, it was suggested that the expression of SV40 genome is sensitive to the action of interferon only if the SV40 genome is not integrated into the cell genome[13,22]. Since the question of the integration of the EBV genome into the cellular genome has not yet been completely resolved, it may be very important to transform CBL in the presence and/or absence of interferon and examine the LCL thus obtained for the relation of EBV genome to cellular genome in terms of integration.

Table 2 Sensitivity of CBL to the anti-viral action of interferon as tested against cytocidal effect by herpes simplex viruses types 1 and 2*

Virus type	Virus dose ($log_{10}TCD_{50}$ ml^{-1})	Interferon concentrations (U per 0.2 ml per 200,000 cells) 0	10	100	1,000
HSV 1	10^2	12†	38	70	71
	10^3	10	20	30	39
HSV 2	10^2	24	20	65	63
	10^3	10	17	40	42
Control (CBL cultures)	—	92	99	99	97

*CBL from a single donor were preincubated with interferon for 48 h. Virus was then added to these cultures which were further incubated for 96 h at 37 °C, and the cells examined for viability by Trypan blue dye exclusion test.

†Figures represent percentage of viable cells in each of the above conditions.

Growth of bacilli on methyl-α-D-glucoside

METHYL-α-D-GLUCOSIDE (αMG) is an analogue of glucose that is used extensively for studies of glucose transport in microorganisms[1,2]. This use implies that the analogue enters the cell and is phosphorylated[2], but is not further metabolised It is known[2] that *Escherichia coli* do not grow on αMG and Freese *et al*[3] reported that *Bacillus subtilis* (strain 60015) can grow on αMG only after a long lag period: the subsequent growth rate being very slow. This may not, however, be typical of bacilli since here we report several strains of bacilli which grow readily on αMG.

E. coli (KL16), *B. stearothermophilus* var *non-diastaticus*, *B. subtilis* (Marbourg) and *B. licheniformis* (A5) were grown on nutrient broth and then inoculated into salts medium (for *E. coli* see ref. 4; for *B. stearothermophilus* ref. 5; for the others ref. 6) containing 25 mM of one of the following sugars as the sole carbon source: αMG, 2-deoxyglucose, cellobiose, melibiose, maltose, lactose, sucrose or glucose. The cultures were incubated aerobically overnight (*B. stearothermophilus* at 55 °C, the others at 37 °C) to establish which sugars supported the growth of these organisms. The results show that whereas *E coli* does not grow on αMG (nor sucrose, nor cellobiose), all of the bacilli tested grew readily on these carbohydrates. All organisms tested grew readily on glucose and maltose, but not on 2-deoxyglucose.

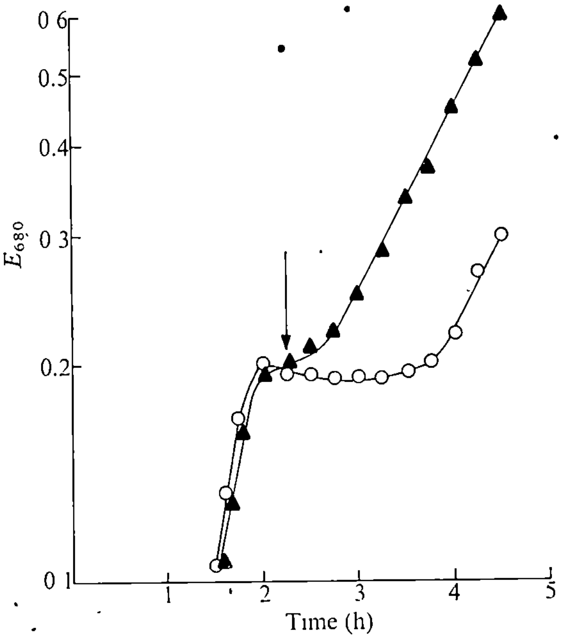

Fig. 1 Growth of *B licheniformis* on glucose (○), and maltose (▲), and subsequent growth on αMG (2 mM added as indicated by the arrow)

In view of the fact that the bacilli grow on αMG, the growth rates and yield of cells were compared from bacilli growing on αMG and on glucose *B. stearothermophilus*, *B. licheniformis*, *B. megaterium* and *B. subtilis* were grown on nutrient broth and then inoculated into salts medium containing either 2 mM glucose or 2 mM αMG. The cultures were incubated aerobically at 37 °C and growth followed by measuring the absorbance of the cultures at 680 nM. When both of the cultures had just run out of substrate, αMG to 2 mM was added to the culture that had grown on glucose and the time before growth of the culture began on the new substrate was recorded as the lag period for the organism to adapt from metabolising

Table 1 Growth of *B. stearothermophilus*, *B. licheniformis*, *B. megaterium* and *B. subtilis* on glucose and αMG

Organism	Incubation temperature (°C)	Glucose (2 mM) Doubling time (min)	Glucose (2 mM) ΔE_{680}	αMG (2 mM) Doubling time (min)	αMG (2 mM) ΔE_{680}	Lag period (min)
B licheniformis	37	50	0.315	90	0.405	120
B. megaterium	37	45	0.420	70	0.520	90
B. subtilis	37	60	0.390	120	0 460	50
B stearothermophilus	55	50	0.285	70	0.365	75

The organisms were first grown on nutrient broth and then inoculated into salts medium containing 2 mM of either glucose or αMG. When the glucose cultures had exhausted the added glucose, 2 mM αMG was added. The interval before exponential growth resumed was recorded as the lag period between the metabolism of glucose and that of αMG.

glucose to metabolising αMG. The results (Table 1) show that all the bacilli grow more slowly on αMG than on glucose but that the yield of cells from each substrate is about the same. Furthermore, there is a lag period between a bacillus metabolising αMG and metabolising glucose. In contrast, bacilli grown on maltose will immediately grow on αMG with no corresponding lag (Fig. 1). This suggests that bacilli possess a methyl-α-glucosidase which could be similar to that demonstrated in yeast (*S. cerevisiae*) which was shown to be specific for αMG in this organisms, and was coinduced by growth on maltose[7-9].

The results of this study show that bacilli grow readily on αMG, the metabolic enzyme (possibly methyl-α-glucosidase similar to that in yeast) being induced by growth on maltose and αMG. This means that αMG can only be used as a non-metabolisable analogue of glucose in bacilli if the organism has not been grown on maltose, and providing αMG is used for only a short period of time.

This work was supported by the Science Research Council through a grant to Professor H. L. Kornberg. We thank Professor N. Grossowicz for a gift of *B. stearothermophilus* var. *non-diastaticus*.

Methyl-α-D-glucoside uptake and splitting by a thermophilic bacillus

THE presence and properties of a phosphoenolpyruvate (PEP)-dependent phosphotransferase system in a thermophilic bacillus has been described recently by Harris and Kornberg. The formation of the glucose and methyl-α-D-glucopyranoside (αMG) uptake and phosphorylation is induced by glucose[1].

In the course of a study on the transport of glucose and αMG in the same thermophilic bacillus[2] we noticed that growth occurred in a minimal medium supplemented with αMG as the sole carbon source. The generation time at 58 °C was found to be 52 min. The growth rates in presence of αMG, glucose and succinate are given in Fig. 1. In addition to αMG, other α-glucosides, that is, maltose, sucrose, trehalose and turanose can also serve as sole carbon sources.

Washed suspensions of αMG grown cells incorporated ^{14}C-αMG into the macromolecular constituents of the cell (Table 1). Almost no ^{14}C-αMG was incorporated with suspensions of glucose-grown cells. Cellular extracts of αMG and maltose-grown cultures which were allowed to take up ^{14}C-αMG showed by thin-layer chromatography and autoradiography several spots, representing, presumably, different degradation products of the sugar; whereas extracts from cells grown on glucose revealed only a single spot in addition to the residual αMG (Fig. 2), corresponding to an αMG phosphate (to be published).

The above results demonstrate the presence of an enzyme system in the thermophilic bacillus responsible for the hydrolysis (and metabolism) of αMG. A study was carried out to identify the enzyme(s) and conditions for their activity, using intact cell suspensions and *p*-nitrophenyl-α-D-glucopyranoside (PNPG) as substrate. PNPG hydrolysis was linear with time for about 30 min and cell concentrations up to at least 0.25 mg dry weight.

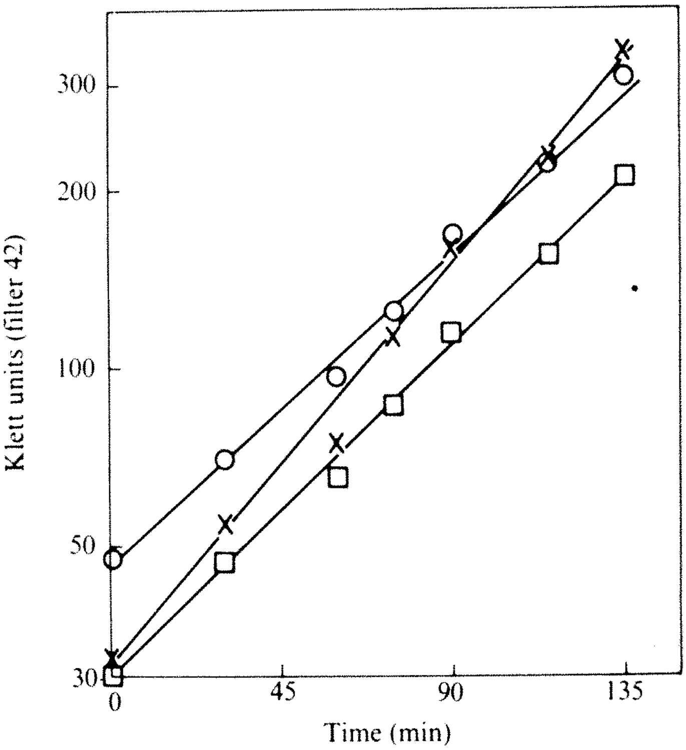

Fig. 1 Growth of the thermophilic bacillus at 58 °C on various carbon sources; 0.5% αMG (○), 0.5% Na-succinate (□) and 0.5% glucose (×). The tyrosine–leucine auxotroph and the TL-minimal medium were used; growth conditions were as described elsewhere[3].

High αMG-hydrolysing activity was induced by αMG or maltose; turanose and trehalose were much poorer inducers, while sucrose was completely inactive (Fig. 3). Higher levels of induction were obtained in rich medium than in the minimal medium.

In contrast to the ability of induced intact cells to split PNPG or αMG, no activity was found when using cell-free preparations. Moreover, impairment of the integrity of the cell membrane (by treatment with toluene, sonic oscillation or lysozome) resulted in the loss of the α-glucosidase activity. Addition of phosphoenolpyruvate (PEP), glucose-6-phosphate or adenosine triphosphate (10 μmol each) to the cell-free system failed to restore enzymatic activity.

It was shown by Harris and Kornberg[1] that glucose induces the uptake and phosphorylation of glucose and αMG by cultures of the thermophilic bacillus grown in either acetate or succinate. As shown in Table 2 the PEP-dependent phosphorlyation of ^{14}C-αMG was induced not

Table 1 ^{14}C-αMG incorporation into the macromolecular fraction of the thermophilic bacillus

Carbon source for growth	c.p.m. per sample Whole cells	 5% TCA precipitate
Na succinate+glucose	4,700	360
Na succinate+αMG	21,045	11,680
αMG	22,076	12,420

Cells were grown at 58 °C in TL-minimal medium[3] supplemented with the indicated carbon source. Duration of uptake of ^{14}C-αMG (1×10^{-4} M; specific activity, 3 μCi μmol^{-1}), in medium lacking carbon source, was 10 min. Thereafter, two 0.2-ml samples, 0.1 mg dry weight of cells each, were taken for determinations of the total uptake and radioactivity in cold TCA (5%) precipitate[3]. Uptake refers to the radioactivity accumulated in cells, and thus includes both label of the sugar and metabolic products derived from it.

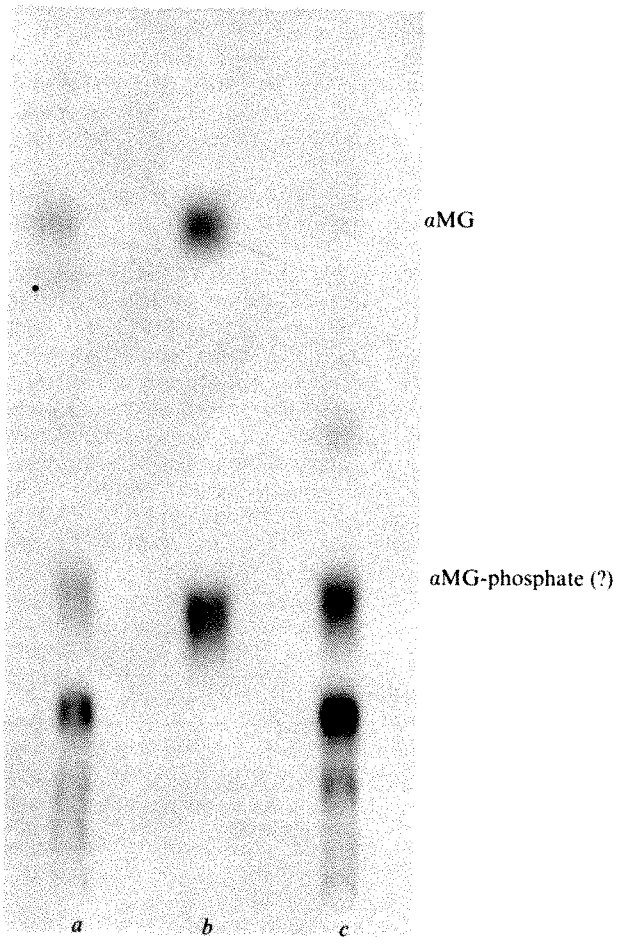

Fig. 2 Metabolism of ^{14}C-αMG. ^{14}C-αMG (2×10^{-4} M, specific activity 3 μCi μmol^{-1}) was added to washed suspensions (0.3 mg dry weight per ml) from *a*, αMG; *b*, glucose and *c*, maltose grown cultures; total volume 4 ml. After 1 min at 58 °C the cells were collected on membrane filters, washed and immediately plunged into boiling 1 mM Tris-HCl buffer at *p*H 9.0 and held for 6 min. Cell debris was removed by centrifugation. The supernatant fluid was concentrated by lyophilisation and aliquots were chromatographed on cellulose-coated sheets using ammonium acetate 1 M (*p*H 4.0)–95% ethanol (2 : 5 v/v) solvent system. The autoradiograms were observed after 7 d of exposure.

only with glucose, but also with αMG. According to these investigators[1] the uptake of αMG by intact cells of the thermophilic bacillus was directly correlated with the activity of the phosphotransferase, which catalyses the PEP-dependent phosphorylation of αMG. It seemed, therefore, worthwhile to test the possibility that αMG induces its own transport. Figure 4 shows that induction of αMG transport could indeed be achieved not only by glucose but also by αMG; the differential rate of the synthesis of the

Table 2 Induction of αMG phosphotransferase activity

Incubation mixture	Cell-free extract from cultures grown on Succinate	Succinate+glucose	Succinate+αMG
Complete	1,500	10,400	6,170
Without PEP	910	1,015	330
Without PEP; +ATP	1,020	2,030	505

Cultures were grown in TL-minimal medium with the indicated carbon sources and were collected in the log phase; the cells were washed and resuspended in 0.05 M potassium phosphate buffer (*p*H 7.2), treated with lysozyme (0.1 mg ml^{-1}) and then sonicated for 60 s using the MSE sonifier. The sonicates were centrifuged for 10 min at 750 r.p.m. and the supernatant assayed for ^{14}C-αMG phosphorylation ability at 58 °C according to Freeze *et al.*[4]. The reaction was stopped after 10 min and assayed for DEAE-cellulose-adsorbable radioactivity. Results are expressed in c.p.m. per mg protein.

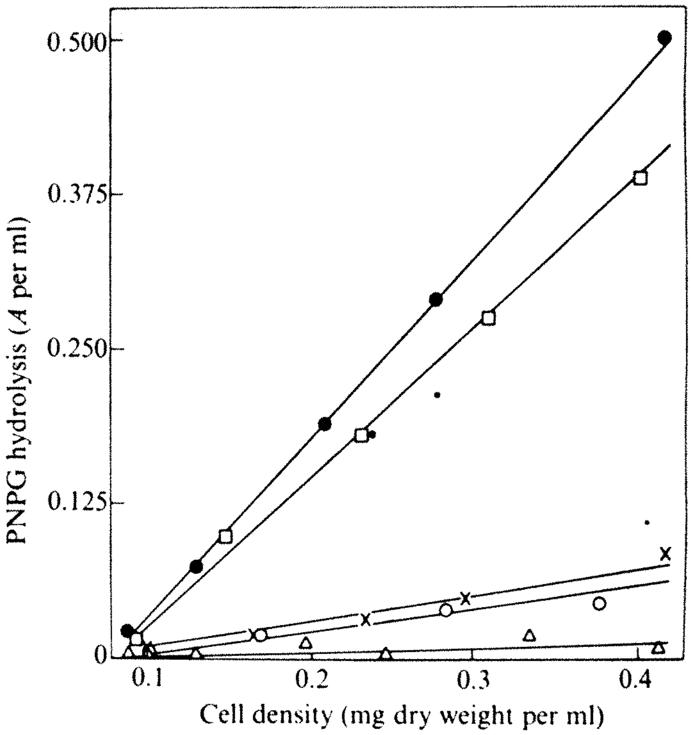

Fig. 3 Induction pattern of PNPG splitting activity by cell suspensions. Cultures were grown at 58 °C in TL-minimal medium supplemented with 10% (v/v) rich medium[3]. For PNPG hydrolysis samples were withdrawn during growth, filtered and the cells resuspended in minimal medium. The reaction was started by adding PNPG (1×10^{-3} M) and terminated by the addition of 1 ml of 2 M Na_2CO_3. The liberated aglycone was determined at 420 nm using a Spectronic 88 spectrophotometer. Controls without substrate were included and the absorbance obtained was subtracted. Carbon source during growth: 0.5% αMG (●); 0.5% maltose (□); 0.5% turanose (×); 0.5% trehalose (○); 0.5% sucrose (△).

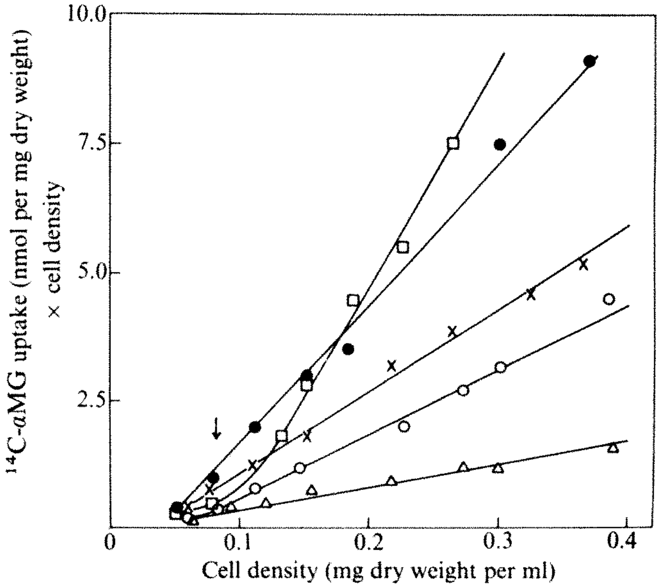

Fig. 4 Induction of ^{14}C-αMG uptake by the thermophilic bacillus. Cultures were grown in TL-minimal medium at 58 °C. Samples were withdrawn during growth, filtered and suspended in the minimal medium lacking the carbon source. Duration of uptake 0.5 min. The ^{14}C-αMG concentration was 5×10^{-5} M, specific activity 3 μCi μmol^{-1}. Carbon sources during growth, 0.5% Na-succinate (△), 0.5% Na-succinate+0.5% αMG (○), 0.5% αMG (×), 0.5% glucose (●), 0.5% Na-succinate+0.5% glucose (□). Arrows show the time of addition of inducer (αMG or glucose) to succinate-grown cultures. For further details see legend to Table 1 and ref. 3.

αMG transport system was, however, much higher in the presence of glucose than in the presence of αMG.

It has already been pointed out by Harris and Kornberg[1] that glucose and αMG differ in their uptake properties. Our results accentuate these differences and show clearly that both the αMG phosphotransferase and the αMG transport system can be induced by αMG and not only by glucose. Although both glucose and αMG induce the uptake of αMG, the αMG-hydrolysing activity is induced by αMG and maltose, but not by glucose. The possibility, therefore, exists that the transport system induced by αMG is different from the one induced by glucose. A study of the specificity of the two inducible transport systems may clarify this point. The existence of an α-glucosidase in various yeast cells is well established[5,6]. In *Saccharomyces cerevisiae* the simultaneous induction of two specific α-glucosidases, that is maltase and αMG-splitting enzyme, by either maltose or αMG have been reported[7].

It remains to be seen whether the α-glucosidases induced by maltose and αMG in the thermophilic bacillus possess different and specific enzymatic activities or they represent a single enzyme with a substrate specificity towards both maltose and αMG.

In summary, our results clearly indicate that the thermophilic bacillus is able to catabolise αMG after it is transported into the cells, although αMG-splitting activity seems rather rare in prokaryotic organisms[8]. This report also demonstrates the ability of αMG to induce its own transport across the cell membrane. The substrates of the α-glucosidase activity, the optimal conditions for the enzymatic hydrolysis, and the reaction products formed, are being studied.

Note added in proof: Similar findings were recently reported with the mesophilic *Bacillus subtilis*[9].

Inhibition of malformin activity by hydroxyproline and restoration by proline

MALFORMIN, (cyclo-D-cysteinyl-D-cysteinyl-L-valyl-D-leucyl-L-isoleucyl)[1], is produced by the fungus *Aspergillus niger* van Tiegh., induces severe malformations on stems and petioles of various plants, and causes root curvature[2]. When ^{14}C-malformin was supplied to cuttings of the bean *Phaseolus vulgaris* L. most of the ^{14}C was found in the wall fraction and was liberated from a protein-like component in the walls as ^{14}C-malformeic acid (SO_3H-malformin) by oxidation[3]. Previous results indicated that malformin inhibited wall synthesis and altered wall composition[4–6]. We recently found that malformin is a potent stimulator of plant growth and inhibits several phytochrome- and ethylene-mediated responses. Because some effects of light and ethylene on plant growth have been attributed to an increase in extensin[8–11], a hydroxyproline-rich protein in plant walls, it was suggested that malformin may alter the synthesis or function of this wall component[7]. Because malformin activity is inhibited by reducing agents[12] and it reacts with sulphydryl compounds[13], involvement of wall sulphydryl groups in the activity of malformin was also proposed[7]. We report here on the effect of hydroxyproline and proline, amino acids important in the synthesis of extensin, on the growth-stimulating and root-curving activities of malformin.

Cuttings from 4-d-old green seedlings of *P. aureus* Roxb., grown in vermiculite, were obtained by excision 7.0 cm below the apical bud. The cuttings were transferred randomly to 12-ml vials containing 6.0 ml of test solution (12 cuttings per vial), and incubated in continuous light (1.35×10^4 erg cm^{-2} s^{-1}, Champion F90T17/w, white fluorescent, 27–29° C). Deionised water was added daily to maintain the volume at approximately 6.0 ml. After 2 d the stem length was measured. Measurements from each vial were averaged and considered as a single determination. The growth increment ratio (GIR) was determined by dividing the growth increment of treated cuttings by that of controls (water treated). Malformin-induced root curvatures were determined by germinating seeds of *Zea mays* L. WF9 × 38-11 for 3 d in Petri dishes containing a sheet of Whatman No. 1 filter paper (9.0 cm) moistened with 3.0 ml of test solution, and counting the number of roots with at least a 90° C curvature from the original direction of growth[2].

Table 1 Effect of L-proline and L-hydroxyproline on growth stimulation and root curvature induced by malformin

Treatment	*Phaseolus aureus* growth stimulation (GIR)*	*Zea mays* root curvature (%)†
H_2O	—	1.4 ± 1.3
Malformin 0.1 μM	1.64 ± 0.06	57.8 ± 11.8
Malformin 0.1 μM, proline 10 mM	1.42 ± 0.04	60.7 ± 10.9
Malformin 0.1 μM, hydroxyproline 10 mM	1.11 ± 0.05	14.3 ± 6.4
Proline 10 mM	0.86 ± 0.06	2.8 ± 2.8
Hydroxyproline 10 mM	0.82 ± 0.05	0.0 ± —

*Growth increment ratio = growth increment of treated cuttings/growth increment of controls (H_2O); ± s.e.

†Percentage roots with at least a 90° curvature; ± s.e.

L-Hydroxyproline markedly inhibited plant growth stimulation and root curvatures induced by malformin, but L-proline had little or no effect (Table 1). Although proline and hydroxyproline both inhibited growth of cuttings when applied alone, only hydroxyproline substantially reduced malformin-induced growth stimulation. Reduction of malformin-induced growth by proline was only slightly greater than that which occurred in the absence of malformin, but that of hydroxyproline was considerably greater. Neither of these amino acids alone stimulated growth or induced root curvatures. L-Leucine, DL-threonine, L-tyrosine, and DL-serine had little effect on malformin-induced growth stimulation, and in earlier experiments L-valine, L-isoleucine, and L-leucine did not inhibit curvatures induced by malformin[12]. We concluded that the inhibition was specific for L-hydroxyproline. Although lower concentrations (1.0, 0.1 mM) of hydroxyproline were effective in inhibiting malformin-induced root curvatures, they had little effect on malformin-induced growth stimulation. Growth changes induced by malformin in corn roots were attributed primarily to effects on cell elongation[6]. In preliminary experiments L-hydroxyproline also reduced the severity of malformations on seedlings of *P. vulgaris* treated with malformin. Malformations on *P. vulgaris* have been described as the result of a change in the orientation of developing cells so that they elongate at an angle to the longitudinal axis of the plant[14].

Table 2 Restoration of malformin activity by L-proline in the presence of an inhibitory concentration of L-hydroxyproline

Treatment	*Phaseolus aureus* growth stimulation (GIR)	*Zea mays* root curvature (%)

Malformin 0.1 μM	1.63±0.04	51.6±4.2
Malformin 0.1 μM, hydroxyproline 10 mM	0.97±0.08	22.9±6.5
Malformin 0.1 μM, hydroxyproline 10 mM, proline 10 mM	1.45±0.05	48.2±4.8
Hydroxyproline 10 mM, proline 10 mM	0.84±0.07	3.1±2.2

Table 3 Proline, hydroxyproline and total amino acid content of cell walls from normal and malformed internodes of *P. vulgaris**

Internode	Total amino acid	Hydroxyproline	Proline	Hydroxyproline / Proline
Normal	21.2±1.6	0.70±0.05	0.68±0.06	1.03±0.17
Malformed	28.6±1.7	2.68±0.12	1.14±0.02	2.35±0.06

*Results are μg amino acid per mg dry weight cell wall ± s.e. Seedlings of *P. vulgaris* cv. Harvester were treated on the apical bud with malformin (10^{-5} M) as described[2]. After 11 d the first internodes above the simple leaves were diced and frozen (−15 °C) until analysed. Frozen material was homogenised for 5 min in 3:1 v/w 0.2 M Tris buffer (*p*H 7.5) and centrifuged at 150*g* for 10 min. The pellet was suspended in 10 ml Tris buffer, homogenised again and centrifuged as described. The cell wall pellet was washed twice with buffer (10 ml) and 3 times with deionised water (10 ml). After each wash the wall fraction was pelleted at 150*g* for 10 min. The wall pellet was washed with trichloroacetic acid (5%, 10 min, 90 °C), cold trichloroacetic acid (5%, 5 min, 10 ml), 95% ethanol (70 °C), ethanol–ether–$CHCl_3$ (2:2:1, 55 °C) and ether–acetone (2:1, 25 °C). After each wash the wall fraction was centrifuged (1,500*g*, 5 min)[18]. The cell walls were air dried, hydrolysed for 24 h by refluxing in 6N HCl (4,000:1 excess HCl) in a CO_2 atmosphere, and the hydrolysate cleared of humin[19] by charcoal and filtration. The hydrolysate was dried *in vacuo* at 60 °C, dissolved in deionised water, and analysed for hydroxyproline[20], proline[21], and total amino acids[22].

Proline rather than hydroxyproline is the usual precursor of bound hydroxyproline in plants[11,15], and the inhibition of cell elongation in the *Avena* coleoptile by hydroxyproline was suggested to result from an inhibition of the formation or utilisation of a hydroxyproline-rich protein in cell walls[16]. Growth inhibitory concentrations (0.5 mM) of hydroxyproline are incorporated directly into coleoptile proteins and proline prevents this incorporation[17]. The ability of proline to restore malformin activity in the presence of inhibitory concentrations of hydroxyproline was examined (Table 2). L-Proline almost completely restored the biological activity of malformin with regard to growth stimulation and root curvatures, although proline itself or in combination with hydroxyproline neither stimulated growth nor induced root curvatures (Tables 1, 2). The amount of amino acid present when proline and hydroxyproline were combined with malformin was double (20 mM) that present when only hydroxyproline was present. To ensure that simply increasing the amount of amino acid did not account for restoration of malformin activity we also assayed malformin activity in the presence of 20 mM hydroxyproline. Malformin activity was not restored.

To determine if malformin alters the metabolism of proline and hydroxyproline we examined the content of these amino acids in cell-wall fractions from normal and malformed internodes of *P. vulgaris*. This tissue was selected because malformin was shown to inhibit wall synthesis and alter wall composition[5], as well as attach to a protein-like component in wall fractions of *P. vulgaris* internodes[3]. On a dry weight basis the amount of total amino acids in wall fractions from malformed internodes was greater than that in similar fractions from normal tissues (Table 3). Malformin induced a marked increase in the amount of hydroxyproline and proline content of wall fractions and increased the hydroxyproline–proline ratio more than twofold. Because malformin seems to have more than one mode of action, stimulates elongation in some systems[7], but inhibits elongation in other systems[2], we are unable to offer an explanation for our results. Since malformin inhibits several phytochrome- and ethylene-mediated responses, the effect of malformin on hydroxyproline-rich wall protein probably differs from that proposed for phytochrome and ethylene[9,10]. But inhibition of malformin activity by hydroxyproline, restoration of activity by proline, and alterations in the hydroxyproline–proline ratio in cell-wall fractions from malformed internodes strongly implicates a role of hydroxyproline-rich protein in the biological activity of malformin.

We thank Mrs P. Phillips for technical assistance.

Parathyroid hormone-responsive adenylate cyclase in induced transplantable osteogenic rat sarcoma

AN apparent paradox prevents accurate assessment of the role of cyclic AMP in the development and maintenance of tumours. Although cell culture experiments indicate that malignant transformation is associated with decreased adenylate cyclase activity and intracellular cyclic AMP levels[1,2], the same is not true of *in vivo* studies with tumours, in which a range of results have been obtained, from low[3] to normal[4] and elevated[5] tumour cell cyclic AMP levels. We report here the development of a transplantable osteogenic sarcoma which has retained through many generations a parathyroid hormone-responsive adenylate cyclase, providing a system which can be used to evaluate the significance of hormone-responsive adenylate cyclase for tumour cell growth and differentiation.

Tumours were induced in Sprague–Dawley rats by injecting carrier-free ^{32}P-orthophosphate according to a schedule which has been shown[6] to lead to a high incidence of osteogenic sarcoma development. After an initial intraperitoneal injection of 1 μCi per g body weight, six subsequent injections of 0.6 μCi per g body weight were given at 2-week intervals. After a lag period of 6–9 months tumours became palpable, usually in the tibiae or femora, in approximately 50% of treated animals. Some microscopic features of primary and transplanted tumours have been described by Geddes-Dwyer *et al.*[7].

All the rats used for tumour induction and subsequent transplantation were derived from one original litter. Tumour transplantation was carried out initially by forcing small pieces of tumour through 60-mesh stainless steel gauze, and injection into the flank of recipients. In later experiments with established tumours, cells were dispersed by collagenase and hyaluronidase digestion, counted in a Coulter counter, and injected (10^6–3×10^6 cells) subcutaneously into the flank. In these conditions tumour transplantation had virtually a 100% success rate. Tumours appeared 2–3 weeks after transplantation and rapidly grew to a large size requiring further transplantation or leading to the death of the animal within 6 weeks.

Although in the early stage of growth the cut surfaces of tumours have a fleshy appearance, calcification eventually occurs in all tumours, frequently with large calcified deposits but sometimes detectable only microscopically. Figure 1 illustrates the microscopical appearance of a transplanted tumour showing early calcification. The mineralisation is not related to necrosis, and takes place on an intercellular ground substance which can readily be shown, with appropriate staining, to consist of collagen and PAS-positive material, presumably mucopolysaccharide. The tumour used for the biochemical and histological experiments described here consisted of fairly uniform cells (Fig. 1) not showing the pleomorphism often seen in human osteogenic sarcoma. In spite of a search through many sections of lightly and heavily calcified tumour, no osteoclast-like cells were seen. Similarly, using electron microscopy the cells were of uniform morphology with prominent polyribosomes and intercellular collagen fibres.

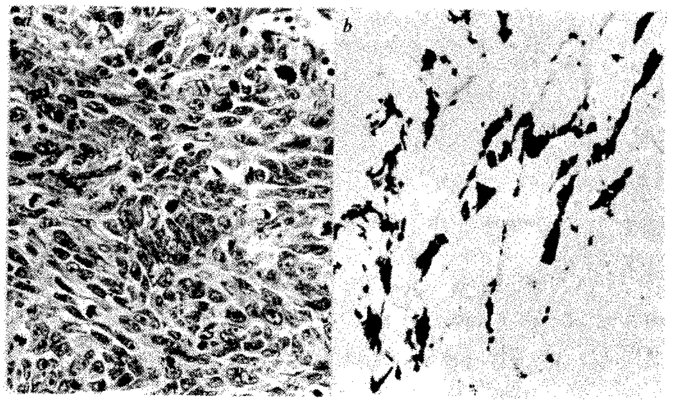

Fig. 1 Section of the tumour stained with haematoxylin and eosin (*a*) and by von Kossa's method (*b*). The tumour cells are slightly elongated, of relatively uniform morphology, and show much mitotic activity. Mineralisation of the intercellular matrix is shown by the dark areas in the von Kossa stained preparation (× 196).

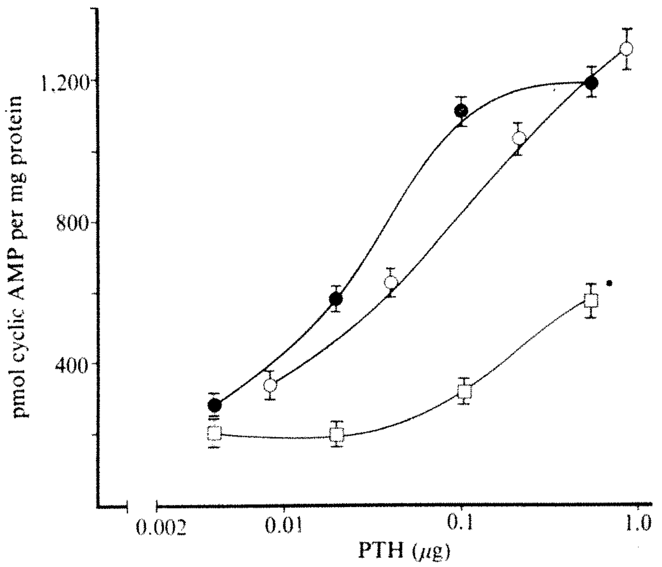

Fig. 2 Adenylate cyclase response of partially purified plasma membranes from rat osteogenic sarcoma on treatment with various preparations of PTH. Membranes were prepared and assay carried out as for Table 1. The hormone preparations used were as follows: ●, synthetic bovine PTH (1-34); □, synthetic bovine PTH (2-34); ○, highly purified bovine PTH, potency 2,500 U mg^{-1} (preparation 72/286, MRC Division of Biological Standards).

In all but those tumours in advanced stages of calcification dispersed cells could readily be prepared, and subcellular preparations made. The remaining experiments to be described were carried out with partially purified plasma membrane preparations, in which the adenylate cyclase activity of the tumour was studied. The response to various hormones is shown in Table 1. The major effect was obtained with parathyroid hormone (PTH) and lesser effects with prostaglandins E_1 and E_2. Isoprenaline, glucagon, and salmon calcitonin stimulated adenylate cyclase to a small extent. The experiment of Fig. 2 illustrates that the interaction between PTH and the receptor in the sarcoma cell membranes resembles that between the hormone and its receptor in rat renal cortex membranes, in that parallel dose responses were obtained with highly purified bovine PTH and the synthetic peptide based on the first 34 amino acids of the hormone's sequence. Furthermore the synthetic (2-34) peptide had approximately the same relative effect in this system as it has been shown to have in rat renal membranes[8]. Oxidised PTH, which is ineffective biologically in other systems, had no stimulatory effect on adenylate cyclase in the tumour cell membranes. Thus the tumour seems to possess a PTH receptor which resembles in certain major features that present in the rat kidney. Although there is some information available regarding the response of bone cell adenylate cyclase to PTH[9], it is not sufficiently complete to enable comparison with the present data.

These experiments were carried out on a tumour which had been transplanted almost 20 times over a period of 2 yr. Several other membrane preparations were examined, derived from other primary osteogenic tumours induced in the same way, and all were found to have a PTH-responsive adenylate cyclase. It is also important to note that in the tumour of this study no detectable change in the nature of the hormonal response took place during intensive study over a period of 6 months, encompassing six transplantations, and furthermore the hormone responsiveness remained constant through all stages of growth of individual tumours.

Changes in adenylate cyclase activity and its hormonal control have been observed in several experimental and

Table 1 Effect of various hormones on adenylate cyclase activity in partially purified plasma membranes from rat osteogenic sarcoma

Treatment	Concentration	Adenylate cyclase activity (pmol cyclic AMP formed per mg protein)*
Nil	—	55.8 ± 2.8
PTH	2×10^{-7} M	175.4 ± 4.9
	2×10^{-6} M	471.4 ± 1.9
Salmon calcitonin	3×10^{-7} M	69.5 ± 1.2
Glucagon	5×10^{-6} M	74.2 ± 1.8
Isoprenaline	10^{-5} M	98.4 ± 2.8
Prostaglandin E_1	10^{-5} M	146.8 ± 4.1
Prostaglandin E_2	10^{-5} M	138.4 ± 2.1
Prostaglandin $F_{2\alpha}$	10^{-5} M	71.2 ± 1.7
Fluoride	10^{-2} M	542.6 ± 35.8

Tumour was chopped and homogenised at 4 °C with six strokes of a loose fitting Dounce homogeniser (10 ml per g wet weight 0.25 M sucrose, 1 mM EDTA in 10 mM Tris-HCl, *p*H 7.4). Centrifugation was carried out in 50-ml tubes in the SS-34 head of a Sorvall RC2B centrifuge. The centrifuge was switched on, allowed to reach 2,000 r.p.m., and immediately slowed down with the brake applied. The supernatant was centrifuged for 10 min at 4,300 r.p.m. The upper, creamy layer from this pellet was removed in the same buffer and centrifuged at 6,000 r.p.m. for 10 min. The pellet was resuspended in the adenylate cyclase assay buffer and immediately assayed (50 µl suspension per assay tube). Protein was measured by the method of Hartree[15]. Adenylate cyclase incubations were carried out at 37 °C for 12 min. Assay mixtures consisted of the following components in a volume of 100 µl: 25 mM Tris-HCl, *p*H 7.4; 1 mM α-^{32}P-ATP (specific activity about 10 c.p.m. pmol^{-1}, Radiochemical Centre); 1 mM cyclic AMP; 2.5 mM phosphoenol pyruvate; 1.5 IU pyruvate kinase; 0.013% (w/v) bovine serum albumin; 30 mM KCl; 4.5 mM $MgCl_2$; 160 µg membrane protein; and hormone concentrations as indicated. Reaction was stopped by addition of 100 µl 40 mM ATP and boiling for 2 min. The generated ^{32}P-cyclic AMP was purified by the method of Salomon *et al.*[16] as described previously[17]. Bovine PTH of potency 1,000 U per mg was used, and other hormones were as follows; salmon calcitonin (synthetic, gift of Armour Pharmaceuticals), prostaglandins E_1 and E_2 (gift of Dr J. E. Pike, Upjohn), and glucagon (Eli Lilly). In addition to the hormones indicated, the following had no significant effect on adenylate cyclase activity at the concentrations indicated: insulin (3×10^{-6} M); human growth hormone (3×10^{-6} M); ovine prolactin (3×10^{-6} M); pentagastrin (ICI, 10^{-5} M); arginine vasopressin (Sandoz, 10^{-5} M); human adrenocorticotropic hormone (6×10^{-6} M).

*Results are means ± s.e.m. of triplicate determinations.

human tumours[10–13] and in the premalignant stage of chemical carcinogenesis[4,14]. The significance of these changes is not yet clear, and no unified concept could be developed at present. The hormone-responsive transplantable osteogenic sarcoma described here will facilitate testing of the effect of hormone-mediated changes in cyclic AMP on malignant cell proliferation. Moreover, differentiation of the tumour will be particularly amenable to study in view of its osteogenic capability, allowing it to progress from a soft tumour to one which has a network of mineralised matrix; this lends itself to relatively simple quantification.

Reduced muscle acetylcholine sensitivity in rats immunised with acetylcholine receptor

ANIMALS immunised with acetylcholine receptor (AChR) purified from the electric organ of *Electrophorus electricus* or *Torpedo marmorata* develop a muscular weakness which is alleviated by injections of anticholinesterases[1–6]. This observation has provided a valuable animal model for study of the disease myasthenia gravis. Sera from rats immunised with electric eel receptor contain antibody to AChR isolated from rat skeletal muscle[2,6], suggesting that the muscular weakness is due to a reduced endplate sensitivity to ACh. We report here a reduction in the ACh sensitivity of denervated muscles from immunised rats. Furthermore, there is a factor in the serum of immunised rats which can reduce the ACh sensitivity of denervated rat muscles *in vitro*.

Female Lewis rats (10 weeks old) were injected on a single occasion at multiple intradermal sites with 100 pmol of AChR protein, purified from the electric organ of *E. electricus*, in 0.1 ml of phosphate-buffered saline, emulsified in 0.1 ml of Freund's complete adjuvant. As additional adjuvant 2×10^{10} *Bacillus pertussis* organisms (special vaccine product, Eli Lilly) were injected subcutaneously. Rats immunised in this way develop two episodes of weakness; an initial transient episode after 8–9 d and a second chronic episode after 4 or more weeks.

Table 1 Reduction of extrajunctional ACh sensitivity of denervated hemidiaphragm muscle fibres by rat anti-AChR antiserum

Anti-rat ACh receptor titre (10^{-8} M)	Complement inactivation	Incubation period (min)	$\frac{\text{ACh sensitivity (serum treated)}}{\text{ACh sensitivity (control)}}$ (%)
1.03	No	120	23*
1.53	No	45	28*
1.31	No	75	29*
1.61	Yes	120	29†
0.62	Yes	60	43‡
0.24	Yes	75	50*

In some experiments complement was inactivated by heating the serum for 30 min at 56 °C. Extrajunctional ACh sensitivities were measured in 15–20 fibres of 1-cm wide muscle strips before and after incubation with sera for 45–120 min at 37 °C. All sensitivity measurements were made at 21–23 °C. Anti-rat AChR titre is expressed as mol ^{125}I-α-cobratoxin binding sites precipitated per l of serum[6]. This assay in which rat antibody bound to ^{125}I-α-toxin-AChR is precipitated by rabbit anti-rat IgG, measures antibody directed against sites on the AChR molecule other than the ACh binding site. Statistical significance was determined using a *t* test.

* $P<0.0005$.
† $P<0.025$.
‡ $P<0.05$.

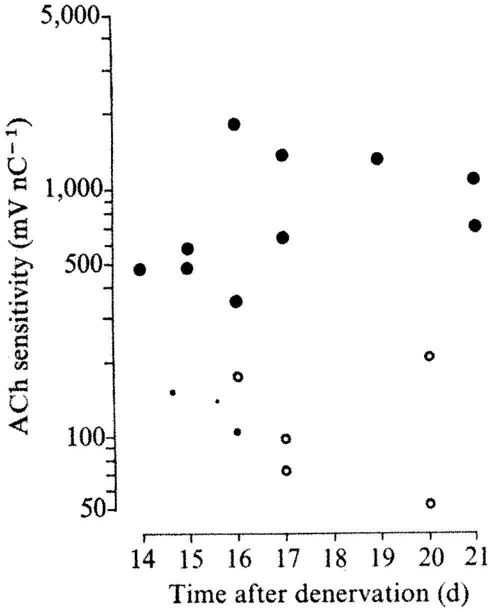

Fig. 1 Mean extrajunctional ACh sensitivities of denervated hemidiaphragm muscle fibres from adjuvant-treated rats (●) and rats immunised with AChR (○). Each point represents the mean sensitivity of 15–22 fibres measured at points 3–5 mm from the myotendonous junction. Extrajunctional ACh sensitivities were determined at room temperature (21–23 °C) by iontophoretic application of ACh from pipettes filled with 3 M AChCl (resistances 200–350 M Ω) positioned within 50 μm of the intracellular recording electrode. Sensitivities are expressed as mV nC^{-1} (ref. 10), that is the amplitude of the ACh potential in mV per electric charge in nC passed through the iontophoretic pipette.

All experiments were made on animals during the second episode shortly after the appearance of generalised weakness. Control animals were injected with adjuvants only. Rat sera were tested for antibodies to rat AChR by immunoprecipitation using ^{125}I-α-cobratoxin-labelled receptor as described elsewhere[6]. Isolated hemidiaphragm muscles were examined electrophysiologically at room temperature (21–23 °C) in a modified Krebs solution (150 mM NaCl; 5 mM KCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 11 mM glucose, 5 mM HEPES–NaOH, *p*H 7.4, bubbled with 100% oxygen) using standard techniques.

As reported previously[5], miniature endplate potential (m.e.p.p.) amplitudes were reduced in animals immunised with receptor. The mean m.e.p.p. amplitude at 20 control endplates was 0.74±0.06 mV (mean±s.e.m.) while m.e.p.p. amplitudes in muscles from immunised rats were usually less than 0.2 mV. The mean m.e.p.p. amplitude estimated at 34 endplates was 0.14±0.01 mV. This value, however, probably overestimates the true amplitude, as m.e.p.p. amplitude histograms were often highly skewed, suggesting that smaller m.e.p.p.s. were lost in the recording noise level. Several properties of muscle fibres which affect m.e.p.p. amplitudes were similar in control and immunised rats. Muscle fibre resting potential and the reversal potential of the endplate potential showed little or no change. Also input resistance and membrane time constant in fibres of immunised rats (0.39±0.02 MΩ (mean ±s.e.m., $n = 66$), 2.36±0.08 ms ($n = 25$)) were not significantly different (*t* test, $P > 0.1$) from the values in control animals (0.37±0.03 MΩ ($n = 57$), 2.22±0.06 ms ($n = 34$)). The decrease in m.e.p.p. amplitudes is therefore likely to result either from a reduction in the size of the ACh quanta released from the nerve terminals or from a reduced postjunctional response to ACh. The latter possibility was examined by measuring the ACh sensitivity of extrajunctional regions of denervated muscles. Although extrajunctional receptors differ in some respects to junctional AChRs[7], denervated muscle offers a convenient preparation for analysing changes in ACh sensitivity.

Hemidiaphragm muscle fibres were denervated under ether anaesthesia by sectioning the left phrenic nerve close to the muscle. Extrajunctional ACh sensitivities were determined after 2–3 weeks of denervation. The mean extrajunctional sensitivities of control denervated muscles ranged from 340–1,900 mV nC^{-1}, while muscles from immunised animals showed mean sensitivities of 51–200 mV nC^{-1} (Fig. 1). Resting potential, input resistance and membrane time constants were similar in muscles from control and immunised rats denervated for an equivalent period. The lower ACh sensitivity in immunised rats must therefore result either from a reduction in the number of functional AChRs in the muscle membrane or from a reduction in the amplitude or time course of the conductance change associated with individual receptor activation.

The reduction in ACh sensitivity in muscles of immunised rats could be due to an alteration in the function of receptors by the binding of circulating antibodies. To test this idea, the effect of immune sera on the function of ACh receptors was studied *in vitro*. Extrajunctional ACh sensitivities of denervated hemidiaphragm muscle fibres were measured before and after incubation for 45–120 min with either control rat sera or sera from immunised rats. Immune rat sera reduced extrajunctional ACh sensitivities (Table 1), while sera from control rats inoculated with adjuvants were without effect. This finding suggests that the lower extrajunctional ACh sensitivity of denervated muscles in immunised rats is due to receptor modification by circulating anti-receptor antibodies. Since the antigenic determinants on AChRs that react with anti-receptor antibodies are common to both junctional and extrajunctional receptors[9], the reduction of m.e.p.p. amplitudes in immunised animals may similarly be due to an antibody-mediated reduction in ACh sensitivity. This possibility is supported by the finding that sera from rabbits immunised with AChR can reduce m.e.p.p. amplitudes at frog motor endplates *in vitro*[5].

Further information about the mode of action of anti-receptor antibodies must await the results of experiments using ACh noise analysis. These will show whether antibodies act by inactivating receptors in an 'all-or-none' manner, or by modifying the conductance change associated with individual receptor activations.

Development of difference between red and white muscles in sensitivity to Ca^{2+} in the rabbit from embryo to adult

VARIOUS properties of the Ca^{2+}-activated troponin system are different in red (slow twitch) and white (fast twitch) muscle; these differences are in molecular weight[1,2], amino acid sequences of the subunits[3], Ca^{2+} binding to troponin[1,2], and biochemical measures of contraction (actomyosin ATPase activity and superprecipitation[4-7]). Although the preceding differences have been investigated, no report on physiological differences in Ca^{2+}-activated tension have been published. We compared the development of Ca^{2+}-activated tension in an oxidative muscle fibre (soleus) and that in a glycolytic muscle fibre (adductor magnus) of the rabbit from embryo to adult. We used a technique recently developed in our laboratory[5] for mechanically disrupting the sarcolemma of skeletal muscle fibres. We then examined the data, in view of the known biochemical differences, for possible clues to the roles that troponins have in the Ca^{2+} sensitivity of the various types of muscle.

The sarcolemmas of fibres (~1 mm long) from the soleus, (red), and adductor magnus, (white), muscles of rabbits were disrupted by homogenisation as originally described by Kerrick and Krasner[5]. One red fibre and one white fibre in identical solutions were studied simultaneously. The fibres were mounted into stainless-steel clamps in a tension transducer similar to that used by Hellam and Podolsky[6]. They were then immersed in relaxing and contracting solutions, and their steady-state tensions were recorded[7].

All solutions contained 70 mM of K^+, 10^{-7} M of H^+, 10^{-3} M of Mg^{2+}, 2×10^{-3} M of $MgATP^{2-}$, a total of 7×10^{-3} M of EGTA, and an ionic strength equal to 0.15. The major anions in the solutions were propionate and the *p*Ca of the test solutions was varied from 8 to 3.6. The relaxing solutions had a calculated *p*Ca of 8.0, and the maximally contracting solution had a *p*Ca of 3.6. Imidazole propionate was varied in all solutions such that ionic strength was held at 0.15. The total concentrations of K propionate, Mg propionate, Ca propionate, Na_2ATP, Na_2CP, and imidazole needed for the desired concentrations of the various ionic species and the ionic strength were determined by computer program[8]. The binding constants used in the program were taken from the literature[8].

Data points for each of the *p*Cas were determined and the means and standard errors of the means computed. In general, one data point for each *p*Ca was collected for each fibre and several fibres were used. When a fibre broke or generated too small a force, a new fibre was mounted and studied.

The sensitivity of red muscle to Ca^{2+} was approximately 2.5 times greater than that of white muscle in the adult (Fig. 1*a*). In contrast, Ebashi *et al.* found that the calcium binding to troponin in white muscle was greater than in red. Both red and white muscle showed the same sensitivity to calcium ion in the embryo (Fig. 1*c*), but red muscle had about ten times greater sensitivity to $[Sr^{2+}]$ than white muscle in the adult (Fig. 1*d*). Sensitivity to calcium ion increases in red muscle with development from 26-d embryo to adult (Fig. 1*b*), but remains constant in white muscle (Fig. 1*c*). The difference in sensitivity between red muscle and white muscle develops from embryo to adult, primarily from increasing sensitivity to Ca^{2+} or Sr^{2+} (Fig. 1*d*) in the red muscle.

These data show that sensitivity to calcium ion and strontium ion changes during development in the soleus muscle but not in the adductor magnus muscle. Thus, if troponin is entirely responsible for muscle sensitivity to calcium ion, then changes in the troponin molecule itself must take place during development.

In contrast, studies of the biochemical measures of contraction have shown greater Ca^{2+} sensitivity of Ca^{2+}-activated ATPase activity and Ca^{2+} binding to troponin in white muscle than in red[7]. Thus, these differences are not in agreement with the differences in the biochemical measures of contraction[7]. The discrepancy between the two may be due to either disruption and isolation or removal of proteins, such as light chains of myosin.

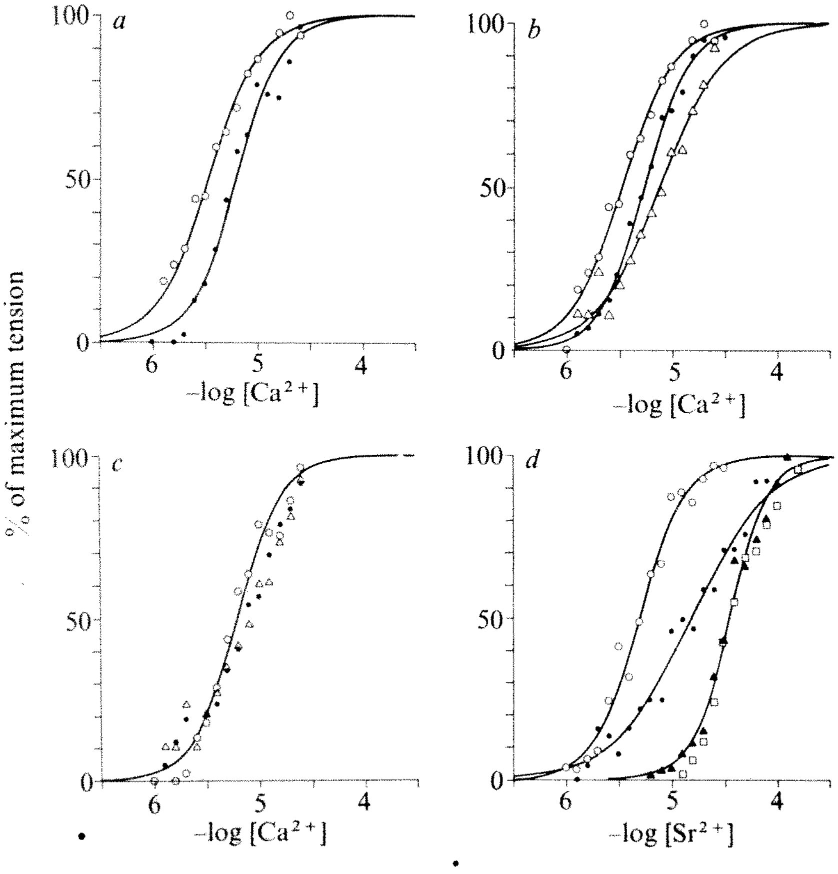

Fig. 1 The relationship between *p*Ca or *p*Sr ($-\log_{10}(X^{2+})$) (M) and percentage of maximum tension for mechanically disrupted rabbit adductor and soleus muscle fibres during development. Smooth curves were obtained by fitting the data to the Hill equation

$$\log_{10}\left(\frac{\%T}{100-\%T}\right)=n\log_{10}(X^{2+})+R$$

where *n* and *R* are constants. *a*, *p*Ca–tension relationship for adult rabbit soleus (○) ($n = 1.7$, $R = 9.6$) and adductor (●) ($n = 2.0$ and $R = 10.5$). *b*, *p*Ca–tension relationship for rabbit adult soleus (○) ($n = 1.7$, $R = 9.6$), 5-d-old soleus (●) ($n = 2.0$, $R = 10.5$), and embryo soleus (△) ($n = 1.4$, $R = 7.3$). *c*, *p*Ca–tension for rabbit adult adductor (○) ($n = 2.0$, $R = 10.5$), 26-d embryo adductor (●), and 26-d embryo soleus (△). *d*, *p*Sr–tension for rabbit adult soleus (○) ($n = 2.0$, $R = 10.5$) and adductor (□) and 5-d-old soleus (●) ($n = 1.2$, $R = 5.7$) and adductor (▲) ($n = 2.3$, $R = 10.2$). The largest s.e.m. computed for any data point was ±5.5%.

Unfortunately, no data have been published on the biochemical changes that occur in the troponin of the rabbit's red muscle and that of white muscle during development. Biochemical differences in subunits of troponin between red and white muscle have, however, been reported. One of these subunits (TNI) from white muscle inhibits Mg^{2+}-activated actomyosin ATPase activity of desensitised actomyosin more effectively than TNI from either red muscle or cardiac muscle. Studies of subunits from skeletal and heart muscles have also indicated differences in effect on actomyosin ATPase[9]. Because in the above studies researchers used incomplete contractile protein systems or preparations of more than one type of muscle, their experimental results cannot be related directly to the results reported in this paper.

Fluorescent antibody techniques show that three types of troponin and heavy chains of myosin (red slow, white fast, and cardiac) exist in individual chick muscle cells and that during development to adult only the troponin and myosin that are characteristic of a muscle type are retained[10]. One possible interpretation of these findings is that the troponin characteristic of white muscle may dominate the Ca^{2+} control of embryonic muscle, but is superseded during development by the troponin characteristic of red or cardiac muscle.

There is some evidence of a Ca^{2+}-sensitive regulatory system in the myosin molecule. It has been clearly demonstrated in scallops[11]. Haselgrove[12] and Huxley[13], using frog skeletal muscle that had been stretched so that there was no overlap of the actin and myosin filaments, demonstrated that the X-ray diffraction pattern associated with the myosin filaments changed when the muscles were electrically activated. Chaplain and Gergs[14], using X-ray diffraction, noted that the cross bridges moved away from the thick filament on the addition of Ca^{2+} in adult glycerinated rabbit muscles stretched so that there was no overlap of thick and thin filaments. Further evidence for a conformational change of myosin comes from Morimoto and Harrington[15]. Using rabbit back muscles, they measured sedimentation coefficient and found it to change in a range from 10^{-6} to 10^{-5} M Ca^{2+} concentration; they then noted that the viscosity of myosin changed in this range of concentrations.

The light chains of myosin may modulate Ca^{2+} control of muscle since Ca^{2+} binding has been associated with the DTNB light chains of myosin in the rabbit[14]. The light chains of white muscle in the chick embryo are reported to be more similar to the light chains of white muscle in the adult than the red; this finding is consistent with our finding of unchanged Ca^{2+} sensitivity of white (adductor) muscle during development[16]. The myosin from white muscles show characteristic light chain patterns that are different from those of red muscles of the rabbit[16]; possibly, the development of light chains in red (soleus) muscle may have some role in the difference in and the change in development of Ca^{2+} sensitivity observed in this study.

We conclude that Ca^{2+} binding to troponin in red and white muscles does not entirely determine the sensitivity of these muscles to Ca^{2+}, in spite of indications by previous biochemical experiments; that differences either in the troponin molecule or in light chains of myosin, or other unknown factors are responsible for the difference in sensitivity of calcium between the two types of muscles; and that molecular changes from embryo to adult change the Ca^{2+} sensitivity in red muscle. These data show the importance of using muscles of one type in experiments designed to show the exact molecular mechanism for activation of a contraction by Ca^{2+}.

Is chromatid-type damage in ataxia telangiectasia after irradiation at G_0 a consequence of defective repair?

THE radiosensitivity of patients with ataxia telangiectasia (AT) has been indicated by *in vivo* studies[1–3] and *in vitro* studies on skin fibroblasts[4]. We present data here to show that this radiosensitivity is observed at the chromosomal level in blood lymphocytes X irradiated at different stages of the cell cycle and for the same range of doses as our survival experiments[4]. Our results are consistent with the hypothesis that there is a defect in some form of DNA repair in these patients. From the observation of the types of chromosome aberrations seen in AT lymphocytes after irradiation at G_0/early G_1, we propose a mechanism for the origin of these aberrations, based on the premise that the G_0/early G_1 chromosome contains a single DNA double helix, in which one polynucleotide chain can be damaged independently of the other.

From previous work on radiation cytogenetics we expected to see only chromosome-type damage (rings, dicentrics and fragments) in the mitosis following G_0 irradiation[5]. These observations have led to the concept that the chromosome at this phase responds to X irradiation as though it were a single linear entity[6]. Chromatid-type damage according to this theory is seen after irradiation in late G_1, S and G_2.

Heparinised blood was obtained from four AT patients and five controls. Table 1 shows the results of full chromosome analyses of unirradiated lymphocytes. Spontaneous chromosome aberrations are a recognised feature of AT[7]. Although gaps and breaks are fewer in these four patients than in others previously reported[7], the number of cells with non-clonal rearrangements is greater in AT patients than in normals. (Two AT patients show the presence of a lymphocyte clone.) Irradiated lymphocytes were analysed for the presence of chromosome- and chromatid-type aberrations. The results of irradiation with 200 and 400 rad in G_0 are shown in Table 2. AT lymphocytes do not show rings and dicentrics at a consistently higher frequency than controls, but the total number of fragments (terminal and interstitial deletions) is greater in AT cells. It is accepted that one fragment is associated with each major exchange[8], but allowing for incomplete exchanges, the ratio of fragments to rings and dicentrics is expected to be greater than unity. In our controls this ratio was 1.59 after each dose of radiation. The ratio was higher in AT cells and increased with larger X-ray doses (1.77 at 200 rad and 2.44 at 400 rad). In AT cells therefore there is a large excess of deletions which are not associated with chromosome-type exchanges.

Our results also show that AT cells exhibit chromatid-type damage when irradiated in G_0. This is seen as a large number of gaps and breaks, but most striking is the appearance of numerous chromatid interchanges, particularly triradials (Fig. 1*a*). The presence of these interchanges at

0.4 ml blood was cultured in 4.0 ml Ham's F10 medium supplemented with 10% bovine serum, 1% phytohaemagglutinin, penicillin and streptomycin (100 IU ml^{-1}). Unirradiated lymphocytes were fixed after 48 h in culture, during their first division.

a high frequency after G_0 irradiation clearly distinguishes AT cells from controls. Chromatid-type damage of any kind is rarely seen in normal lymphocytes irradiated at G_0.

Irradiation during G_2 induced a very high level of chromatid gaps and breaks in AT lymphocytes (Fig. 1*b*) compared with controls (Table 3), agreeing with a previous report[9]. The frequency of chromatid interchanges was again higher in AT cells after both radiation doses, although interchanges were also present in irradiated controls at G_2. So far we have no data on subchromatid aberrations which can be observed at the second mitosis after irradiation at G_2.

We investigated the possibility that some AT lymphocytes showing triradial formation after irradiation at the time of culture initiation, were in G_2 and not in G_0. By scanning lymphocytes from uncultured blood on a Vickers microdensitometer, we found that the DNA content in all cells (from two AT patients and two controls) was consistent with their being in G_0. Cells in G_2 were used as positive controls. This evidence, together with the fact that unstimulated lymphocytes cultured for 48 h showed no mitoses, suggests that all lymphocytes from the AT patients were in G_0 at the time of irradiation. We believe, therefore, our observations show that chromatid damage by X rays is not restricted to late G_1, S or G_2 in AT cells, but can occur after irradiation at G_0.

To explain the types of chromosome aberration seen in both AT and normal cells after irradiation at G_0 we propose that the chromosome at G_0 and in early G_1 behaves as a double-stranded structure. While we appreciate the difficulties of extrapolating from observations on chromosomes to the molecular level, we suggest that the observations are consistent with the basic unit being the DNA double helix. X rays can resolve the two strands at G_0, producing single-strand damage (breaks or base damage). In normal cells such damage is usually repaired before S, since chromatid aberrations are rarely seen at mitosis. The chromatid-type damage after late G_1 irradiation may be a consequence of insufficient time between G_1 and S phase for single-strand damage to be repaired (as Bender suggested[11]). In AT cells, however, we suggest that much of the damage to single strands of DNA is not repaired and persists to manifest itself as chromatid-type damage (including triradials) at the next mitosis. Double-strand damage produces chromosome-type aberrations after G_0

X irradiation was carried out using a Pantak X-ray machine (300 keV, 12 mA, half value thickness 1.5 mm Cu, FSD 50 cm, 180 rad min^{-1}). Whole blood was irradiated at G_0, that is, immediately before being put into culture. Doses of 200 and 400 rad were used. The lymphocytes were collected in their first post-irradiation division at 52 h and 50 cells were analysed for each dose used.

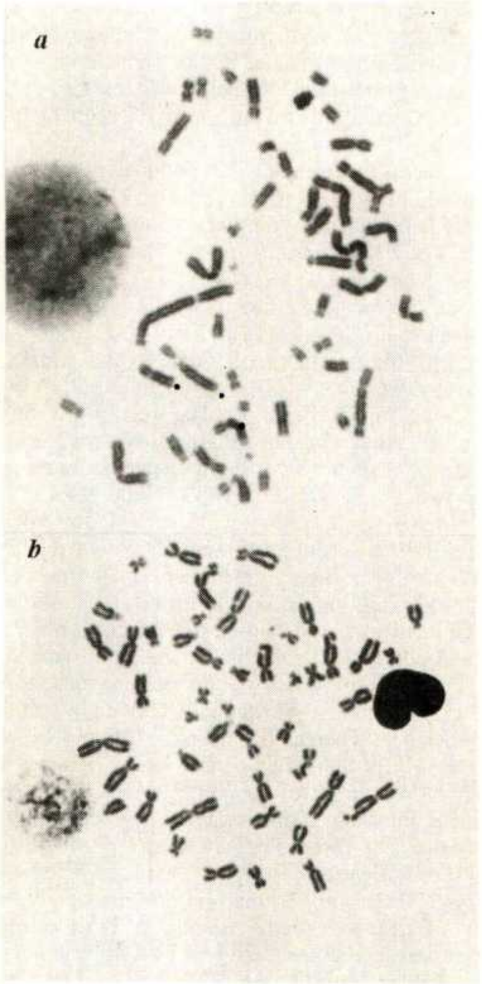

Fig. 1 *a*, Triradial chromosome (chromatid-type damage) together with dicentrics (chromosome-type damage) in an AT lymphocyte irradiated with 400 rad at G_0. *b*, Level of chromatid damage (gaps and breaks) in an AT lymphocyte irradiated with 200 rad at G_2.

irradiation, and chromatid damage after G_2 in normals. The high level of deletions after G_0 irradiation and chromatid-type damage after G_2 in AT cells, implies either a high level of double-strand breakage or failure to rejoin. Using alkaline and neutral sucrose gradients, however, we have previously shown normal single-strand rejoining and also, we believe, normal double-strand rejoining in AT cells[4]. The enhanced levels of both types of chromosome aberrations in AT cells after normally sublethal doses of X irradiation may be a consequence of a failure to excise lesions in the DNA. Paterson *et al.*[10] have confirmed that AT cells show normal single-strand rejoining and, using supralethal doses of γ rays, have shown that AT cells are defective in excision repair of γ-ray induced base damage.

Many reports[11–16] have speculated on the possibility that incomplete repair mechanisms facilitate resolution of molecular damage at the chromosomal level, including aberrations induced by ultraviolet light and chemical compounds. The possible role of failure to repair damage in the production of chromosome aberrations has been shown in cells from patients with xeroderma pigmentosum (XP)[17]. The high incidence of malignancies in both AT and XP may be a consequence of the defective DNA repair in both of these syndromes, giving rise to cytogenetically abnormal cells with a potential to become malignant.

We thank Professor J. H. Edwards, Drs S. Bundey, W. Schutt, R. A. Thompson and M. M. Oo for the cases of AT; Dr P. Fowles for use of facilities in the Birmingham Radiation Centre; Dr H. Wallace for the use of the microdensitometer, and Miss C. J. Harrison, Mrs K. E. Vause and Mr P. Wattie for technical assistance. Defective excision repair of γ-ray-damaged DNA in human (ataxia telangiectasia) fibroblasts

ATAXIA telangiectasia (AT) (Louis–Bar syndrome) is a rare human neurovascular disease displaying an autosomal recessive pattern of inheritance[1-3]. Affected individuals, although clinically normal at birth, symptomatically develop cerebellar ataxia (loss of muscular coordination) and oculocutaneous telangiectasis (chronic dilation of the small blood vessels) in early childhood. The course of the disease follows a variable progression commonly leading to total neurological incapacitation before puberty. Accessory complications include lymphoreticular neoplasia[2,3], bronchiectasis[1,2], recurrent sinopulmonary infections[1,2], decreased levels of serum immunoglobulins IgA and IgE (refs 3 and 4), impaired cellular immunity[3,4], and widespread chromosomal instability[5]. AT patients, on receiving conventional radiotherapy for tumour treatment, tend to develop unusually severe complications often culminating in premature death[6-8]. Pronounced radiosenitivity is also observed at the cellular level in laboratory studies; the number of radiation-induced chromosomal aberrations is enhanced in leukocytes obtained from AT donors[9]. Moreover, diploid fibroblasts cultured from affected individuals exhibit a reduced ability to form colonies following exposure to γ radiation[10] and radiomimetic chemicals[11]. Since the principal damage induced by both types of agents occurs in the DNA and seems to be acted on by the same enzymatic repair mechanisms[12,13], it would seem probable that the molecular basis for the clinical radiosensitivity of AT patients stems from a deficient DNA repair mechanism. We therefore measured the DNA repair properties of AT fibroblasts after exposure to γ radiation. Data presented below provide direct biochemical evidence that diploid strains from AT donors are indeed impaired in DNA repair; in particular, these cell lines possess an enzymatic defect in an excision-type repair process operating on γ-modified nitrogenous base residues.

The ability of AT strains to carry out two repair processes, rejoining of γ-induced single-strand breaks (that is, scissions in the sugar–phosphate backbone of individual polynucleotide chains) and excision of γ-modified base residues, was evaluated with the aid of two complementary physicochemical techniques: (1) *in vitro* enzymatic assay[14,15] and (2) equilibrium density-gradient centrifugation[16]. The enzymatic assay monitors the DNA separately for the restitution of strand breaks and for the disappearance of base defects, during *in vivo* incubation after γ irradiation. Base defects are detected as sites susceptible to γ endonuclease activity in a crude extract of the bacterium *Micrococcus luteus*[17] (referred to as γ endonuclease-susceptible sites). The equilibrium centrifugation technique measures the magnitude of radiation-induced repair replication; this parameter reflects the sum total of nucleotides inserted at damaged sites along each strand during the course of repairing both types of radioproducts[18].

Our experiments were carried out with five (two control, three AT) human diploid strains: CRL 1141 and CRL 1147, cultured from two clinically normal volunteers; and AT3BI, CRL 1312, and CRL 1343, derived from three AT patients of unrelated kindred (for details, see Table 1).

To monitor the metabolic fate of γ radioproducts, irradiated cultures of normal (CRL 1141) and AT (AT3BI) strains were incubated and the numbers of single-strand breaks and γ endonuclease-susceptible sites remaining in the DNA at various times were measured (Fig. 1). The restitution of directly induced strand breaks in AT cells occurred with exponential kinetics indistinguishable from those displayed by normal cells. The other two AT strains, CRL 1312 and CRL 1343, also exhibited similar strand-rejoining kinetics (data not shown). Thus, in spite of their pronounced sensitivity to γ inactivation[10], AT strains seem to possess a normal enzymatic mechanism for rejoining radiation-induced single-strand breaks. Others[10,20] have independently arrived at the same conclusion.

In marked contrast to the efficient repair of strand breaks, the rate of disapperance of γ endonuclease-susceptible sites was more than four times slower in AT3BI than in CRL 1141 cells. For instance, whereas the normal strain achieved 80% site removal within 3 h, the mutant strain required twice as long to act on only 50% of the initial sites. In as much as (1) the strand-rejoining mechanism seems to proceed in a manner similar to the last three steps in excision repair (excision, repair synthesis, ligation), probably using similar, if not the same, enzymes[12,13]; and (2) this rejoining process seems to be normal in AT strains, it seems reasonable that the time course of site disappearance reflects the first step in excision repair of γ-modified base residues *in vivo*. Thus, the simplest conclusion is that the AT3BI strain lacks a fully functional γ endonuclease considered to initiate this excision-repair process.

If the observed disappearance of γ endonuclease-susceptible sites indeed reflects an excision-repair process acting on γ-induced base damage, it follows that the impaired ability of AT3BI cells to effect site removal should be accompanied by a reduction in the magnitude of γ-stimulated repair replication. That is, a defective capacity to excise base defects should accordingly lead to a decrease in the number of gaps which need to be filled by repair synthesis. We therefore measured the amount of repair replication occurring in normal and AT strains during 2 h after irradiation (Fig. 2). The level of repair replication detected in two normal cell lines, CRL 1141 and

†Expressed as cell population doublings since biopsy, although cultures were actually diluted 1:3 at each subcultivation.

AT3BI was provided by A. R. Lehmann, University of Sussex; the remaining four were obtained from the American Type Culture Collection, Rockville, Maryland. Using standard cell culture procedures, monolayer stocks of each fibroblast strain were routinely maintained at 37 °C in thymidine-free F12 medium[19] supplemented with 15% (v/v) foetal calf serum (Gibco) and a penicillin–streptomycin mixture (100 IU each $\mathrm{ml^{-1}}$). Unless otherwise indicated, all cell culture supplies were purchased from Microbiological Associates Inc.

Experimental cultures in late logarithmic growth phase were prepared by seeding $\approx 8 \times 10^5$ cells in plastic Petri dishes (15 cm diam., Lux Scientific) followed by incubation for 24–48 h at 37 °C. In this and subsequent experimental incubations the F12 medium contained newborn (10%, v/v) rather than foetal calf serum. Radiation treatment was administered at ice-bath temperature with either *a*, ^{60}Co γ rays (dose rate, 26–27 krad $\mathrm{min^{-1}}$) delivered in a Gammacell 220 (Atomic Energy of Canada Ltd) or, in certain control studies, *b*, far ultraviolet radiation (chiefly 254-nm wavelength; incident fluence rate, 1.1 $\mathrm{J\,m^{-2}\,s^{-1}}$)[14]. Cultures were maintained under anoxia during γ irradiation by introducing a stream of N_2 gas into aspirated Petri dishes for 5 min before, and during the exposure. All remaining experimental manipulations and treatment schedules, including those involved in the *in vitro* enzymatic assay and equilibrium density-gradient centrifugation, were performed as described briefly in the figure captions and in detail elsewhere[14-16].

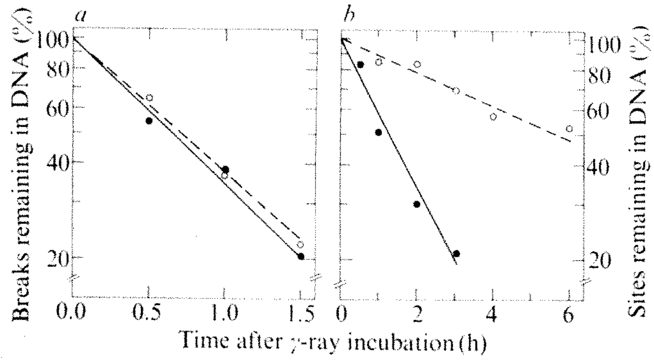

Fig. 1 Time-dependent disappearance of γ radioproducts from the DNA of normal (●, CRL 1141) and AT (○, AT3BI) fibroblasts exposed under anoxia to 50 krad ^{60}Co γ-radiation. *a*, Single-strand breaks and *b*, γ endonuclease-susceptible sites were monitored by an *in vitro* enzymatic assay similar to that described earlier for the quantitation of ultraviolet-induced pyrimidine dimers[14,15]. The DNA of the cells was labelled for 24–48 h with either ^{3}H-methylthymidine (specific activity, 2 Ci mmol^{-1}) or 2-^{14}C-thymidine (specific activity, 45–53 mCi mmol^{-1}) (Amersham, Searle) added to the F12 incubation medium at a concentration of 1.0 μCi ml^{-1}. After removing the radioactive medium, ^{3}H-labelled cultures of each strain were irradiated and immediately incubated for various times in parallel with ^{14}C-labelled, unirradiated (control) cultures. Parallel cultures were lysed and their ^{3}H- and ^{14}C-DNAs were coextracted *in toto*. Two samples of the purified DNA were then incubated for 30 min at 37 °C, one with, and the other without, a crude cell-free extract from *M. luteus* (the equivalent of fraction II of Carrier and Setlow[25]). Typically, the 200-μl reaction solution contained: 2 μmol potassium phosphate (*p*H 7.5); 0.2 μmol EDTA; 0.2 μmol 2-mercaptoethanol; 1 μg ^{3}H-labelled, irradiated DNA (≈15,000 d.p.m.); 1 μg ^{14}C-labelled, unirradiated DNA (5,000 d.p.m.); 10 μg tRNA (General Biochemicals); 20 μg (protein) *M. luteus* extract (an amount in excess of that needed to complete the endonuclease reaction). At the completion of incubation 50 μl 2 N NaOH was added, and the samples were subjected to velocity sedimentation (40,000 r.p.m. at 20 °C for 135 min in a Spinco SW-56 rotor) in alkaline sucrose gradients (5–20%, w/v; 0.5 M NaCl; 0.21 N NaOH; 10 mM EDTA). After fractionation and liquid scintillation counting, computer analysis of the radioactivity distributions in the gradient profiles yielded the number of single-strand breaks in the irradiated, compared with non-irradiated, DNA. The value obtained for the DNA sample incubated alone is taken as the number of directly induced strand breaks remaining in the radiation-damaged DNA, whereas the additional breaks in the extract-treated sample represent the number of nuclease-susceptible sites. Data for each curve were normalised by expressing the lesion incidence in DNA from incubated cultures as a percentage of the corresponding value for the non-incubated culture, that is, the number initially produced per 10^{7} daltons DNA = 100% (≈0.8 single-strand breaks; ≈1.2 nuclease-susceptible sites). Experimental points represent the average of triplicate determinations (s. d. ≤ 13%).

CRL 1147, increased rapidly with γ-ray doses up to 75 krad at which stage the level seemed to approach a plateau value. Although the general response of three AT strains, including AT3BI, to radiation treatment was also dose dependent, the maximal extent of repair replication attained by each (45–60 d.p.m. per μg DNA) was only about half that (≈110 d.p.m. per μg DNA) found in the normal strains. It seems, therefore, that the level of repair replication attained in the AT strains after γ irradiation is lower than that achieved by the normal strains, providing additional evidence that AT strains are impaired in excision repair of γ-induced base defects.

It was crucial to establish further that the observed malfunction was specific and not an artefactual consequence of some systematic peculiarity in the general properties of the mutant strains; particularly as excision repair of γ radioproducts was not totally absent from the AT strains. Repair efficiency was independent of biological age, both *in vivo* (chronological age of donor at biopsy) and *in vitro* (age in culture). The repair deficiency in AT strains did not simply stem from a general depression in cell growth rate in culture. The population doubling times for the two normal and three mutant cell lines did not vary greatly, nor was a positive correlation found between the kinetics of excision repair and growth rate (see Table 1). All strains were mycoplasma-free as judged by assaying exogenous ^{3}H-uracil/^{3}H-uridine incorporation into RNA[21].

The response of AT strains to ultraviolet radiation was also monitored, since excision repair of ultraviolet photoproducts and γ radioproducts is thought to be mediated by parallel mechanisms[13] which, except for specific endonucleases acting on the different ultraviolet and γ lesions[12,13], may well use common enzymes. As is evident in Fig. 3, normal CRL 1141 and mutant AT3BI cells executed excision repair of ultraviolet photoproducts with identical proficiencies, assayed as either the rate of removal of ultraviolet endonuclease-susceptible sites (that is, pyrimidine dimers[14]) or the level of ultraviolet-stimulated repair replication. The other two mutant strains, CRL 1312

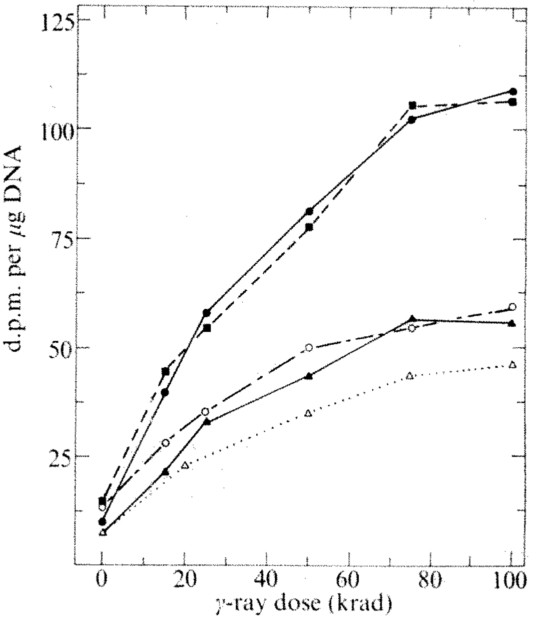

Fig. 2 Dose-dependent levels of repair replication induced in the DNA of normal (●, CRL 1141; ■, CRL 1147) and AT (○, AT3BI; ▲, CRL 1343; △, CRL 1312) strains by ^{60}Co γ-radiation delivered under anoxia. To assess their ability to carry out γ-stimulated repair replication, the human cell lines underwent a standard regimen designed to maximise the incorporation of exogenous nucleotides into DNA at repaired sites while inhibiting *de novo* synthesis[18]. Unlabelled cultures containing 2–4 × 10^{6} fibroblasts were grown for 2 h in F12 medium containing 65 μM bromodeoxyuridine (BUdR) and 1 μM fluorodeoxyuridine (FUdR), γ-irradiated under nitrogen, and immediately labelled for 2 h with 10 μCi ml^{-1} ^{3}H-methylthymidine (specific activity, 45–53 Ci mmol^{-1}; Amersham, Searle) in F12 medium supplemented with 65 μM BUdR, 1 μM FUdR and 1 mM hydroxyurea. Finally, the cultures were incubated for an additional 1 h in F12 medium containing 65 μM BUdR and 1 μM FUdR. The extent of repair replication occurring during the postradiation labelling period was determined by equilibrium centrifugation of the radioactive and density-labelled DNA in NaI gradients. The method followed was basically that developed by Lohman *et al.*[16] except that one rebanding of 'light' parental DNA was normally necessary to ensure its complete physical separation from contaminating 'heavy' DNA arising from semiconservative *de novo* synthesis. After lysis and DNA extraction, neutral NaI gradients (6 ml, containing 0.22 mmol Na_2SO_3, 10–20 μg extracted human DNA, 0.1 mg ethidium bromide, 4.69 g NaI, adjusted with addition of either Na_2SO_3 or NaI to 1.5400 g cm^{-3} final density) were prepared and centrifuged to equilibrium (33,000 r.p.m. at 20 °C for at least 60 h in a Spinco Type 40 rotor). After collection (~20 fractions per gradient) the light DNA was pooled (normally six 300-μl fractions) and dialysed overnight against a 10 mM Tris–0.15 M NaCl (*p*H 7.5)–10 mM EDTA buffer. NaI gradients containing the dialysed DNA were prepared and centrifuged as above. After fractionation, the distributions of DNA (measured fluorometrically) and radioactivity were ascertained and analysed to calculate the magnitude of repair replication, expressed as d.p.m. per μg light DNA (typically comprising five 300-μl peak fractions). Datum points represent the average of five or more determinations (s.d. ≤ 15%).

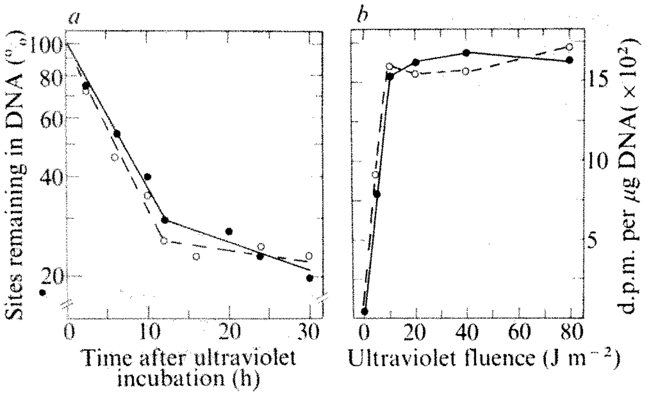

Fig. 3 Excision repair of ultraviolet photoproducts in the DNA of normal (●, CRL 1141) and AT (○, AT3BI) fibroblasts as reflected by *a*, time course of disappearance of ultraviolet endonuclease-susceptible sites; *b*, magnitude of ultraviolet-stimulated repair replication. The fate of nuclease-susceptible sites was monitored with the *in vitro* enzymatic assay as outlined in the caption of Fig. 1 except that: (1) ^{3}H-labelled cultures were exposed to 5 J m^{-2} 254-nm radiation, and (2) extracted DNA was incubated with highly purified *M. luteus* ultraviolet endonuclease (10 μl per DNA–protein reaction mixture) selectively active toward pyrimidine dimers in ultraviolet-irradiated DNA[14]. (The ultraviolet endonuclease was a gift of H. L. Heijneker, Leiden State University, Leiden, The Netherlands.) The amount of repair replication occurring in cultures during 2 h after exposure to specified ultraviolet fluences was determined essentially as described in Fig. 2 except that accurate measurements were obtained without the necessity of rebanding light parental DNA. 100% sites = 2.7 per 10^7 daltons (*a*). Datum points represent the average of triplicate determinations (s.d. $\leq 10\%$).

and CRL 1343, also carried out ultraviolet-induced excision repair with normal proficiency (data to be published elsewhere). It therefore seems that the enzymatic defect in the AT cell lines specifically affects the endonuclease active on γ-modified base residues.

Although the resolution of our assays compelled us to trace the fate of γ radioproducts in moribund cell populations, we are reasonably confident that, within the short postradiation intervals considered here, the metabolic responses assayed portray the actions of *bona fide* repair processes since: (1) the cultures seemed to be normal, both at the cellular and subcellular levels; for example, both control and AT strains remained in monolayer with few floating cells and their nuclear DNA was not subject to rampant degradation; (2) control strains, in particular, seemed to achieve considerable success in restoring their DNA to an undamaged stage (Fig. 1).

As observed in *Escherichia coli* minicells[17], the ratio of γ endonuclease-susceptible sites to strand breaks is much greater when the irradiation is delivered to human fibroblasts in anoxic rather than oxic conditions (M.C.P. and B.P.S., unpublished). We therefore maintained cultures in an N_2 atmosphere during irradiation, thereby greatly amplifying the signal-to-noise ratio in both repair assays.

Based on current insight into DNA repair mechanisms[13,18], a simple interpretation of our complementary data is that AT cells lack the full complement of functional γ endonuclease and thus fail to initiate excision repair of γ-induced base defects normally. We cannot, however, exclude other less direct explanations including the possibility that the AT strains carry a mutation affecting a later step in the repair process, thereby impeding the normal action of an otherwise unaltered endonuclease activity.

The results of our experiments have important practical and theoretical ramifications, especially in the fields of radiology and molecular radiobiology. Five, in particular, merit brief comment: (1) An inherited deficiency in a specific DNA repair mechanism is indicated as the molecular basis of ataxia telangiectasia. Aside from offering a reasonable and direct explanation for the reported clinical radiosensitivity of AT patients[6–8], our data provide new insight into the cause of this congenital disorder and, although admittedly problematic at present, may ultimately indicate the direction to follow in remedial treatment. (2) AT (ref. 2), like xeroderma pigmentosum[18] (XP), is a congenital disorder in which afflicted individuals are predisposed to an elevated incidence of malignancy, providing additional evidence that defective DNA repair has an aetiological role in at least some forms of neoplastic transformation[18,24]. (3) AT patients evidently defective in excision repair of radiation-damaged DNA bases are at an adaptive disadvantage; thus, it logically follows that a proficient mechanism to repair these radioproducts is of vital importance to the survival and reproductive capacity of humans. (4) AT strains are proficient in excision repair of ultraviolet photoproducts but defective in excision repair of γ radioproducts, whereas the reverse is found in XP strains[18]. These observations are consistent with a working model for this process in which the initial incision step is carried out by different enzymes, γ endonuclease or ultraviolet endonuclease, depending on the type of damage, whereas the remaining steps are executed by common enzymes. A similar model has been proposed for bacterial systems[22,23]. (5) Considerable success has been achieved in elucidating the excision-repair process active on ultraviolet photoproducts in DNA of human systems[18] after the discovery that XP fibroblasts are defective in ultraviolet-stimulated repair replication[24]. Since AT seems to be a γ-ray analogue of XP, it might be expected that comparable advances in our understanding of excision repair of γ radioproducts will be forthcoming.

We thank Drs A. R. Lehmann and A. M. Marko for discussions and encouragement; Drs A. M. R. Taylor and D. I. Hoar for preprints of articles[10,11]; and Drs D. R. Champ and N. E. Gentner for critical commentary on the manuscript. During the preliminary stages of this research P.H.M.L. was at Chalk River as an A.E.C.L. visiting scientist, and A.K.A. (Waterloo University, Waterloo, Ontario) and L.F. (McGill University, Montreal, Quebec) were undergraduate summer students.

Sister chromatid exchanges in ageing and repair-deficient human fibroblasts

THE nature of the involvement of DNA repair in the formation of sister chromatid exchanges (SCEs) and their connection with chromosome aberrations is unknown. Some mutagens that damage DNA, including ultraviolet light and mitomycin C, considerably increase the incidence of SCEs[1–6], whereas other agents, such as X rays[6–8], nitrosoguanidine[2] and 8-ethoxycaffeine[5] cause only a slight increase, although they are potent inducers of lesions at the DNA and chromosome levels. Hamster cells infected with adenovirus 12 show no increased SCEs in spite of extensive fragmentation of the entire chromosome complement (our unpublished results). These findings suggest that the mechanism of formation of SCEs is not unitary. Whereas the mechanism of induction of SCEs could be studied by analysing their frequency after application of agents with known action on DNA, spontaneously occurring SCEs can be studied in cells with defects in the DNA repair system. This report deals chiefly with the frequency of spontaneous SCEs in several strains of xeroderma pigmentosum (XP) fibroblasts which show various levels of repair capacities, in Fanconi's anaemia (FA) cells and in control human cells at different stages of ageing.

We used three XP cell strains with different DNA repair capacities[9–11], three FA cell strains from unrelated patients and three fibroblast strains from unaffected subjects. All cultures were grown in Eagle's minimal essential medium supplemented with 15% foetal calf serum, and they were used for experiments at their earlier passages. To study SCE, cultures were treated for 38–42 h with 5-bromo-2′-deoxyuridine (BUdR) at various concentrations and fixed for chromosome preparation after 1 h of treatment with either colchicine or Colcemid. Chromosome preparations were made by the air-drying method and stained with acridine orange[2]. SCEs were scored under fluorescence microscopy.

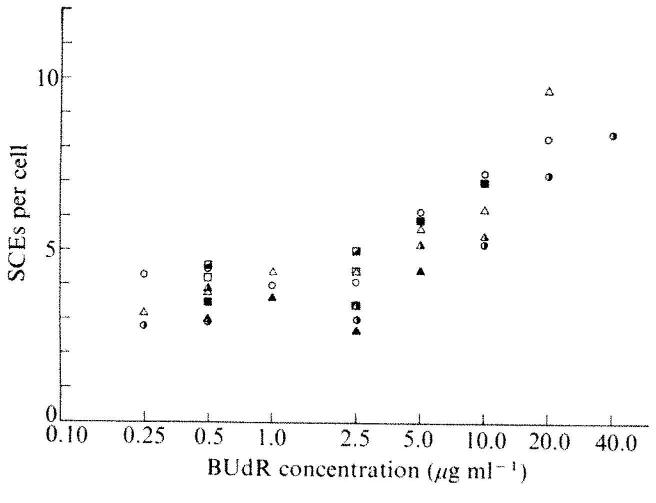

Fig. 1 Effects of BUdR on the frequency of SCEs in various human fibroblast strains. PEG (○) and BRU (half-shaded circle) were control strains established from skin punch biopsies of normal subjects. XP-E (△) and XP-C (half-shaded triangle) were obtained from skin biopsies of two unrelated XP patients and showed 21% and 32%, respectively, of normal unscheduled DNA synthesis after ultraviolet irradiation[6,8]. XP 1162 (▲) was obtained from the American Type Culture Collection (ATCC). This strain has been reported to have a normal repair capacity as measured by unscheduled uptake of ^{3}H-thymidine after ultraviolet irradiation. FA 122 (□) was an ATCC strain. FA 40400 (half-shaded square) and FA 15100 (■) were gifts from Dr Siminovitch University of Toronto. Each point was determined based on 10–25 cells which had been collected at the 2nd metaphase after labelling and stained with acridine orange (0.125 mg ml^{-1}).

Table 1 The frequency of sister chromatid exchanges in chromosomes of various human fibroblasts labelled with BUdR at concentrations lower than 2.5 μg ml^{-1}

Cell strains (sex)	No. of cells observed	No. of SCEs scored	SCEs per cell (± s.e.m.)	Cells with chromosome aberrations† (%)
Normal				
PEG (F)	90	382	4.24±0.22	—
BRU (M)	60	193	3.22±0.23	1.8
HE-1* (F)	350	1,325	3.78±0.10	1.2
Xeroderma pigmentosum				
XP-E (F)	57	249	4.37±0.28	2.9
XP-C (M)	80	289	3.61±0.21	1.5
XP 1162 (M)	30	91	3.03±0.32	0
Fanconi's anaemia				
FA 122 (M)	40	173	4.33±0.33	13.6
FA 40400 (F)	27	130	4.81±0.42	11.0
FA 15100 (M)	50	169	3.38±0.26	15.0

*Embryonic fibroblast strain at passage 12 (a gift from Dr Nakagome of National Institute of Genetics, Mishima). Exact ages of other cultures are uncertain but all were used for experiments within 2–3 passages after thawing of frozen stocks prepared earlier at passages after initiation or purchase of the cultures.

†Determined on 70–200 cells each. There is no statistically significant difference in the aberration frequencies between the normal and XP cells as well as among strains in each group, while the frequencies obtained for all FA cells differ significantly from those in cell strains in the other two groups ($P < 0.01$). Most aberrations detected in FA cells as well as in the other strains were chromatid gaps and breaks.

Figure 1 shows that SCE frequency varied only slightly in each cell strain after treatment with BUdR in concentrations ranging from 0.25 to 2.5 μg ml^{-1}, confirming previous results[2,4]. We refer to this plateau level as spontaneous SCE although we cannot exclude the possibility that even these exchanges resulted from the application of BUdR[12]. To compare the frequencies of SCEs in various cell strains, samples were treated with BUdR at concentrations less than 2.5 μg ml^{-1}. There was no major difference in SCE frequency among fibroblast strains (Table 1). Irrespective of the DNA repair capacity of the cell, SCE frequencies varied between 3 and 4.5 per diploid chromosome complement. It is interesting that FA cells, in spite of high incidence of spontaneous chromosome aberration (Table 1) showed no increased level of sister chromatid exchanges. This observation suggests that, at least in the FA cells examined, the formation of spontaneous chromosome aberrations is dissociated from processes leading to SCE. XP cells seem to have a reduction in the endonuclease activity which is necessary to initiate excision repair[13]. But a class of XP, the XP varient, is characterised by its normal excision repair and suspected to be defective in post-replication repair[14]. FA cells are believed to be defective in some DNA repair mechanisms[15,16], probably lacking one or more enzymes[17]. Our present results are consistent with previous reports on the yield of SCE in XP[18] and FA cells[19]. The genesis of spontaneous SCEs may be independent of these particular repair mechanisms.

The spontaneous exchange frequency seems to be affected by the age of cell culture. The normal human fibroblast strain HE-1, at passage 12, was used as a starting culture and grown for about two months; its SCE frequency was examined periodically. To minimise division delay caused by frequent subculturing, we used a 1:6 split scheme at 3 or 4-d intervals during the first month of culture and at

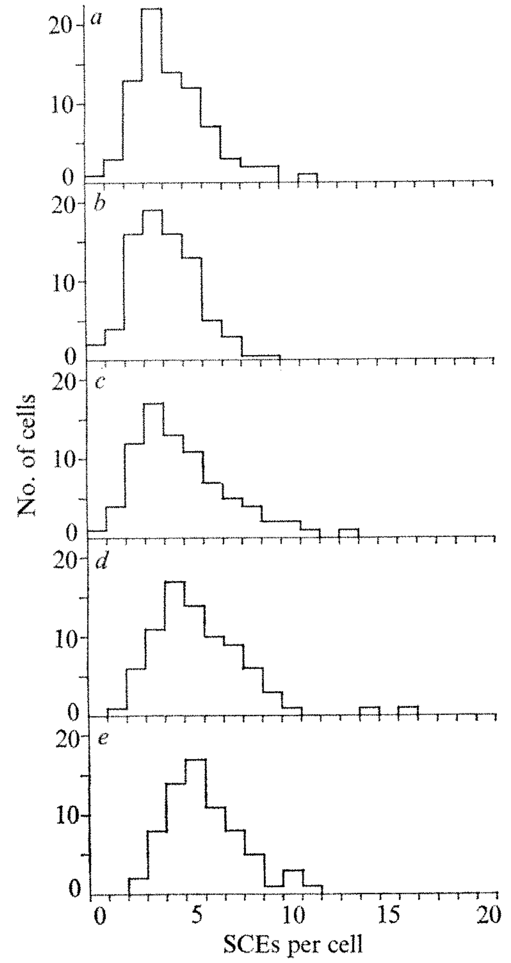

Fig. 2 The shift in SCE frequency during long term culture of HE-1. According to the subculturing scheme used, the culture is considered to undergo about two and a half population doublings per passage. Passages 13(*a*), 19(*b*), 24(*c*), 27(*d*) and 30(*e*) may therefore correspond roughly to 33, 48, 60, 68 and 75 population doublings, respectively. Cultures were treated for 40 h with BUdR (0.25 μg ml^{-1}) before collection. Mean ± s.e.: *a*, 3.99±0.22; *b*, 3.63±0.21; *c*, 4.46±0.24; *d*, 5.28±0.26; *e*, 5.41±0.26.

longer intervals thereafter. According to this scheme each passage would correspond roughly to 2.5 population doublings. In these conditions, cells ceased growth after passage 32, about 80 d after the start of the experiment. A statistically significant increase in SCE frequency was observed during long term culture but only at the end of the life span of the culture. As Fig. 2 shows the modal value of the exchange frequency per diploid chromosome complement was 3 at the onset of the experiment (at the 33rd population doubling level). This value remained unchanged up to passage 24 (60 doublings), then moved to 4 at passage 27 (68 doublings) and reached 5 at passage 30 (at the 75th population doubling level). At this last period the cell cultures contained many slow growing cells which showed several symptoms of senescence, including considerable variation in size and morphology and an increased level of chromosome aberration. The incidences of cells having chromosome breaks and exchanges were 1.2%, 2.1%, 5.3% and 9.6% at passages 13, 24, 27 and 30, respectively. This increased production of aberrations during the latest part of the life span seems to be compatible with the finding of Saksela and Moorhead's findings[20] with WI-38 cells, and parallels the increase in the SCE frequency.

The results obtained with XP and FA cells obtained in this study support the conclusion[18] that the induction of spontaneous SCE cannot be explained by a simple application of concepts from known DNA repair mechanisms. On the other hand, the observed link between SCE and chromosome aberrations in the ageing cell culture and in Bloom's syndrome[19] and their dissociation in FA cells indicate that the pathways through which both events arise are at least partially different.

Part of this study was carried out while H. K. was at the University of British Columbia at the Laboratory of H.F.S. We thank Miss C. Yoshizawa for technical assistance. Differential chromatid staining by *in vivo* treatment as a mutagenicity test system

DIFFERENTIAL staining of sister chromatids can be demonstrated with Hoechst 33258 fluorochrome[1] and with Giemsa after special pretreatment[2], even if 5-bromodeoxyuridine (BUdR) is present during the first S phase only[3]. These techniques permit the use of the phenomenon of the sister chromatid exchange (SCE). The average spontaneous rate of 10–14 SCEs per metaphase seems to be fairly constant in all cultures from several species[4,5]. A variety of mutagenic factors (that is, ultraviolet light and alkylating agents) produce very high frequencies of SCE even at concentrations far below the level necessary for the induction of chromosomal breakage, whereas others, like X rays or certain chemicals, hardly influence the rate of SCE[6]. Because of the high turnover of BrdU in the liver and the physiologically available thymidine, differential chromatid staining has so far only been produced in *in vitro* systems (cell cultures) and in the chicken embryo.

We have found that the additional application of 5-fluorodeoxyuridine (FUdR) which inhibits thymidine synthesis leads to differential chromatid staining in metaphases prepared directly from bone marrow. This method proved to be a sensitive test system for mutagenicity as demonstrated by the increasing frequencies of SCE after application of two alkylating agents.

Mature mice were injected with 0.4 mg FUdR per g body weight intraperitoneally; beginning 3 h later they received

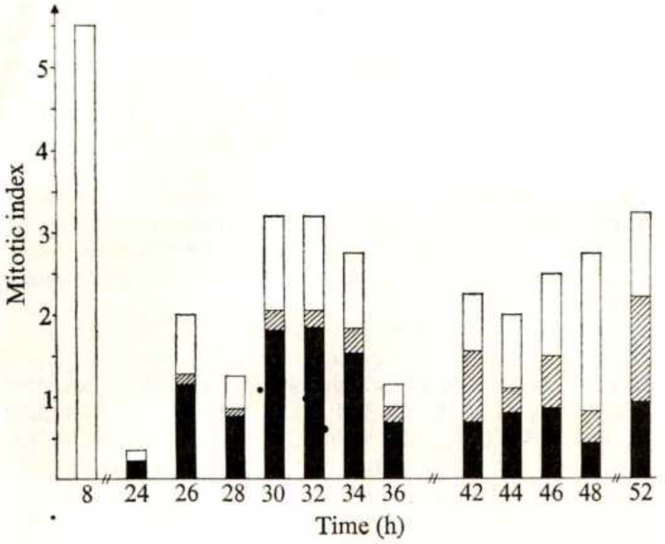

Fig. 1 Solid column, second mitoses (complete differential chromatid staining); hatched column, third mitoses.

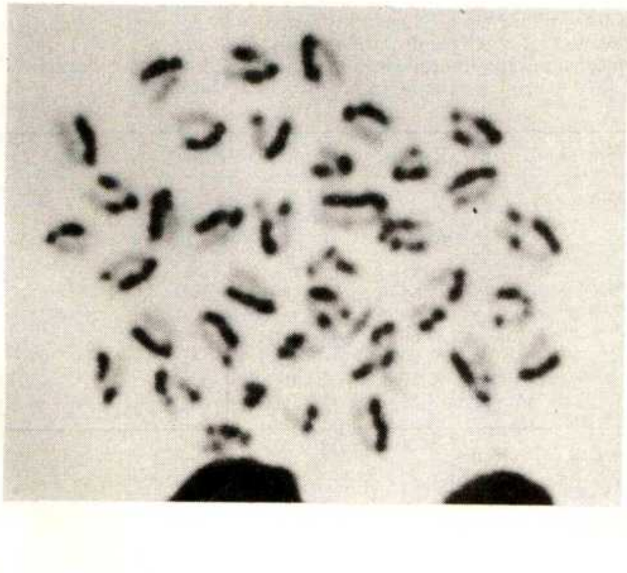
six times 0.04 mg BUdR per g body weight during 6 h. Colcemid (16 μg) was administered 3 h before killing. Metaphases from bone marrow were prepared using standard methods without culturing, and stained according to Epplen *et al.*[8]. Mitotic indices and frequencies of differential chromatid staining in the second and the following mitoses are given in Fig. 1. The highest incidence of second mitoses appears about 30 h after the first BUdR injection. About 2 h after BUdR treatment a replication pattern can be found.

Table 1 SCE per metaphase after administration of various concentrations of triaziquon and cyclophosphamide

μg per g body weight	SCE per metaphase
Triaziquon	
0	4
0.0025	6
0.0125	10
0.125	30
Cyclophosphamide	
0	4
12.5	15
25	24

Each value represents at least 20 metaphases of two different specimens.

Fig. 2 Bone marrow metaphase with differential chromatid staining showing a high incidence of SCE after *in vivo* treatment of the mouse with cyclophosphamide.



Thus a method has been developed with the capacity to induce differential chromatid staining by *in vivo* treatment. Compared with *in vitro* studies the 'spontaneous' rate of SCE turned out to be extremely low (4 per metaphase). Possible explanations for this difference may include, for example, the complete absence of light from the cells in the bone marrow or a lower mean concentration of BUdR during treatment. To demonstrate the efficiency of the method for mutagenicity testing we have studied the induction of SCE by two alkylating agents *in vivo*. Both substances produce a dose-dependent increase in SCEs (Table 1) which can be detected at concentrations below those inducing chromosomal breakage (Fig. 2). Using higher concentrations, the mitotic index and the proportion of differentially stained metaphases is greatly reduced by the toxic activity of the drugs. As to be expected, the effect of cyclophosphamide is evident in our *in vivo* system, whereas it was inert in *in vitro* studies[6]. In so far as the induction of SCE can be regarded as an indication for mutagenicity[9], our method enables the application of this test system to *in vivo* studies.

Since *in vitro* systems of mutagenicity testing are subject to methodical errors, the transfer of these systems into physiological conditions, that is, *in vivo*, is preferable. If the restrictions with respect to the significance of SCE are borne in mind[9], our method may turn out to be a useful tool in mutagenicity testing.

Analysis of sister chromatid exchange formation *in vivo* in mouse spermatogonia as a new test system for environmental mutagens

SPERMATOGONIA, as stem cells of male gametes[1,2], constitute a highly relevant system for studying the genetic hazards of potential mutagens. Gross chromosome aberrations in spermatogonia have been used as a gauge of the genetic damage induced in animals exposed to agents such as mitomycin C (refs 3–5). Sister chromatid exchanges (SCEs) formed in response to DNA damage constitute even more sensitive indices of the impact of alkylating agents and other clastogens on chromosomes[6–8]. Analysis of SCE induction in cultured cells has been greatly facilitated by techniques in which substitution of DNA with the base analogue 5-bromodeoxyuridine (BUdR) is detected either with fluorescent dyes[9,10] or by modified Giemsa procedures[11–13]. This approach has so far been limited to *in vitro* trials, with the exception of one system[14] in which SCEs were visualised in chromosomes of chick embryos after exposure to BUdR *in ovo*. We report here a BUdR technique which enables the detection of SCEs formed in spermatogonial cells of intact mice. As a prototype of a

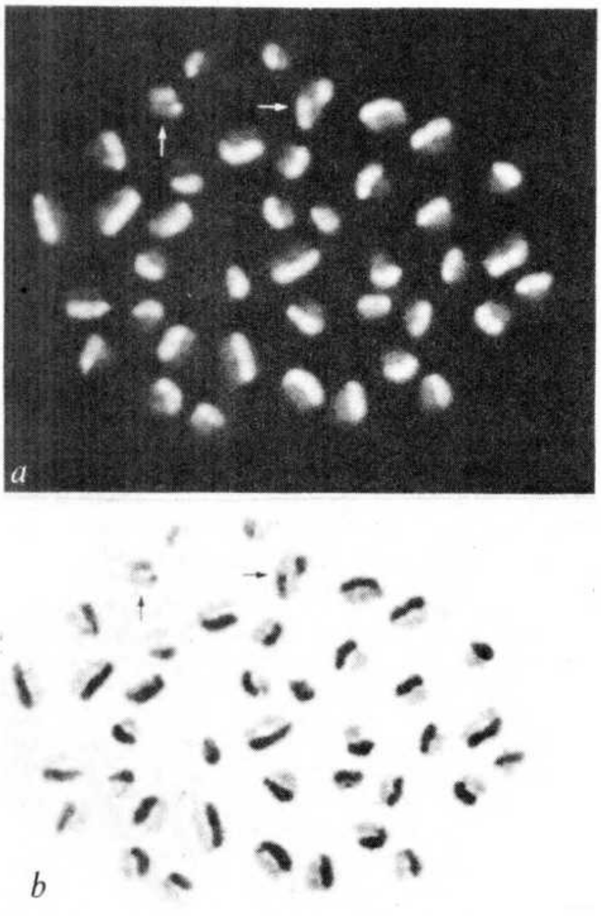

Fig. 1 Sister chromatid differentiation and SCEs in mouse spermatogonia. After *in vivo* administration of BUdR and slide preparation as described in the text, this cell was stained with 33258 Hoechst. *a*, Result of fluorescence microscopy; *b*, appearance of the same cell following subsequent Giemsa staining. SCEs indicated by arrows.

general *in vivo* mutagenesis test, this procedure has been utilised to demonstrate a several-fold increase in the sister chromatid exchange frequency in mouse spermatogonia after injection of the animals with small amounts of mitomycin C.

Substitution of spermatogonial chromatids in 3–5-month-old male CBA/J mice was effected by administering 14 hourly intraperitoneal (0.2 ml) injections of BUdR (10^{-2} M) together with deoxycytidine (5×10^{-3} M), the latter to reduce BUdR toxicity[15]. The series of injections served to replenish exogenous nucleotide which is thought to undergo rapid depletion *in vivo*[16]. The total duration of exposure to BUdR (approximately 14 h) is presumed sufficient for incorporation of this base analogue into all spermatogonial subpopulations, including the predominating type B spermatogonia which exhibit the longest DNA synthesis periods[17]. Mitomycin C, when administered, was injected as a single intraperitoneal dose (0.025–0.5 mg kg^{-1}) 26 h after the initial injection of BUdR. After an additional 28-h period, Colcemid was injected (0.6 mg kg^{-1}, intraperitoneally) and the animals were killed by ether narcosis 3–5 h later. Spermatogonial chromosomes were prepared from isolated seminiferous tubules[18], stained with 33258 Hoechst[9,19], and sister chromatid differentiation examined by fluorescence microscopy which, in many cases, was followed by Giemsa staining [11,12].

Most of the metaphase cells examined revealed the differential chromatid fluorescence characteristic of 33258 Hoechst stained cells which had replicated twice after administration of BUdR[20] (Fig. 1). Similar patterns could be observed with Giemsa staining after the intense illumination used for fluorescence microscopy[12]. In view of the schedule of BUdR administration and the generation times of the spermatogonial cells[17], the present sister chromatid differentiation is believed to reflect one cycle of BUdR

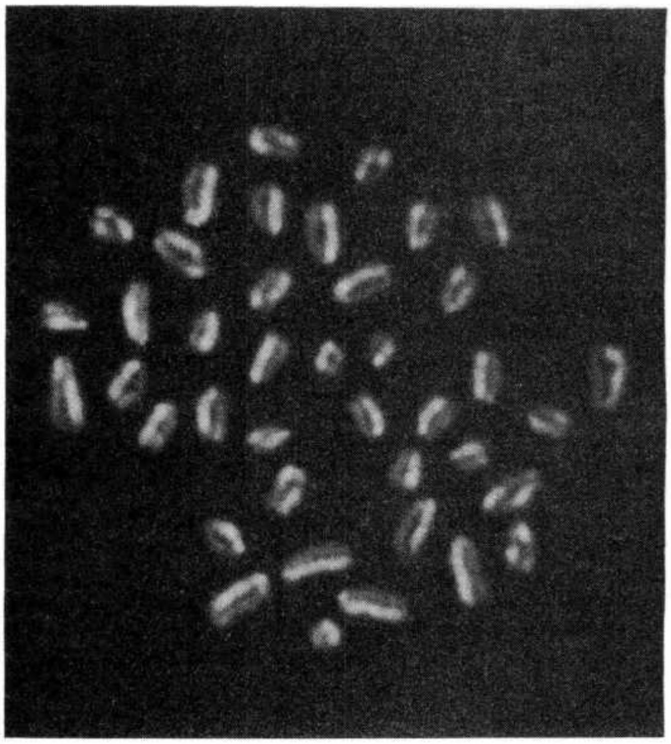

Fig. 2 Extensive induction of SCEs in a mouse spermatogonial cell by mitomycin C. This cell was treated as described in Fig. 1, except that a single dose of mitomycin C (0.5 mg kg^{-1}) was injected intraperitoneally into the animal 32 h before collection. Eighteen SCEs are evident in this cell.

Table 1 SCEs and chromosome aberrations induced by mitomycin C in BUdR-substituted spermatogonia

§Aberrations included translocations, chromatid breaks and quadriradial figures.

incorporation followed by a second cycle in the relative absence of analogue. Metaphase cells collected at earlier times (23 h after initiation of BUdR administration) and stained with 33258 Hoechst demonstrated the lateral fluorescence asymmetry expected for satellite DNA containing centromeric regions which have undergone one round of BUdR incorporation[21]. An occasional second division cell exhibited a longitudinal fluorescence differentiation, reflecting BUdR incorporation for only part of a DNA synthesis period, thereby suggesting usefulness of this method for studying replication kinetics.

An average of somewhat less than 2 SCEs per cell were observed for control animals given BUdR but not mitomycin C (Table 1). Frequencies are normalised for the numerous multiple genome figures reflecting the interconnected cell populations characteristic of male germinal tissue[22]. The SCE rate increased to two, three and four times that of control at mitomycin C doses of 0.05, 0.3, and 0.5 mg kg^{-1}, respectively. The last dose, which markedly increased the exchange frequency (Fig. 2), induced fewer than 0.1 morphological aberrations (breaks, rearrangements) per second division metaphase. Consistent with other reports[3,23], higher doses of mitomycin C (1.0–5.0 mg kg^{-1}) markedly reduced the number of metaphase cells available for analysis, presumably by retarding the proliferation of severely damaged spermatogonia. Preliminary observations using the techniques described above indicate that intraperitoneal injection of mitomycin C is also capable of inducing SCEs in mouse bone marrow cells.

The use of intact animals in the present study provides a highly relevant test system which takes into account host metabolism and possible activation of the drug[24,25], as well as passage of the drug across the blood–testis barrier[26]. Technical improvements in this procedure, in particular those simplifying the administration of BUdR to animals, should facilitate application of this approach. The precise relationship between SCE induction and mutagenesis remains to be determined, although the two events exhibit a high correlation[8]. Mitomycin C-induced chromosome rearrangements in spermatogonia have already been implicated in mutagenesis[4,27] and errors potentially associated with SCE formation may similarly contribute to the mutation frequency[28]. Thus, SCE analysis in mammalian spermatogonia should constitute an important new test of environmental mutagenesis.

An additional potential of a spermatogonia cell system for BUdR-dependent differentiation between sister chromatids is its natural extension for experimental studies of meiosis. If collection of the seminiferous tubules is delayed for approximately 2 weeks after BUdR administration, BUdR and therefore sister chromatid differentiation might be present in condensed meiotic chromosomes[29]. Optical detection of chromatid exchange between homologues should then enable high resolution analysis of meiotic recombination, which could also be compared with SCE frequencies in different cell types of the same animals

Fate of thiazolidine ring during fragmentation of penicillin by exocellular DD-carboxypeptidase-transpeptidase of *Streptomyces* R61

LIKE various β-lactamases, acylases and esterases[1], the exocellular DD-carboxypeptidase-transpeptidase of *Streptomyces* R61 degrades benzylpenicillin and other β-lactam antibiotics[2–4]. The R61 enzyme, however, markedly differs from the other penicillin-degrading enzymes in causing fragmentation of the penicillin nucleus. By using 8-^{14}C-benzylpenicillin (benzyl labelled) as substrate, one of the fragments produced was shown to be ^{14}C-phenylacetylglycine[5]. The reaction with the R61 enzyme is also peculiar in that it is a slow process. This is because of the long half life of the stoichiometric complex transitorily formed between the antibiotic and the enzyme. Thus, for example, the value of the half life for the complex formed with benzylpenicillin is 80 min in 10 mM phosphate buffer (*p*H 7.0) and at 37 °C. As breakdown of the complex proceeds, however, phenylacetylglycine (when benzylpenicillin is used as substrate) is released and the enzyme concomitantly recovers its ability to bind penicillin. We have now characterised the fragment (hereby designated as the Y product) arising from the thiazolidine ring of penicillin as a result of the fragmentation of the antibiotic molecule by the R61 enzyme.

The large amount (about 20 μmol) of ^{14}C-phenylacetylglycine previously produced from 8-^{14}C-benzylpenicillin through a series of enzyme inactivation and reactivation (total time for the operation, 100 h) could be purified by filtration of the reaction mixture on a column of Sephadex G-25 on the basis that phenylacetylglycine was eluted at a volume slightly larger than the salt volume[5]. Examination of the fractions containing ^{14}C-phenylacetylglycine by NMR spectrometry failed to reveal any lines that could be attributed to methyl groups. In marked contrast, the NMR spectrum in D_2O of the non-radioactive material obtained from the salt-containing fractions exhibited lines characteristic of methyl groups. The spectrum indicated that the thiazolidine ring had been opened and suggested that the split product was either *N*-formyl-D-penicillamine or di-(*N*-formyl-D-penicillamine)disulphide (Fig. 1). Direct chromatography of a sample of this fraction on Aminex A5 ion-exchange resin yielded only very minor ninhydrin-positive peaks. Mild acid hydrolysis (1 h in 1 N HCl at 60 °C, that is, in conditions which are known to release the formyl group from di-(*N*-formyl-D-penicillamine)disulphide[6]) produced one important ninhydrin-positive compound which had the same behaviour on the Aminex column as di-(D-penicillamine)-disulphide. Finally, mild acid hydrolysis followed by performic oxidation yielded a highly acidic ninhydrin-positive product which, on the same Aminex column, was indistinguishable from the product obtained by performic oxidation of D-penicillamine.

In order to characterise the Y product further and to study the kinetics of its release, various radioactive penicillins with the radioactive label in the thiazolidine portion of the molecule were prepared. ^{3}H-Benzylpenicillin (labelled in the β-methyl

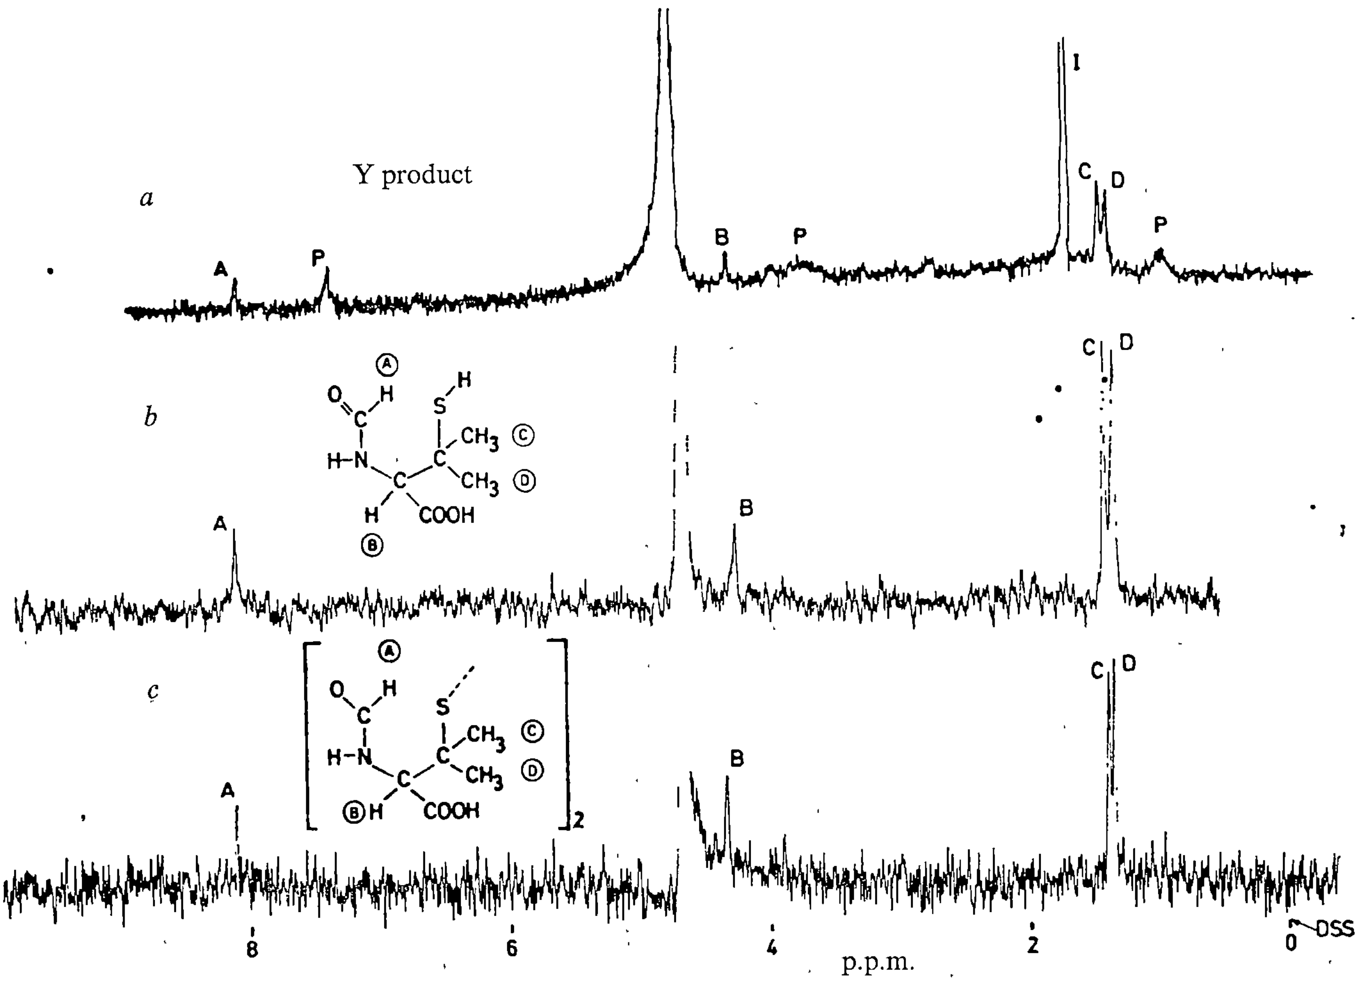

Fig. 1 NMR spectra in D_2O of Y product (*a*), *N*-formyl-D-penicillamine (*b*) and di-(*N*-formyl-D-penicillamine) disulphide (*c*). The spectra were obtained with a Varian XL100-15 spectrometer operated in the ^{2}D internal lock mode. The I line exhibited by the Y preparation (*p*H 7.0) was attributed to an impurity and the P lines were attributed to the presence of a small amount of penicilloic acid. The A, B, C and D lines, occurring in the ratios of 1: 1: 3: 3, were attributed to the Y product The 6 Hz distance between the methyl lines (C and D) excluded the presence of an intact thiazolidine ring (in which case the distance value should have been 38 Hz) The spectra of the Y product, *N*-formyl-D-penicillamine and di-(*N*-formyl-D-penicillamine)disulphide were virtually superimposable with respect to lines A (8.09, 8.11 and 8.09 p.p.m., respectively), B (4.31, 4.28 and 4.34 p.p.m., respectively), C (1.40, 1.38 and 1.36 p.p.m., respectively) and D (1.46, 1.45 and 1.41 p.p.m., respectively). The p.p.m values are relative to 2,2-dimethyl-2-silapentane-5-sulphonate (DSS). Further confirmation was obtained by extracting the Y product (after acidification) with ethylacetate. The extract was evaporated to dryness and the residue dissolved in $CDCl_3$ in the presence of dimethylsulphoxide Proton B of the CH group located in the vicinity of the NH group gives a characteristic doublet (9 Hz splitting) The SH proton, however, could not be seen because of the presence of a large impurity peak in its resonance region and it was therefore impossible to decide whether the Y product was *N*-formyl-D-penicillamine or di-(*N*-formyl-D-penicillamine)disulphide. The *N*-formyl-D-penicillamine used as standard (spectrum *b*) was prepared by dissolving D-penicillamine HCl (550 mg) in 7 ml formic acid (95%) containing 200 mg of sodium formiate After addition of 2 ml of acetic anhydride, the reaction proceeded for 1 h at room temperature. Melting point 146–148 °C; (α^{20}_{D}+63 (C= 1, pyridine)). The optical rotation is in agreement with the value published previously[6]. The di-(*N*-formyl-D-penicillamine)disulphide (spectrum *c*) was prepared from *N*-formyl-D-penicillamine by oxidation in air in the presence of FeCl[6].

group, 1.7 mCi mmol^{-1}), 5-^{14}C-benzylpenicillin (0.07 mCi mmol^{-1}) and 5-^{14}C phenoxymethylpenicillin (that is, penicillin V; 0.08 mCi mmol^{-1}). As determined by the bioassay and iodometric assay, the purity of the compounds was higher than 98%. Thin-layer chromatography showed, besides the penicillin spot, a small amount of penicilloic acid (±2%) but no other radioactive impurities.

In a first series of experiments, maximal amounts of ^{3}H-Y and ^{14}C-Y products were prepared from ^{3}H-benzylpenicillin and 5-^{14}C-benzylpenicillin, respectively. In these assays, the R61 enzyme was maintained saturated by successive additions of radioactive penicillins to the reaction mixtures. The total period of time for the whole operations was 24 h and a total amount of 0.5 μmol of each radioactive benzylpenicillin was converted into degradation products. The accumulated ^{3}H-Y and ^{14}C-Y products were partially purified by filtration on Sephadex G-25 The following observations were made. (1) Both radioactive Y products had the same *Rf* values by thin-layer chromatography and with the two solvents used, these *Rf* values were identical to those of di-(*N*-formyl-D-penicillamine)-disulphide (Table 1). (2) At least 95% of the radioactive labels originally engaged in the reactions, cochromatographed on the Aminex A5 column exactly with exogenously added, non-radioactive di-(*N*-formyl-D-penicillamine)disulphide (as revealed by ninhydrin after acid hydrolysis of a sample of the fractions obtained; Fig. 2*a*). (3) Treatment of the ^{3}H-Y product with 1 N HCl for 60 min at 60 °C produced (95% yield) a radioactive compound which on the Aminex column cochromatographed exactly with exogenously added, non-radioactive di(D-penicillamine)disulphide (as revealed directly with ninhydrin; Fig. 2*b*). (4) HCl Treatment of the ^{14}C-Y product in the same conditions as above yielded a non-radioactive compound which also behaved on the Aminex column as di(D-penicillamine)disulphide (and was directly revealed with ninhydrin). Since the ^{14}C-Y product was formed by action of the R61 enzyme on 5-^{14}C-benzylpenicillin and since treatment of the ^{14}C-Y product under conditions known to release the formyl group from di-(*N*-formyl-D-penicillamine)disulphide

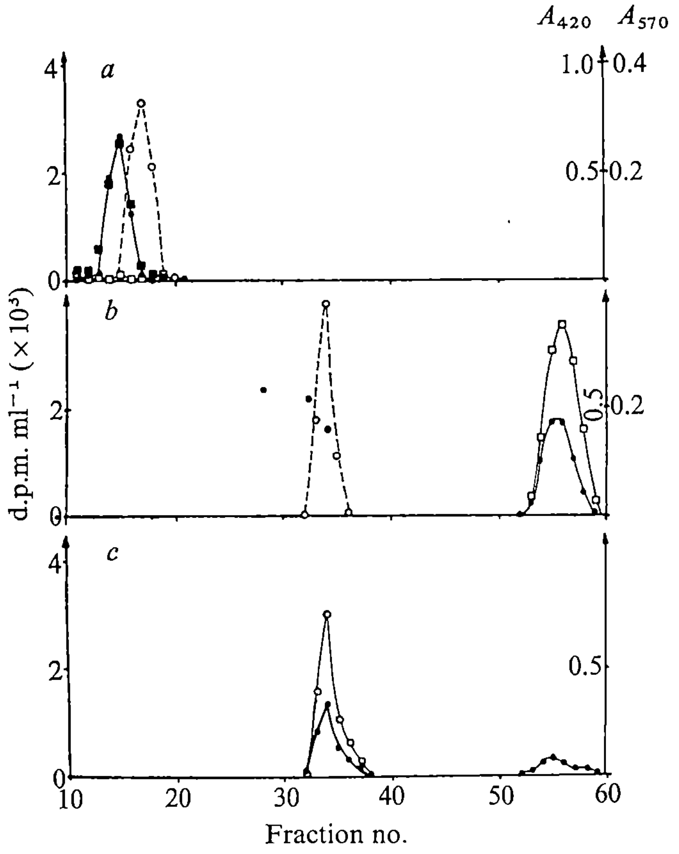

Fig. 2 Identification by chromatography on Aminex A5 of the Y products released from benzylpenicillin after interaction with the R61 enzyme under prolonged (*a* and *b*) and short (*c*) incubation times. The column (9×540 mm) was equilibrated against 0.2 M sodium citrate–HCl buffer (*p*H 3.17). Elution was performed with the same buffer at a flow rate of 80 ml h^{-1} (volume of the fractions: 3.2 ml). *a*, A mixture containing 10 nCi of ^{3}H-Y product and 200 μg of each *N*-formyl-D-penicillamine and di-(*N*-formyl-D-penicillamine)disulphide was deposited. Radioactivity (●) was measured on 1-ml samples. The *p*H of 0.4-ml samples was adjusted to 7.5–8.0 by addition of 40 μl of 2 M Tris base and the free sulphydryl groups (○) were estimated by adding 20 μl of 50 mM Tris-HCl buffer (*p*H 8.0) containing 40 μg of 5,5′-dithio-*bis*(2-nitrobenzoic acid) (A_{420}). The free amino groups were estimated by reaction with ninhydrin (A_{570}) before (□) and after (■) a 60 min incubation at 60 °C in 1 N HCl. *b*, A mixture containing 10 nCi of ^{3}H-Y product and 400 μg of di-(*N*-formyl-D-penicillamine)disulphide was incubated at 60 °C for 60 min in 1 N HCl. The *p*H was then adjusted to 2.2, 200 μg of D-penicillamine were added and the mixture was deposited on the column. Radioactivity (●) was measured on 1-ml samples. Free sulphydryl groups (○) and free amino groups (□) were estimated on 0.4-ml and 0.5-ml samples, respectively, as in *a*. *c*, Chromatography of the HCl-hydrolysed tritiated compound prepared by a 2-h incubation of ^{3}H-benzylpenicillin with the R61 enzyme (for conditions, see text) The radioactivity (●) was measured on 1-ml samples. Free sulphldryl groups (○) were estimated as above. The A_{570} value after colour development of D-penicillamine with ninhydrin is about 7% of that obtained with equivalent amount of D-penicillamine disulphide.

actually resulted in the release of the radioactive label, it seems clear that the formyl group of di-(*N*-formyl-D-penicillamine)-disulphide arises from C5 of the penicillin nucleus. (5) Thin-layer chromatography in solvent B (for composition, see Table 1) of the hydrolysed ^{3}H-Y and ^{14}C-Y products revealed the presence of a radioactive ninhydrin-positive spot and of a non-radioactive ninhydrin-positive spot, respectively, exhibiting the same *Rf* value (0.27) as di-(D-penicillamine)disulphide. (6) Finally, performic oxidation of the HCl-treated ^{3}H-Y product yielded a very acidic ^{3}H compound (90% yield) which, on the Aminex column, cochromatographed exactly with exogenously added penicillamine previously oxidised with performic acid.

In a second series of experiments, a half life of 90 min for the ^{3}H-benzylpenicillin–R61 complex (in 10 mM phosphate buffer (*p*H 7.0) and at 37 °C) was determined on the basis of the release of the radioactive label. In previous studies[3], an average half life of 80 min had been determined for the complex formed with the R61 enzyme. Within the limits of experimental errors therefore, recovery of enzyme activity and release of the two fragments arising from the benzylpenicillin molecule occur with the same rate constant (1.4×10^{-4} s^{-1}). This result together with the facts that after complete enzyme recovery, more than 90% of the original radioactive labels were recovered as ^{14}C-phenylacetylglycine and either ^{3}H- or ^{14}C-di-(*N*-formyl-D-penicillamine)disulphide (depending on the radioactive benzylpenicillins used), show clearly that phenylacetylglycine and di-(*N*-formyl-D-penicillamine) are produced in stoichiometric amounts.

Since the Y product characterised as di-(*N*-formyl-D-penicillamine)disulphide was isolated after several cycles of enzyme inactivation and reactivation (that is, after prolonged incubation), we wondered whether it was actually the one initially released through breakdown of the penicillin molecule. In a third series of experiments, two samples, each containing 5 nmol of ^{3}H-benzylpenicillin and 6 nmol of R61 enzyme, were incubated for 2 h at 37 °C under nitrogen. Reaction of one of the samples with 5,5′-dithio-*bis*(2-nitrobenzoic acid) indicated free SH groups. Non-radioactive *N*-formyl-D-penicillamine (125 μg) was added to the second sample and the solution was treated with 1.2 N HCl (final concentration) for 16 h at 60 °C, that is in conditions where release of the formyl group from *N*-formyl-D-penicillamine was known to occur[6]. Chromatography on Aminex A5 revealed that 80% of the radioactive product present in the hydrolysate was penicillamine (Fig. 2*c*). About 20% of penicillamine disulphide was detected. Thus *N*-formyl-D-penicillamine was probably the primary product released and di-(*N*-formyl-D-penicillamine)disulphide was a product subsequently formed by oxidation. Surprisingly, however, by incubating 50 nmol of *N*-formyl-D-penicillamine for 16 h at 37 °C, in 100 μl of 10 mM phosphate buffer (*p*H 7.0), either as such, or in the presence of 0.5 nmol of heat-inactivated R61 enzyme (5 min at 100 °C), or in the presence of the same amount of active R61 enzyme, it was observed that 80–90% of the SH groups originally present remained titratable by dithio-*bis*-nitrobenzoic acid after incubation in the absence of enzyme or in the presence of inactivated enzyme but that 80% of these groups had disappeared after incubation in the presence of native enzyme. Thus, it is not impossible that the enzyme preparation somehow participated in the oxidation of the *N*-formyl-D-penicillamine initially released.

Table 1 Thin-layer chromatography on silica gel (G) of radioactive Y product and of non-radioactive *N*-formyl-D-penicillamine and di-(*N*-formyl-D-penicillamine)disulphide

Compound	*Rf* values in solvents A	 B
^{3}H- or ^{14}C-Y product	0	0.69
N-formyl-D-penicillamine	0.34	0.68
di-(*N*-formyl-D-penicillamine)disulphide	0	0.67

Solvent A, $CHCl_3/CH_3OH/CH_3COOH$: 88/10/2 (v/v/v).
Solvent B, 1-butanol/$H_2O/C_2H_5OH/CH_3COOH$: 10/4/3/3(v/v/v/v).
Both the peaks of radioactivity (detected by scanning the thin-layer plates in a radiochromatogram scanner) and the spots of di-(*N*-formyl-D-penicillamine)disulphide (as revealed by spraying the plates with an alcoholic solution of bromocresol green) were perfectly symmetrical.

Comparable results were obtained with 5-^{14}C-phenoxymethylpenicillin which was degraded into ^{14}C-*N*-formyl-D-penicillamine and non-radioactive phenoxyacetylglycine.

In summary, it seems that within the limits of experimental

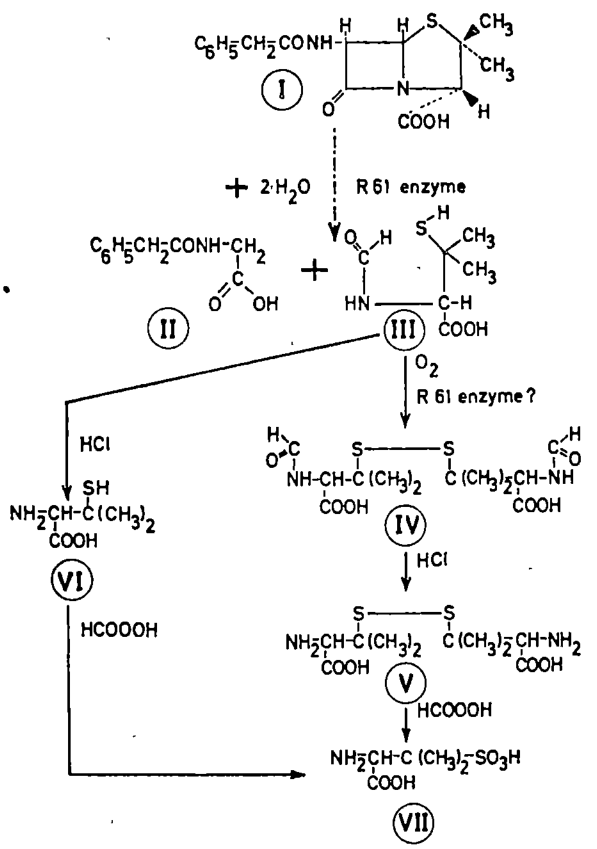

Fig. 3 Degradation of benzylpenicillin I, benzylpenicillin; II, phenylacetylglycine; III, N-formyl-D-penicillamine; IV, di-(N-formyl-D-penicillamine)disulphide; V, D-penicillamine disulphide; VI, D-penicillamine; VII, dimethyl cysteic acid. Degradation of III into VI requires acid treatment (1 N HCl) during several hours at 60 °C. Degradation of IV into V can be achieved by the same acid treatment during 1 h.

error, Nα-(acyl)-glycine and N-formyl-D-penicillamine are released in stoichiometric amounts from the complex formed between penicillin and the exocellular R61 DD-carboxypeptidase-transpeptidase, and that release of these fragments and enzyme reactivation are concomitant events. If penicillin is benzylpenicillin, phenylacetylglycine is released. If penicillin is phenoxymethylpenicillin, phenoxyacetylglycine is released. Globally, the reaction consists in the addition of two H_2O molecules and results in the hydrolysis of the amide bond and in the rupture of both C5–C6 and C5–S linkages (Fig. 3) The nature of the acyl substituent on the antibiotic molecule is important; although it does not modify the pathway of the reaction, it obviously influences the half life of the complex formed between penicillin and the enzyme The released N-formyl-D-penicillamine undergoes subsequent oxidation with formation of the disulphide derivative.

Studies[7,8] with isolated membranes have shown that enzyme–penicillin complexes found in membranes do not always give rise to the products we have found with purified enzyme. Further work is required in order to unravel the exact mechanism of the reactions.

Phage-coded protein prevents restriction of unmodified progeny T4 DNA

HOST-controlled restriction modification systems usually prevent the survival of unmodified genomes in bacterial cells[1–4]. Phage DNA can be modified by methylation (λ and f1)[5–7] or by glucosylation (T-even phages[3]). Modification of the λ genome is mediated by a host methylase[8] whereas modification of the T4 genome is by phage coded α- and β-glucosyl transferases[9]. The restriction systems of *E. coli* (*rgl*) acting on non-glucosylated (glu$^-$) T-even phages are called r_6 and $r_{2,4}$ (ref. 10): r_6 restricts all glu$^-$ T-even phages, whereas $r_{2,4}$ restricts only T2 and T4 glu$^-$ phages. Hattman and Fukasawa[11] showed that when glu$^+$ T4 DNA was injected into an *rgl*$^+$ uridine diphosphoglucose (UDPG) pyrophosphorylaseless mutant, the progeny glu$^-$ DNA replicated and was matured into virions which they called T*. To explain why the replicating glu$^-$ progeny DNA is not restricted in the *rgl*$^+$ host while the entering T* virion DNA is, Fukasawa[12] postulated that the *rgl* system is localised in the membrane. Incoming glu$^-$ parental DNA would be restricted during passage through the membrane. Incoming glu$^+$ parental DNA (which is not restricted) would be replicated as glu$^-$ DNA in the absence of UDPG. Since the replicating DNA is not subject to the restriction system localised in the membrane it should not be restricted. Not surprisingly, r_6 was shown to be localised in the membrane[13,14]. There is, however, good evidence that $r_{2,4}$ can restrict replicating DNA[15,16] and is, at least in that sense, cytoplasmic. Thus, the question why $r_{2,4}$ does not restrict unmodified progeny DNA is still unresolved. We report here that the phage specifies a protein which prevents the action of $r_{2,4}$. The anti-$r_{2,4}$ activity specified by the modified parental genome prevents restriction of the unmodified progeny DNA by $r_{2,4}$.

Of the two restriction activities of the host, coded by the *rgl* system, r_6 seems more readily and rapidly inactivable, since it is inhibited by phage infection even in the absence of expression of the phage genome[13,14]. Table 1 shows that the inactivation of $r_{2,4}$, in contrast to r_6, requires expression of the phage genome. Infection of $r_6^+r_{2,4}^-$ cells inactivates the r_6 activity in the presence or absence of primary phage expression. In $r_{2,4}^+$

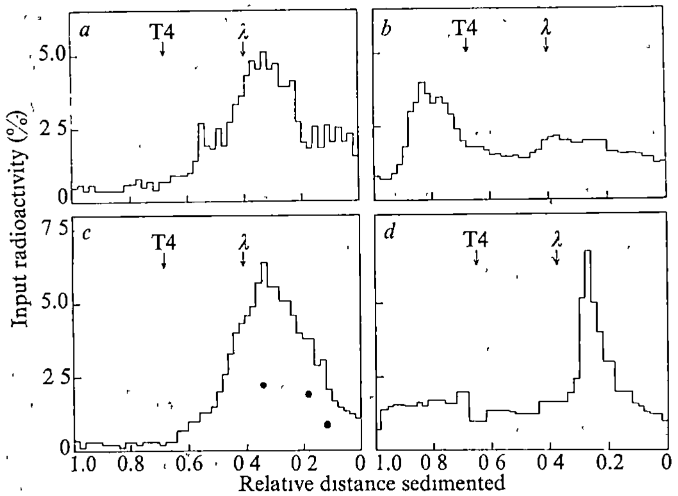

Fig. 1 Demonstration of a protein inhibiting the cleavage of superinfecting glu$^-$ T4 DNA. *rgl*$^+$ exo V$^-$ (W3110 recB$^-$) cells infected with T4 *imm*$^-$ *s*$^-$ phage (which permit less leakage of *imm* expression late in infection[18]) in the presence or absence of chloramphenicol, were superinfected with ^{32}P-glu$^-$ T4 (T4α' gt^{am8} βgt^{am10}.K rgl$^-$ su$^-$) after 10 min. Five minutes after superinfection, native DNA molecules were extracted[20] and analysed in neutral sucrose gradients. The same preparations, denatured by adding sodium hydroxide to 0.4 N, were also analysed in alkaline sucrose gradients[16]. Centrifugation was for 110 min at 147,000*g* at 20 °C. ^{3}H-λC$_{1857}$susS$_7$ particles[19] were added to the infected *E. coli* during lysis of spheroplasts by detergent, to serve as a marker. The calculated[21] position of T4 DNA was confirmed on several occasions. *a*, Chloramphenicol absent, alkaline gradient; *b*, chloramphenicol absent, neutral gradient; *c*, chloramphenicol present, alkaline gradient; *d*, chloramphenicol present, neutral gradient.

cells the primary infecting *imm*$^-$ phage prevents the breakdown of superinfecting glu$^-$ phage, only when primary phage expression takes place. In these cells, when primary phage expression is prevented by chloramphenicol or ultraviolet irradiation (UV), of the primary infecting virions the superinfecting glu$^-$ T4 is broken down. This implies that the primary infecting phage codes for a protein which prevents the breakdown of glu$^-$ T4 DNA. We have shown that the restriction of unmodified T4 *in vivo* takes place in two steps[16]. The first step caused by the restriction endonuclease, which we call cleavage, results in double-stranded breaks in the unmodified genome. The large trichloroacetic acid (TCA)-insoluble double-stranded pieces are further degraded by exonuclease (exo) V (the rec BC enzyme) to small acid-soluble and insoluble fragments[13,16]. We call this second step DNA breakdown.

T4 makes a protein which prevents exo V action[17,18]. In the experiment described above we measured only DNA breakdown. The inhibition of breakdown by the primary phage-coded proteins may reflect either inhibition of exo V or inhibition of cleavage by restriction enzymes or both. To see whether cleavage was inhibited, we measured the cleavage reaction alone in exo V$^-$ hosts. *E. coli rgl*$^+$ infected with T4 *imm*$^-$*s*$^-$ phage, permits superinfection by glu$^-$ T4 phage without DNA breakdown[13]. Figure 1 shows the fate of this superinfecting phage DNA. When sedimented on an alkaline sucrose gradient the strands are shown to be fragmented to 1/4–1/20 their original length, as might be expected for restriction cleavage of glu$^-$ DNA by *rgl* (Fig. 1*a*). But this same DNA, when native, sediments mainly as concatemers (Fig. 1*b*). This, however, is the result expected for glu$^-$ DNA on a phenotypically *rgl*$^-$ host, that is if $r_{2,4}$ were inactivated. When this

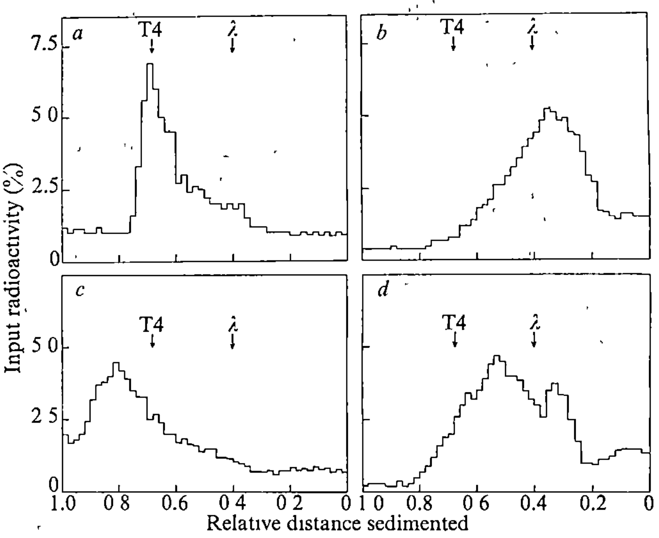

Fig. 2 Demonstration of a chloramphenicol-sensitive nicking enzyme in T4 *imm*$^-$*s*$^-$ infected cells. Ten minutes after primary infection with T4 *imm*$^-$*s*$^-$ phage the cells were superinfected with the appropriate ^{32}P-phage. Five minutes after superinfection DNA was extracted and analysed for size distribution in native and denatured conditions. Experimental details are described in legend for Fig. 1. *a*, *E. coli* K *rgl*$^-$ cells superinfected with glu$^-$T4, chloramphenicol present, alkaline gradient; *b*, *E. coli* K *rgl*$^-$ cells superinfected with glu$^-$T4, chloramphenicol absent, alkaline gradient; *c*, *E. coli* K *rgl*$^-$ cells superinfected with glu$^-$T4, chloramphenicol absent, neutral gradient; *d*, *E. coli* K *rgl*$^+$ exo V$^-$ cells, superinfected with T4 wild-type phage, chloramphenicol absent, alkaline gradient.

Table 1 Effect of primary infecting phage-coded function(s) in the breakdown of superinfecting glu$^-$ T4

Bacterial strains	Chloramphenicol	Primary phage	Superinfecting phage	% DNA breakdown
$r_6^-r_{2,4}^-$	−	T4glu$^-$	—	4
	−	T4*imm*$^-$	T4glu$^-$	3
	+	T4*imm*$^-$	T4glu$^-$	3
	−	UV.T4	T4glu$^-$	14
$r_6^+r_{2,4}^-$	−	T4glu$^-$	—	28
	−	T4*imm*$^-$	T4glu$^-$	4
	+	T4*imm*$^-$	T4glu$^-$	3
	−	UV.T4	T4glu$^-$	16
$r_6^-r_{2,4}^+$	−	T4glu$^-$	—	30
	−	T4*imm*$^-$	T4glu$^-$	7
	+	T4*imm*$^-$	T4glu$^-$	28
	−	UV.T4	T4glu$^-$	43
$r_6^+r_{2,4}^+$	−	T4glu$^-$	—	35
	−	T4*imm*$^-$	T4glu$^-$	5
	+	T4*imm*$^-$	T4glu$^-$	36
	−	UV.T4	T4glu$^-$	35

Phage and bacterial strains, culture conditions and other techniques used in this study are described previously[16]. Log phage cells (5×10^8 cells per ml) were infected with 3–4 T4 *imm*$^-$ phage per bacterium. 2–3 ^{32}P-glu$^-$ T4 was added 5 min after primary infection. DNA breakdown was determined as trichloroacetic acid (TCA)-soluble fraction of DNA, 5 min after superinfection. Chloramphenicol (100 μg ml^{-1}), when required was added 3 min before primary infection. The data given are not corrected for adsorption, which was 85–95%.

experiment is repeated in the presence of chloramphenicol not only are nicks observed in the isolated strands (Fig. 1*c*) but double-stranded cleavage (Fig. 1*d*) is observed, as expected for glu$^-$ DNA in an *rgl*$^+$ host. Thus it seems that the cleavage activity of $r_{2,4}$ on double-stranded DNA is inhibited by a primary infecting phage-coded protein, the synthesis of which is inhibited by chloramphenicol.

To be certain that nicking in Fig. 1*c* was caused by $r_{2,4}$, we repeated the experiment using an *rgl*$^-$($r_6^-r_{2,4}^-$) host cell. *rgl*$^-$ cells infected with T4 *imm*$^-$*s*$^-$ in the presence of chloramphenicol were superinfected with glu$^-$ T4. Single strands of DNA sediment mainly as whole strands (Fig. 2*a*), but in the absence of chloramphenicol the superinfecting glu$^-$ DNA is nicked (Fig. 2*b*). Thus there are two different nicking (endonuclease) activities in the cell at different times. The first, the host *rgl* system, nicks complementary DNA strands in close proximity leading to DNA cleavage. This cleavage activity of the host *rgl* system can be demonstrated even in the presence of chloramphenicol in *rgl*$^+$ cells but not in *rgl*$^-$ cells in the absence or presence of chloramphenicol (compare Figs 1*d* and 2*c*). The host cleavage activity is inhibited by a phage-coded protein which appears after primary infection and is not made in the presence of chloramphenicol (compare Fig. 1*b* and *d*). The second, a phage-coded enzyme, produces single-stranded nicks but does not cleave double-stranded DNA. We think that this enzyme is probably the phage endonuclease demonstrated *in vitro* by Altman and Meselson[22]. Thus, in the absence of chloramphenicol, when *rgl* cleavage activity is inhibited, nicking activity is still apparent (compare Fig. 1*a* and *c*). This activity is independent of the *rgl* system and requires phage protein synthesis (compare Fig. 2*a* and *b*). The nicking activity is also not greatly affected by glucosylation since both glu$^+$ and glu$^-$ DNA are nicked in these conditions (compare Figs 2*d* and 1*a*). In any case, data in Figs 1 and 2 show that a protein is made, after primary phage infection, which prevents initial cleavage of superinfecting glu$^-$ DNA by $r_{2,4}$. We call this protein anti-$r_{2,4}$.

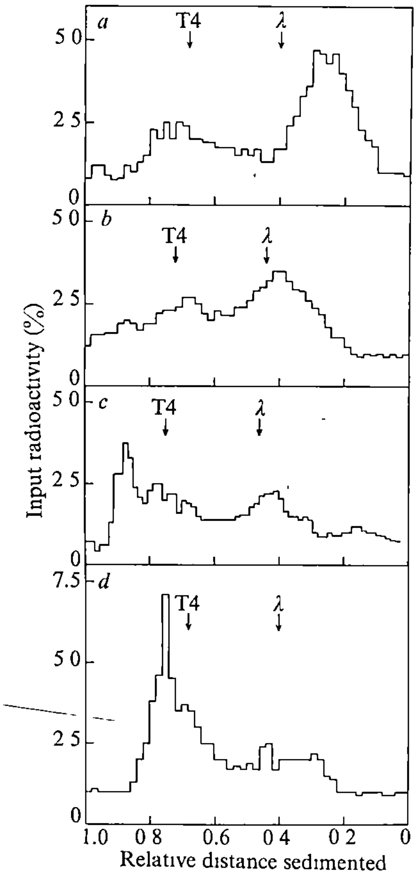

Fig. 3 Time of appearance of anti-$r_{2,4}$.*rgl*$^+$ exo V$^-$ cells infected with T4 *imm*$^-$*s*$^-$ phage were superinfected with ^{32}P-glu$^-$T4 at various times. Native DNA was analysed 5 min after superinfection. *a*, *b*, *c* and *d* were superinfected at 1, 2, 5 and 7 min after primary infection respectively.

To establish the time of appearance of the anti-$r_{2,4}$ activity we infected *E. coli rgl*$^+$ with T4 *imm*$^-$*s*$^-$ phage and superinfected with glu$^-$ T4 at various times after primary infection. Figure 3 shows that large molecules, of mature T4 DNA size or larger, accumulate as the time of superinfection is delayed. This anti-$r_{2,4}$ activity appears quite soon after infection. The exact time of its appearance is difficult to establish in these experiments, however, since it is still being synthesised between the time of superinfection and completion of cleavage of the superinfecting glu$^-$ phage DNA. Therefore, the 1-min point has probably allowed more than 1 min of expression by the primary phage. By 7 min after infection, when unmodified progeny DNA synthesis is expected to start, $r_{2,4}$ activity has disappeared.

An intriguing problem in the restriction system of glu$^-$ T4 is the successful replication of intracellular unmodified genomes in contrast to the complete restriction of entering parental unmodified genomes. The demonstration of the anti-$r_{2,4}$ activity gives a satisfactory explanation for the resistance of unmodified progeny genomes to restriction. This does not seem to be so in the case of phage λ. The analogous experiment, infection of restricting bacteria ($r_{\rm K}^+$) by modified λ in the presence of an inhibitor of S-adenosylmethionine (SAM) production, leads to the production of normal unmodified phage[23]. SAM (unlike UDPG in the case of T4) is, however, needed for restriction as well as modification[8]. When a similar experiment was repeated using a P1 lysogen, the λ progeny were restricted as SAM is needed for P1 modification but not for restriction[23]. This experiment also shows that no inhibitor of the P1 restriction enzyme is made in this case. Nevertheless it is possible that complementation of modified λ by superinfecting unmodified λ in a non-permissive host[24] may involve production of anti-$r_{\rm K}$. Direct measurement *in vivo*, of cleavage activity by $r_{\rm K}$ (ref. 16) in these conditions should decide this question. It is probable, however, that complementation by cleaved unmodified fragments is enhanced by the inactivation of exo V[25] by the gamma gene-product from the primary infecting modified λ phage[26].

matters arising

Tornado forum

RECENTLY the proposal was made that motor traffic has contributed significantly to the sixfold increase in incidence of tornadoes in the USA in the past forty years.[1] The authors saw the vorticity introduced into the atmosphere by traffic driving on the right as favouring the generation of cyclonic tornadoes, and they were encouraged in this hypothesis by an increase in the proportion of cyclonic to anticyclonic tornadoes, and also by the low incidence of tornadoes reported on Saturdays, when traffic would be lower and more unidirectional (away from large cities).

The suggestion has provoked many responses and to publish them all would have occupied more space than we could allot. So we print below abridged versions of some of the communications received, followed by a reply from the authors.

[1] Isaacs, J D, Stork, J W., Goldstein, D B., and Wick, G. L, *Nature*, 253, 254–255 (1975).

A MOTOR vehicle or any other projectile in air produces vortices in its wake, but no net vorticity. If there are anticyclonic vortices along edges of the highway, as shown in Fig. 1 of Isaacs *et al.*, their vorticity must be balanced by cyclonic vorticity in the median strip.

The width of a highway is small compared to a cloud, and a significant updraft entraining the vortices produced by motor vehicles would realise no net contribution from that source. The main atmospheric phenomena produced by cars are turbulence, and gaseous and particulate combustion products along the highway, dissipating and diffusing downwind.

The low incidence of tornadoes on Saturdays perhaps reflects some unfortunate vagaries in reporting. Or, conceivably, changes in the atmospheric radiation budget and aerosol content induced by weekend factory closings and lowered air pollution produce changes in static stability and cloud particle development.

EDWIN KESSLER
National Severe Storms Laboratory,
Norman, Oklahoma 73069

WE believe that the mechanism for vorticity generation and accumulation in the atmosphere proposed by Isaacs *et al.* is based on misconceptions about the nature of vorticity. The atmosphere contains background vorticity arising from the rotation of the Earth and relative vorticity from weather disturbances and boundary effects, including moving vehicles. In fact the background vorticity can be ignored to high accuracy in the dynamics of flow around vehicles, since Coriolis effects are minute. The following argument depends, however, mainly on kinematical results, which are exact.

We begin by considering the generation of vorticity by a single moving vehicle. Absolute vorticity can be generated in a homogeneous fluid only at boundary surfaces moving relative to the fluid[1], and so is generated at the sides, top and bottom of the vehicle, at its wheels and at the ground in its neighbourhood. Once generated it is advected with the air stream into the vehicle's wake. The vortex filaments of the resulting relative vorticity vector field ω must either form closed loops or terminate at a boundary rotating relative to the Earth; and on this basis we can distinguish two constituents in the relative vorticity generated at a moving vehicle:

(1) When the vehicle moves in a straight line, closed vortex loops are shed continuously into its wake. These profoundly affect local levels of vorticity close behind the vehicle, but have no effect whatever either on the circulation round a contour enclosing the wake, or on the bulk integral

$$\int_V \omega \mathrm{d}V$$

over a volume V including the wake and the neighbourhood of the vehicle, because each vortex filament is closed. (None of these facts is changed by the presence within V of more vehicles whether driving on the right or on the left.)

(2) Vorticity having a net vertical component is generated when a vehicle turns, at a rate proportional to minus the rate of change of angular velocity of the vehicle about the vertical; see equation (1). There is an additional net horizontal component associated with the rotation of the wheels, which need not concern us further.

It is immediately clear that randomly varying vehicle movements can have no systematic gross effect over a large area as claimed by Isaacs *et al.* The vehicles could, however, produce localised concentrations of vorticity (changing sign over length scales of a few metres) the significance of which will depend very much on persistence and hence on interdiffusion rates. We shall discuss this question further elsewhere, but remark here that order-of-magnitude estimates based on plausible levels of turbulence suggest persistence times of minutes rather than hours, and vortices of dust devil rather than tornado scale.

If, as an opposite extreme, a large number of vehicles were to be driven simultaneously in fast clockwise circles, there would indeed temporarily be a cyclonic (that is, anticlockwise) contribution to the bulk vorticity integral. But this can be shown to be associated entirely with the air below vehicle rooftop level or, more precisely, below a plane surface s lying just above all the vehicles. When summed over the vast bulk of the atmosphere lying above s, the total component of vorticity normal to s caused by the vehicles is, and must remain, exactly zero (see equation (2) below). This is a consequence of the simple fact that each vehicle-generated vortex filament passing upward through s must go back down through s at another point, possibly terminating on a moving surface such as the underside of the same vehicle.

In summary, neither mechanism (1) nor (2) can plausibly be connected with the generation of tornadoes, which takes place high above the ground and which involves air motions coherent over length scales of kilometres.

Isaacs *et al.* stated that cyclonic vorticity "is generated by the torque between the two opposing streams of traffic", and this led to their view that it is better to drive on the left than the right of the road. Unfortunately torque does not determine the generation of vorticity, either locally or globally. Although doubling the separation of two traffic streams may approximately double the torque (to say nothing of the far larger contribution from unidirectional traffic on widely-separated highways) it has absolutely no effect on the net generation of vorticity. The vorticity due to the traffic streams is, to an excellent approximation, the sum of the contributions produced at the surface of each vehicle, locally redistributed by advection and diffusion; and any effects on the bulk vorticity integral have nothing to do with the separation of traffic streams, nor with left as against right hand drive.

The basic mathematical fact underlying our discussion is the solenoidal property of ω: since ω is the curl of a velocity field, $\nabla.\omega$ is identically zero. It follows that

$$\int_V \omega_i dV = \int_V \frac{\partial}{\partial x_j}\left(x_i\omega_j\right)dV$$
$$= \int_S x_i(\omega.\mathrm{n})dS$$

where V is a suitable piece of the atmosphere, partially bounded by the surface S, comprising the ground and the surfaces of stationary and moving objects (vehicles, their wheels, aeroplanes) which are envisaged as the source of the contribution ω to the relative vorticity, itself supposed confined within V. From this identity it may readily be shown that

$$\int_V \omega dV = -2\sum \Omega_r(t)V_r \qquad (1)$$

where $\Omega_r(t)$ is the angular velocity of the rth moving body, and V_r its volume. We here use the fact, fundamental to the vorticity generation mechanism, that the no slip condition[1] applies at all parts of the surface S.

Further, if all the moving objects lie below a plane surface s then, if ω_3 is the component of ω normal to s and v is the part of V above s,

$$\int_S \omega_3 dS = -\int_V \nabla.\omega dV = 0$$

Hence, by integration with respect to x_3,

$$\int_V \omega_3 dV = 0 \qquad (2)$$

The results (1) and (2) are both exact, even for an atmosphere in which the motion is baroclinic, compressible, and turbulent.

ISAACS *et al.* assert that the opposing streams of traffic on a road induce a net cyclonic vorticity in the atmosphere. Because vorticity diffuses exponentially slowly at large distances from a source, however, this is not so.

If the opposing traffic streams are modelled by infinite plates a distance D apart, then the resulting mean flow field at any finite time after the motion begins is of the form shown in Fig. 1. The detailed behaviour of the mean velocity profile near the plates is unimportant. Although the motion near the plates is turbulent in general, any far-field disturbance must propagate normal to the plates by the action of molecular diffusion, and so the mean velocity decays exponentially as $y \to \infty$. Thus, integrating the mean vorticity $\partial U/\partial y$ with respect to y, we find that the total vorticity per unit distance along the plates in the region $|y| > D/2$ is finite and equal to $2U_0$, whereas the total vorticity in $|y| < D/2$ is equal to $-2U_0$, where U_0 is the speed of each plate. Thus the cyclonic vorticity in the region between the plates is just balanced by the anticyclonic vorticity outside the plates. Alternatively, we see that the net circulation around a closed contour (as shown by the dotted line in Fig. 1) goes to zero as the y dimension of the contour increases. This is because the cyclonic torque induced by the plates is opposed by the inertia of the fluid at infinity, which is at rest.

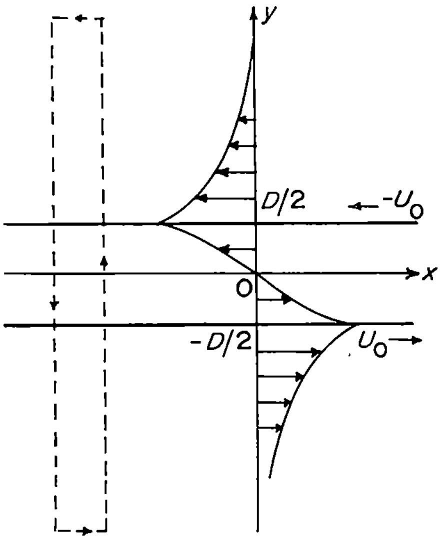

Fig. 1 Mean velocity $U(y)$ associated with the motion of two infinite plates ($y = D/2$ and $-D/2$) travelling at speed U_0 in opposite directions.

This result implies that although cyclonic vorticity is generated between the streams of traffic, there is no net generation of vorticity, because an equal amount of anticyclonic vorticity is also induced. It would seem therefore that, according to the hypothesis of Isaacs *et al.*, either both cyclonic and anticyclonic tornadoes ought to be equally probable, or no tornadoes ought to be generated, depending on whether the air is not, or is mixed horizontally in the process of tornado generation.

On the other hand, Isaacs *et al.* do give some strong circumstantial evidence for the connection between cyclonic tornadoes and traffic-induced vorticity. Their hypothesis can perhaps still be retained if the second ingredient involved in the generation of tornadoes, namely convection, is included. Any vorticity induced by traffic is initially confined to a layer a couple of metres deep near the ground. To produce a tornado, this vorticity must be preferentially advected vertically. Such motions are found in convection, which is an anisotropic process where horizontal mixing is suppressed[1]. Moreover, road pavement in general absorbs more solar radiation than does the surrounding terrain and so the road is expected to be a stronger source of convection than the surrounding terrain. (The cars themselves also act as a local heat source.) Convection therefore ought to occur preferentially from the road. Because the cyclonic vorticity (of mean strength $2U_0/D$) is concentrated over the road while the anticyclonic vorticity is diffused on each side of the road, it would appear that the convection leads to the preferential advection of cyclonic vorticity into the troposphere, as required by Isaacs *et al.* That is, cyclonic tornadoes can be produced because roads are sources of both cyclonic vorticity and convection.

This work was done in the Department of Mathematics, University of British Columbia, and was supported in part by the NRC.

A CALCULATION is indicated, though not shown, by Isaacs *et al.*, purporting to prove that motor vehicle traffic contributes significantly to the atmospheric vorticity over the USA and thereby leads to a more homogeneously cyclonic troposphere and consequently to changes in the broad scale spatial and temporal distribution and frequency of tornadoes. In the following I have attempted to repeat the calculation, with results substantially different from those of the authors.

A typical round trip is taken to be a straight line of length L, a straight line return and a U-turn at each end, with a separation between lanes of width d. If the average force exerted backwards by the wheels on the road is F, then the net anticyclonic angular momentum added to the earth, located at the centroid of the path, is $2FLd/V$, where V is the automobile speed, with nominally equal contributions coming from the straight legs and the U-turns. We assume the force F to be the air drag of the vehicle, given by

$$F = \rho a C_D V^2/2 \qquad (1)$$

where ρ is the air density, a is the cross-sectional area of the vehicle, and C_D is the drag coefficient, taken to be 0.5.

Since the speed while making the U-turns is likely to be much less than that on the straight legs, we ignore those contributions, and the average torque produced by the vehicle is then

$$T = Fd = \rho a C_D V^2 d/2 \qquad (2)$$

Isaacs *et al.* assume that 2×10^6 automobiles are on the road in the USA at any time, and that the contributions to torque from autos and trucks are equal. Using these figures, and assuming a mean cross-sectional area of 3 m^2, $V = 20$ m s^{-1}, the lane spacing $d = 20$ m, and $\rho = 1.3$ kg m^{-3}, we obtain a net torque production of 3.2×10^{10} kg m^2 s^{-2}. In this calculation, the difference in direction between the torques produced in different parts of the USA is ignored, which amounts to assuming the cosine of angles smaller than ~20° to be unity.

The angular momentum, M, of a rotating body is the second radial moment of its vorticity

$$M = \int \zeta r^2 \mathrm{d}m$$

where ζ is the vertical component of vorticity and dm is the mass differential. Over the USA during most seasons, the mean vorticity of the atmosphere is close to the vertical component of the Earth's vorticity, $f \simeq 10^{-4}$ s^{-1}. Thus the angular momentum of the atmosphere of the USA is roughly

$$M = (p_0/g)Afr^2/2,$$

where p_0 is the mean surface pressure, g is the acceleration of gravity, A is the area of the USA, and r is the mean radius, corresponding to the moment of inertia of the USA, which we estimate to be 2,000 km. Taking p_0/g to be 10^4 kg m^{-2} and $A = 8\times10^{12}$ m^2, we obtain $M = 1.6\times10^{25}$ kg m^2 s^{-1}. Thus it would seem that the motor vehicle torque would have to continue for 10^{14} s, about 3 Myr, to show a noticeable effect. The natural turnover time of angular momentum in the atmosphere is of order days or weeks, however, so that the effects suggested by Isaacs *et al.* seem very unlikely.

About the largest effect that could conceivably be produced in the way the authors envisage would occur if all the vehicles in the USA drove in the same direction along highways close to the USA coastlines and borders. In this case the effect would be increased by a factor of 10^5, but would still be too small to be noticeable.

Boulder, Colorado 80302

THERE is a Saturday anomaly in the reporting procedures that affects the final numbers in the paper of Isaacs *et al.* The major source of information about tornadoes in the USA since 1953–54 has been press clippings from out-state newspapers. This drastic change in data-gathering techniques can best be seen in the figure on p. 35 of ref. 1. The average annual totals jumped from ~ 280 yr^{-1} to 640 yr^{-1} beginning in 1954. In Missouri the use of press clipping information coincided with a change in the average annual total reports from 13 yr^{-1} to 33 yr^{-1}. One might conclude, therefore, that in Missouri almost two-thirds of the total reports are strongly dependent on press clipping information. For the entire USA it would seem that more than half of the total number of reports depend to some extent on press clippings.

In general, these additional tornado reports generated by press clipping information tend to be the smaller, short lived mini-tornadoes in largely rural areas. The small amount of property damage and infrequent personal injuries does not make them newsworthy items for the large metropolitan dailies. These storm reports are frequently covered only by local weeklies and the smaller out-state 'daily' papers. It is in these 'dailies' that the anomaly on Saturdays has its origins.

A substantial percentage of out-state daily papers do not publish on Sundays, and a surprising number do not publish on both Saturday and Sunday. In Missouri, for example, 45 of the 61 daily papers do not publish on Sunday and 24 of 61 do not publish on both Saturday and Sunday. Thus, the events of Saturday are frequently old news by the time these dailies go to press on Monday. The minor tornado activity that occurs on Saturday is not nearly as intensively covered as a similar occurrence on any other day of the week. This discontinuity in the basic source of information for tornado reports could easily account for a decrease in Saturday totals of ~ 10–15%. When up to two-thirds of the basic information sources for more than half of the usual total reports cut back to 25–50% efficiency for Saturday events, we end up with an anomaly.

[1] Court, A., *Tornado Incidence Maps, ESSA Tech. Memo ERLTM—NSSL*, 49 (1970).

THE evidence given by Isaacs *et al.* for their discovery is that, first, "the annual centre of tornado intensity weighted by area . . . has increasingly occupied the eastern portion of the continent", and second that of those few tornadoes for which rotation sense was reported, during the past 12 yr (1962–1973) 8.1% were anticyclonic compared with only 36.4% in the preceding 12 yr; and third, especially, that only 1,868 of 15,234 tornadoes during 22 yr occurred on Saturdays.

Tornadoes are reported by people according to damage done, and as the US population expanded westwards so did tornado reports. Since 1925, the apparent centre of tornado incidence has moved generally south-westwards into eastern Kansas (by 1925), to central Kansas (by 1951), and to central Oklahoma (by 1963). Oklahoma, now the region of greatest incidence, was shown as tornado deficient on earlier maps because it was the last Plains state to be settled[1].

Rotation sense is given for too few tornadoes to be of significance; the big surprise is that any anticyclonic tornadoes whatever are reported. "Motor vehicles are the only man-made source of non-random vorticity we know", the authors say. Perhaps they have never seen two railway trains pass at full speed, or noted the action of exhaust fans and rooftop ventilators.

ISAACS*, STORK AND WICK* REPLY—Opposing streams of traffic in the USA exert anticyclonic torques on the solid Earth and, from action and reaction, compensating cyclonic torques on the atmosphere. These torques tend to slow down the Earth's rotation and to increase the cyclonic rotation of the local atmosphere in conservation of angular momentum.

We agree with Kessler[1], Morton *et al.*[2] and Manton[3] that there is zero net vorticity in the total atmosphere caused by traffic. Our original discussion was based on vorticity rather than angular momentum. We were in error in not recognising that a discussion of the process from a consideration of vorticity is much less direct than from a consideration of angular momentum. Angular momentum is a more fundamental quantity in the formation of strongly rotating storms.

There can be little doubt that US automotive traffic introduces cyclonic angular momentum into the local atmosphere, which can participate in the formation of tornadoes. To illustrate how this occurs, consider this example: if you set fluid in a bowl into circulation by periodically immersing your hands and moving them past one another in straight lines always in the same relative direction but in any orientation and location, the fluid will gain angular momentum. Yet for this same fluid the no-slip condition at the boundaries requires zero net vorticity. The boundary

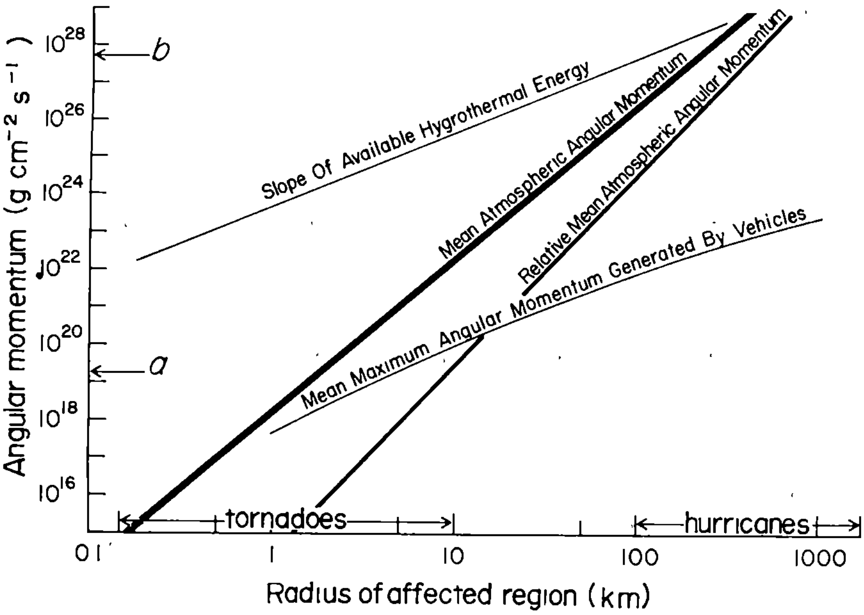

Fig. 1 Atmospheric angular momentum as a function of the affected area and anthropogenic input. The mean atmospheric angular momentum contained in a mass of air is that due to its planetary rotation around its central axis and is involved in radial convergence. It scales as the fourth power of the radius of the affected area. The mean relative atmospheric angular momentum is that involved in linear convergence over the dimensions on the abscissa, and scales as the fifth power of the radius. (Both are at $\sim$45° latitude) The angular momentum generated by the vehicles is based on the area, the residence time of air over the region (10^5–10^6 s) and the maximum density of traffic within such an area. The dimensions involved in the convection of a tornado or hurricane are indicated on the abscissa. The points labelled *a* and *b* indicate the angular momentum of a single giant tornado and of a hurricane, respectively. For a similar atmosphere and similar equilibrium altitude, the hygrothermal energy available to convective storms scales as the square of the radius of the affected region. (The line is drawn with an arbitrary ordinate intercept.)

vorticity does not preclude the formation of a vortex when the fluid is allowed to flow through an orifice in the bottom of the bowl. The important points are that angular momentum can be introduced by linear motions in this way, and that it can participate in a vortex while the net vorticity remains zero.

The apparent paradox of automobile-generated angular momentum with zero vorticity is probably resolved through several mechanisms in the atmosphere. As in the example of the bowl, the boundary vorticity in the atmosphere may propagate and act outside the area of convergence, as we originally proposed. The resolution may not be unrelated to our recent observation alongside a highway bearing heavy traffic that anticyclonic filaments of small-scale rotation are embedded in large-scale cyclonic rotation

At any rate, our calculations of the torque and resulting angular momentum agree with those of Lilly[4], but are more conservative by a factor of about eight. We do not consider, as he did, that the torque on the atmosphere be applied to the entire air mass over the USA as though the atmosphere were a solid body. Rather this torque must exert its influence locally, and in areas consonant with those involved in the convective processes of a tornadic storm. Furthermore, if variations in local vehicle concentrations of two orders of magnitude are taken into account, our calculations show that vehicle-produced torque, over reasonable periods of time, can produce angular momentum of the same order or greater than the natural background (see Fig. 1) The angular momentum introduced annually by vehicles is sufficient to account for that present in $\sim 10^5$ giant tornadoes. (A total of $\sim$ 600 including all sizes are actually reported per year.)

Court's point[5] that the centre of tornado occurrence has moved westward makes it even more impressive that the centre of tornado intensity, which is what we reported, has increasingly occupied the eastern sections of the USA. The obvious inference here is that the more intense tornadoes have been increasingly found in the east in support of our original thesis.

We agree that too few observations of the rotational sense of tornadoes have been reported to make these data highly significant. A χ^2 test based on these data shows, however, a statistically significant shift from anticyclonic to cyclonic tornadoes over the 24-yr period, and thus these data support our hypothesis. The fact that anticyclonic tornadoes exist at all is important in showing that local effects other than planetary rotation can be significant for the formation of tornadoes. One of these local effects could be vehicle-generated cyclonic angular momentum.

Darkow[6] raises an interesting point in attributing the weekly periodicity of the tornado data to periodicity in newspaper reporting. The possibility of reporting peculiarities being the cause has also concerned us. Before our initial publication, one of us contacted the Administrator of the National Oceanic and Atmospheric Administration, who was certain that weekend reporting was adequate or even intensified because of increased exposure to more people at weekends. In addition, since the data on the tornado tape we acquired from the National Severe Storms Forecast Center (NSSFC) are listed by source, we were able to separate out those that were identified as press clipping data (33%). The remaining data showed an even stronger weekly periodicity than reported for the total. These remaining data are considered to be the most reliable data by NSSFC.

As a further check we had plotted tornado injuries, damage, tornado days, path area and sums of *f*-scale numbers by day of week. We thought that tornadoes of sufficient significance to require the reporting of these parameters would not be subject to such reporting vagaries as might affect the reporting of lesser tornadoes. In every case Saturday was low, thus increasing our confidence in the validity of the findings.

Weekend changes in the production of factory wastes could conceivably influence the static stability and cloud-particle development as suggested by Kessler[1]. It is difficult, however, to see why this phenomenon would have its effect only on Saturday and not on Sunday. Presumably a factory that is closed on Saturday will remain so on most of Sunday. As a further check, we have obtained a tape of thunderstorm data from NSSFC and analysed it for weekly periodicity. We found none. Thus it seems that the periodicity in tornado occurrence is not dependent on convective storm periodicity but more probably on the periodicity of input of that unique and essential ingredient of tornadoes–angular momentum

Referring again to Fig. 1, the planetary angular momentum scales by the fourth or fifth power of the radius of the area involved in convection, depending on the type of convergence, while energy scales only as the second power of the radius. Thus a strong argument can be made that, if energy limits the population of strongly rotating convective storms of the magnitude of hurricanes (which seems to be the case), storms of the magnitude of tornadoes are comparatively deficient in planetary angular momentum, as related to energy by at least three orders of magnitude. The fact that most thunderstorms do not involve tornadoes seems to support this statement. This argues that angular momentum, rather than energy, limits the population of tornadoes, and that any input of cyclonic angular momentum increases their incidence, as we have proposed.

Identification of averaged auditory evoked potentials in man

SAYERS *et al.*[1,2], in their work on the Fourier analysis of averaged auditory evoked potentials (AEP) have suggested that suppositions for arithmetic averaging are violated, since there are no differences between the mean powers in the pre- and post-stimulus averaged potentials. Their results contradict the fact that the amplitudes of AEP seem much more pronounced in comparison with averaged spontaneous EEG activity.

Fourier analyses of averaged potentials (Fig. 1) show that the forms of both amplitude and phase spectra in the post-stimulus period, where the AEP can be seen, differ significantly from those in the pre-stimulus period, where no response occurs. The maximum in the amplitude spectra of post-stimulus averaged signals (the region of the AEP) with lower sound intensities diminishes and shifts to lower frequencies. In the pre-stimulus regions the amplitude and phase spectra always have irregular forms and lower amplitudes. Therefore, both the amplitude and the phase spectra are of importance in the objective detection of AEPs by Fourier analysis.

Further, the mean power $(P_{\bar{x}})$ of the post-stimulus averaged signal is higher than in a corresponding length of the pre-stimulus period (Table 1). This behaviour can be observed down to the hearing threshold in cases of low spontaneous EEG activity.

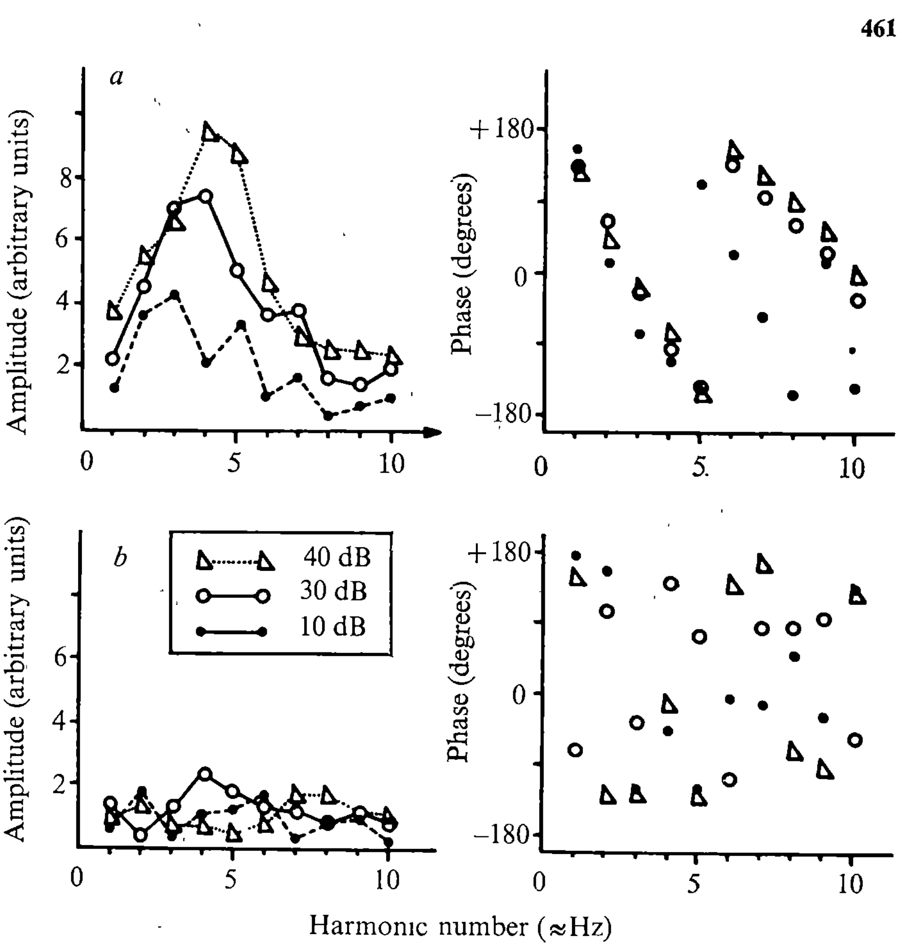

Fig. 1 Normal hearing female adult, binaural stimulation with 1-kHz tone bursts of 300-ms duration and 8-ms rise-fall time, interstimulus interval 3.2 s, $n = 50$ averaging cycles. Parameter: sensation level; frequency interval between harmonics 0.98 Hz; connecting lines illustrate typical behaviour. *a*, Amplitude and phase spectra of averaged responses (post-stimulus periods, 0–1,023 ms after onset of stimulation). *b*, Amplitude and phase spectra of averaged spontaneous activity (pre-stimulus periods, 1,800–777 ms before stimulation). △, 40 dB; ○, 30 dB; ●, 10 dB.

To show that single AEPs consist of an additive contribution to the spontaneous EEG we evaluated the averaged power spectrum (by means of the sum of power spectra of the single EEG responses) for both pre- and post-stimulus periods. The mean power $(\bar{P}_{x_i})$ of pre- or post-stimulus electroencephalic activity can be calculated using this averaged power spectrum. The observed increase of $\bar{P}_{x_i}$ in the post-stimulus period (Table 1) is in agreement with the assumption of an additive superposition of the single AEPs to the spontaneous EEG (see ref. 3).

Averaging the squared single EEG responses, $x_i^2(t)$, gives the same result. The evaluated mean square values

$$\overline{x^2(t)} = (1/n)\sum_{i=1}^{n} x_i^2(t)$$

are proportional to the mean power of the EEG. Because of an additive contribution of single responses to the spontaneous EEG an increase of the mean power in the region of the AEP is detectable down to 20 dB.

Using the mean square values $\overline{x^2(t)}$ it is possible to calculate the standard deviation $s(t)$ of the AEPs. In this way the statistical significance of registrated AEPs can be evaluated without using the Fourier method[2] with its more complex problems of utilisation.

SAYERS AND BEAGLEY REPLY—The power of an averaged sensory evoked EEG response (AER) can increase with suprathreshold stimulus level, as von Specht and Kevanishvili have recapitulated[1]. As pointed out by us[2], it often does so. The observation that even when this effect was negligible both an evident AER and a clear aggregation of Fourier spectral phases with repeated stimuli could still be seen, led us to investigate the relevance and use of phase spectra—our conclusions relate solely to that point.

But we disagree with von Specht and Kevanishvili[1] on three points. First, power changes in the AER cannot be used to deny a phase constraint hypothesis or, more specifically, to argue against the dominant importance of phase effects in respect of pattern that our results suggest.

Second, the evidence for the dominant importance of phase lies not in the extent of any AER power changes but in the finding that imposing the appropriate phase spectrum (that is, that of a suprathreshold AER) on a length of unstimulated EEG, converts this into a pattern highly correlated with the true suprathreshold response. Repeating the experiment by imposing the amplitude spectrum has no such effect.

Third, we think it inadvisable to base the detection of a true response on an assessment of average power in the post-stimulus EEG, in spite of attempts[3] to use that method in support of other procedures. In our experience, spontaneous EEG (especially in the young child, where the auditory evoked response test is of practical importance) is often neither low level nor free from substantial unpredictable power fluctuations. These affect both the power in the averaged response and the average power in the individual lengths of post-stimulus EEG, and so interfere with recognition of any possible response, especially near threshold. In spite of the attractive simplicity of a power method, we therefore abandoned it in favour of a pattern-detection method.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

On the first two points, we wonder if von Specht and Kevanishvili have overlooked the effect of increased coherence (in the sense of pattern similarity, between different lengths of on-going EEG subjected to a phase constraint on major spectral components) that could be expected to follow from increased suprathreshold stimulus level. The amplitude of the resulting averaged post-stimulus EEG would increase substantially, as we can demonstrate using von Specht and Kevanishvili's own results (Fig. 1). Figure 1 shows the result of averaging 30 records of pseudo-post-stimulus EEGs derived from a length of unstimulated EEG subjected to a phase constraint altered according to seven values of a parameter θ. This sets the extent ($\pm\theta°$) of uniformly random phase scatter (added independently and individually for each harmonic and for each of the 30 records) around the mean phase spectrum imposed—in this case, that of the 40 dB-stimulated example shown by von Specht and Kevanishvili[1] (their Fig. 1*a*).

The amplitude spectrum of the spontaneous EEG was retained unaltered throughout. Maximum pattern coherence is achieved for $\theta = 0$, and minimum for $\theta = 180$. Increasing the synchronisation of phase between records at repeated trials ($\theta = 180, 150, \ldots, 0$) in accordance with increased stimulus level thus greatly affects pseudo-AER magnitude and power, and is sufficient to account for the power increase in AER tabulated ($P_{\bar{x}}$). If different lengths of spontaneous EEG are used for each individual pseudo-response record, typical fluctuations of on-going EEG power can intrude. Some trials showed almost no increase in pseudo-AER power for θ-values as small as 80, because of fluctuations in on-going EEG. Others showed larger changes.

This explains our third point of disagreement, matches well our observations, and illustrates why we think that the small change in average power ($\bar{P}_{x_i}$) with stimulus level tabulated by von Specht and Kevanishvili[1] does not significantly support their view. Nevertheless, we do regard the additivity of an evoked response as a useful model; our suggestion is simply that it is increasingly less useful as stimulus threshold is approached, even if only because of the sporadic fluctuations of on-going EEG. Attention is drawn to the importance of phase-constraint effects which, once recognised, suggest other and more objective ways than averaging to detect an evoked response. The phase effects created by a successful stimulus are a property of signal patterns, and are not restricted to the ERA situation.

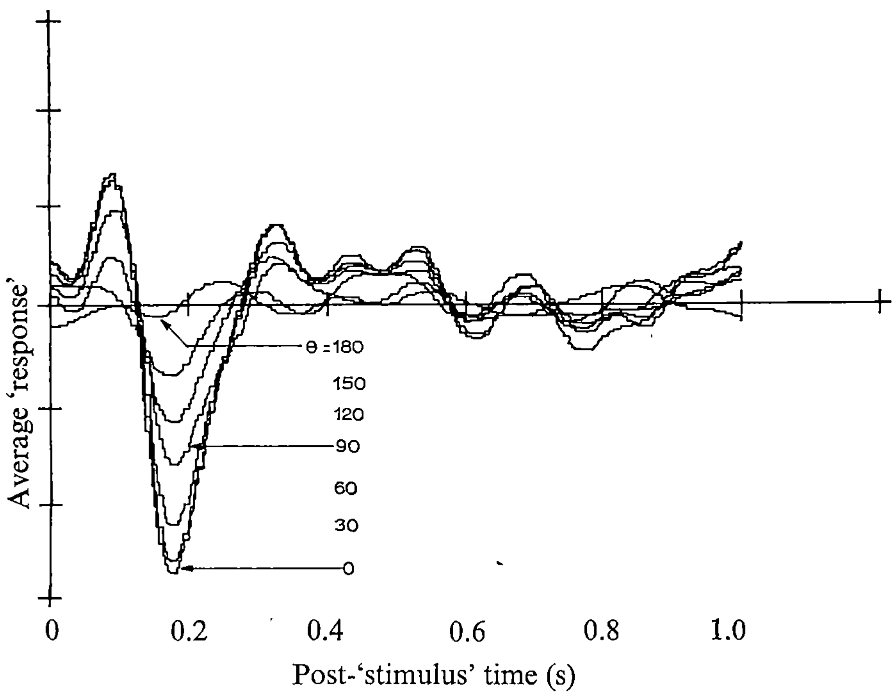

Fig. 1 Average of 30 records of pseudo-post-stimulus EEGs derived from a length of unstimulated EEGs subjected to a phase constraint altered according to seven values of the parameter θ (see text).

reviews

Desert island crystallography

U. W. Arndt

Crystals, X Rays and Proteins. By Dennis Sherwood. Pp. xxii+702. (Longman: London, January 1976.) £12.50.

A (highly) intelligent school leaver about to take up an appointment as an X-ray crystallographer in a biochemical laboratory and wrecked on a desert island on his way, would find the present volume invaluable in equipping him for his new post by the time of his rescue. Dr Sherwood takes the reader in a methodical way through all the necessary steps to the solution of an unknown crystal structure. He starts with an explanation of the fundamentals of crystallography, of wave motion, of diffraction and Fourier transform theory and develops the necessary mathematical methods on the way. He then deals with the theory and practice of crystallographic structure determination—intensity measurement, extinction, Patterson methods, phase determination, refinement and direct methods are dealt with in successive chapters. The final section deals with biopolymers and diffraction by helical structures. In spite of the title, the chapter on protein crystallography as such is the least adequately covered. An appendix discusses a practical example of the solution of an organic structure.

The presentation is clear and fairly mathematical although it is a little doubtful whether it could be followed in its entirety by a reader who had not met any of the concepts before reading this volume. The author adheres throughout to a treatment in which he first states what he is going to say, then says it and finally discusses what he has said. The chapter summaries, in particular, are useful. Other good features are the annotated bibliography and the glossary and index. References are mostly to monographs and reviews, rather than to original papers The illustrations are plentiful and informative, although more modern X-ray photographs of biological materials might have been chosen. The text seems reasonably free of errors and misprints. It is a little strange to find within the same covers an illustration of wave interference in a ripple tank and a derivation of the Harker–Kaspar inequalities, but the author has fulfilled his stated intention of saying something of use for every class of reader in every section. Although the coverage of the theory of X-ray crystallography is fairly complete the reader will have to look elsewhere for a description of experimental methods.

This is a book to keep at home or in the office far from the departmental library, to read up on or verify X-ray crystallographic theory. It is of less value in a library since all the topics which the book covers can be found in readily available standard textbooks, although quite a number of separate ones may have to be consulted.

Do-it-yourself sedimentology

Brian Waugh

An Introduction to Sedimentology. By Richard C. Selley. Pp. xi+408. (Academic: London, New York and San Francisco, January 1976.) £5.90; $14.75.

HAVING recently returned to academic life after several years in the oil industry, Dr Selley has obviously seen the need for a textbook on sedimentology with a distinct emphasis on the more practical and economic aspects of the subject, particularly in its application to petroleum geology. As indicated in the preface, the book presents an overview of the more important fields of sedimentology in an attempt to satisfy the needs and interests of students and practising geologists. It should of course be remembered that sedimentology has evolved rapidly over the past few decades, and presenting an overview must therefore necessarily involve concentrating on concepts rather than detailed analysis Consequently, this book should be regarded strictly as a basic introduction to sedimentology in which subject matter is discussed at a very general level; but one which should also provide the reader with a reasonable background knowledge of the subject The practising petroleum geologist may well have appreciated a more advanced treatment.

The text is presented according to a logical format, commencing with the now familiar summary of the textural characteristics of sediments, including a valuable section on porosity and permeability. A short chapter on weathering is very disappointing, leaving the reader with little more than an elementary understanding of weathering and soil-forming processes. The sedimentary rocks themselves are covered in two chapters on allochthonous and autochthonous sediments, each major rock type being described with respect to classification, petrography and, where relevant, the relationship between diagenesis and porosity development. The sections on carbonates and evaporites are particularly useful summaries, although coverage of the other rock types suffers an inevitable brevity. Physical aspects of transportation and sedimentation are qualitatively reviewed, followed logically by a discussion of the morphology and origin of biogenic and inorganic sedimentary structures. A major section is devoted to a study of sedimentary facies and environments, on the basis of which the author erects a series of informative sedimentary models. Sedimentary basins, their origin, structure and evolution are discussed, including a few short case histories illustrating the sequence and variety of basin fill deposits. The final chapter deals specifically with applied sedimentology, highlighting the role of sedimentological knowledge in the exploration and exploitation of hydrocarbons, together with a tantalisingly brief discussion of sedimentary ores

The book is written in a very informal style, a feature which should appeal to the student reader at least, and the diagrams are on the whole clearly presented and informative. The major criticism of the book—that is, that too much has perhaps been attempted in this overview with the result that many topics are not discussed to any great depth—is perhaps counterbalanced, certainly for the more specialist reader, by the inclusion of most comprehensive reference lists.

Touching the right chord

Disease in a Minor Chord. By E. A. Steinhaus. Pp. xviii+488. (Ohio State University: Columbus, August 1975.) $20.

THE late Edward Steinhaus has come to be regarded as perhaps the most significant 'founding father' of invertebrate pathology. This book was intended, in his own words, to be "semi-historical and semi-biographical", but was never finished because Steinhaus died in 1969. His widow, Mrs Mabry Steinhaus and one of his colleagues at Berkeley, Dr Mauro Martignoni, however, wisely did not attempt to complete the manuscript but instead concentrated on preparation for publication. The result is a book, presented with care and sympathy, which makes for fascinating reading.

Readers not familiar with this field may be surprised to learn of the struggle that Steinhaus had to obtain recognition for the importance and scientific merit of studies on diseases of insects and other invertebrates. Insects alone account for about 75% of the known animal species in the world and are man's greatest competitor for food as well as transmitting some of his most troublesome diseases. Nevertheless, the study of insect diseases remained an esoteric subject known to few men and scarcely at all to science until the late 1940s. It was typical of the period that when Steinhaus required a class text on insect pathology, none was available, so he had to write one himself.

Chapter 1 deals with the early history of insect pathology reaching into Greek science and ending in Chapter 2 with developments in immediate post World War II period. These two chapters will become prescribed reading for any student wishing to study the history of insect pathology. In Chapter 3 the significant contribution made by Californian workers is recounted. The prose in this chapter is perhaps the best in the book and it is the one in which we begin to know Steinhaus as the man rather than a familiar name in the literature. We can share his frustrations and also identify with his ambitions. Anyone who has tried to develop novel and possibly unconventional ideas cannot fail to have understanding, sympathy, but above all admiration for the task that Steinhaus set himself in California. We can rejoice that these hopes and aspirations were largely achieved, although not without pain and anguish. It is true that many major developments in insect pathology have appeared since 1969 but nevertheless it must be acknowledged that the scene for these advancements was set largely by Steinhaus.

Chapter 4 presents an interesting, although inevitably incomplete, account of the European contribution to the knowledge of insect diseases, and in Chapter 5 we have Steinhaus' real and sometimes painful introduction to the intricacies of European scientific politics. Steinhaus the Editor was the creative force behind a scientific journal (*J. Insect Path.*, now *J. invert. Path.*) and an annual review (*A. Rev. Ent.*) which have for many years now been accredited with international standing and the background story to these developments is given in Chapter 6.

It says much for the style and presentation of this book that it can be read and enjoyed by professional and layman alike and as such can be recommended to all. **T. W. Tinsley**

Fungal development

An Introduction to the Biochemistry of Fungal Development. By J. E. Smith and D. R. Berry, pp. 326 (Academic: London and New York, 1975.) £9.50; $20.75.

ALTHOUGH few would deny that there are areas of molecular biology that require consolidation with further research, many molecular biologists (or are they microbial physiologists?) have turned to the comparatively virgin domain of microbial differentiation for a fresh challenge. Differentiation in micro-organisms is rather difficult to define, but fundamentally it entails the formation of morphologically different structures from vegetative organisms. Most microbiologists would go along with the great pioneer of research into biological differentiation, John Tyler Bonner, who believes that differentiation in organisms must be studied for the knowledge that it provides about those organisms. Nevertheless, many biologists who have turned to problems in microbial differentiation have done so because the system they have chosen to study provides a valuable model with which to study more complex metabolic differentiation processes that operate in higher animals and plants, the aim being to establish the basic mechanisms of control of gene expression as a cell switches from vegetative growth to formation of a differentiated structure. Not surprisingly, this upsurge of interest in microbial differentiation has generated texts and symposium proceedings, many of them excellent in their way although they are mostly multi-authored volumes.

The main attraction of the text written by Smith and Berry, which restricts itself to differentiation in fungi, in which so many of the attractive systems are to be found, is that it is of a piece and does not suffer from the 'bittiness' that comes so often with a collection of articles writen by different authors. The first of eight chapters deals with the conceptual basis of morphogenesis, and includes fundamental information on regulation of gene expression and enzyme action in cells. There follow two chapters on development in the slime moulds *Dictyostelium discoideum* and *Physarum polycephalum,* two very popular organisms for studying differentiation in multicellular systems. The fungal spore, the vegetative state, and asexual and sexual reproduction are the subjects of the chapters that follow, and the text concludes with a chapter entitled 'Differentiation, secondary metabolism and industrial mycology' describing production of compounds such as organic acids and antibiotics by moulds in what is essentially differentiation at the level of chemical synthesis as distinct from morphology.

The book has many attractive features. Each chapter ends with a brief summary, which will make it a valuable teaching text. Although at first sight there may seem to be too great an emphasis on fungal differentiation processes that have as yet been poorly researched, this is in many respects a richness for in this way the molecular biologist and biochemist can become acquainted with some of the more esoteric, but in differentiation terms very attractive, regions of mycology.

There are surprisingly few 1973 or 1974 references, which means that the book will quickly become dated. In general, Academic have done a fine job in producing the volume, although this was not helped by the authors electing to use line drawings of organisms rather than photomicrographs or electron micrographs, as well as some very old diagrams of life cycles. The text would have fulfilled its aim of providing an introduction to the biochemistry of fungal development if it had dealt in rather more detail with the molecular basis of regulation of gene expression and enzyme action. There is, for instance, no reference to specific degradation of enzymes or of enzyme inactivation by chemical modification such as adenylylation.

The attractive features of the text, however, far outweigh these reservations, and it should prove a popular introduction for the teacher and for the researcher who wishes to enter this most challenging and fast developing area of biological research.

Anthony H. Rose

Surface physics not clarified

Surface Physics of Phosphors and Semiconductors Edited by C. G. Scott and C. E. Reed. Pp. xiv+644. (Academic: London and New York, November 1975.) £18.80; $48.75.

THE appearance within a few months of two important books which attempt to summarise surface physics suggests that this previously murky field is now beginning to take on a clearer shape. One book (M. Prutton's *Surface Physics,* recently reviewed in *Nature* (**260,** 374; 1976) is a compact organised teaching instrument which deals only with clean surfaces; the other, named above, aims to give a much fuller picture, and caters largely for solid-state device physicists in pursuit of better electronic and opto-electronic devices. It is essentially a series of research reviews which, although they do not overlap greatly, do not interlock too well either.

The first 300 pages contain introductions to the theory and method of surface physics. Our understanding of surfaces has come mainly from studying specially cleaned surfaces; the structure of these has been determined by electron diffraction and spectroscopy whereas theory has been developed by extending the wave mechanics of bulk materials. This section leaves one wondering whether the experiment and theory will ever be brought together to form a proper picture of the electronic nature of a surface state, even that found at a clean vacuum–solid interface, leaving aside the much more difficult problem of the 'real' interface which is formed beneath a native or intentionally-grown oxide film. It cannot be said that this book really grasps that nettle. All the important facts are there but the authors perhaps do not work hard enough at building them into a coherent whole. To quote an example from the editors' own 100-page review of the compound semiconductors: we are told about the striking increases in surface-state concentration in gallium arsenide which are produced by washing the surface with copper ions. Why should this happen? Although the previous 80 pages has described extensive investigations of the surface of compound semiconductors, none of the 'feel' which that might have provided is used to clothe the new, intriguing experimental fact with a few shreds of explanation. One chapter, however, does take the reader gently by the hand; this is Zaininger's highly original survey of some principles of device operation which may be particularly vulnerable to the presence of unwanted surface states.

Although the term 'phosphor' appears in the title, the physics of luminescence is hardly considered at all. The greatest phosphor, zinc sulphide, in fact gets one of the shortest treatments in the book. Few gaps, however, are left in the solid-state microelectronics field (possibly Schottky barriers and electron loss spectroscopy get less than their due) and workers in this field will gain from seeing this set of reviews in juxtaposition. It will also stimulate the thought processes of any physicist working on surface effects and may even spur one of the next generation to write the book which at last pulls together the theory and practice of the physics of semiconductor surfaces.

Andrew Holmes-Siedle

New mind, new body

New Mind, New Body: Bio-Feedback: New Directions for the Mind. By Barbara B. Brown. Pp xiii+464. (Hodder and Stoughton: London, 1975.) £5.25.

THIS book is a well written, informative, popular introduction to biofeedback. Biofeedback is a method for training a person to increase his or her control over their own physiology. Barbara Brown effectively conveys the excitement and promise of this new field. *New Mind, New Body* is packed with information about biofeedback and about the way our mental and emotional selves interact with our bodily selves. To make her personal point (and this is one person's view of biofeedback) Dr Brown selects the evidence, but it's a good, thought-provoking selection. As a popular book, its style may be a little breezy and condescending for the specialist. The references are quite thorough and will be useful to the student and professional alike.

My personal fun was reading Dr Brown's rather caustic comments on the sterility of behavioristic psychology and its total inability to deal with the links between mind and body. She levels other criticism at mechanistic physiologists who have written of their speciality as if they had it in a jar completely isolated from the rest of the whole person. She points out what happened when behavioristic psychology mistook itself for the whole of liberal arts.

Dr Brown makes sure that her role in the "founding" of the Biofeedback Research Society is clearly documented in the early chapters. Researchers in the field knew it already but the public may want to know too. Succeeding chapters are each organised around a particular physiological system. Within each chapter various biofeedback studies are discussed. This makes a readable sequence but it is not, I think, an organisation which identifies the major themes of biofeedback. For instance, mind–body and mind–brain mechanisms for learning, special effects of feedback, parameters of practice, parameters of the external feedback path, biofeedback as a system, are not discussed as salient topics.

The coverage of the bioelectric response of skin, musculature, heart, blood pressure and brain (recorded as a scalp EEG) is comprehensive. Yet, laced through the factual reporting are interpretations which range from expressions of indignation and sarcastic commentary, scientific judgments, to personal and rather woolly kinds of theories. Dr Brown really believes in mind as an object which can be studied by public science. She insists that biofeedback offers a method and that the results of biofeedback research gives a new basis for accepting the mind as a demonstrated phenomena. Her arguments are spirited, and her intentions are clear—she is not trying to pull her wool over the reader's eyes. But it is also a fact that many biofeedback researchers would make very different interpretations of the same data. For example, Dr Brown clearly believes that EEG phenomena can reveal a lot about the mind and that unique mind states are linked to unique EEGs. Yet, most users of EEG would find it difficult to defend the more conservative statement that unique brain states can be revealed in EEGs. The consensus is that the EEG doesn't provide a clue to subjective, mental life, and is a gross representation of the electrical activity of the brain.

The importance of biofeedback for training one's own physiological processes is undeniable and Dr Brown was one of the first to recognise the whole implication of this new technique. She is absolutely correct when she projects what can happen when and if humans learn how to control their own physiology by means of biofeedback.

The importance of biofeedback lies in its efficacy as a training method. Whether scientists know or agree on "how the person does it" is not really relevant to its practical value in laboratory and clinic. In fact the benefits of biofeedback are independent of the mind–brain, mind–body issue.

All-in-all it's a book worth reading. It's a personal journal produced by a lively person, with an informed mind and fearless spirit. As a popular exposition it's excellent and far ahead of its nearest rivals.

T. B. Mulholland

Introducing mouse teratomas

Teratomas and Differentiation. (A Symposium held at the Roche Institute of Molecular Biology, Nutley, New Jersey, May 19–21, 1975.) Edited by M. I. Sherman and D. Solter. Pp. xv+324. Academic: New York and London, November 1975.) $16.50; £8.60.

ALTHOUGH mouse teratomas have been available as an experimental system for more than a decade, it is only over the past few years that the application of immunological, cell culture and embryo micromanipulation techniques has begun to realise their enormous potential for studying regulatory mechanisms in mammalian development. It was in this climate of optimism (not without an element of elite evangelism) that a meeting was held at the Roche Institute of Molecular Biology in May, 1975 to consolidate and assess recent gains.

This book consists of the papers presented at the meeting, and is by far the best introduction to the subject at present available. It is a pity that the book does not also include discussion following the papers, along the lines of the CIBA symposia, so that the reader can enjoy the frisson of dissention and the benefits of a wider range of opinion. This would have been particularly useful following the papers by Barry Pierce and Beatrice Mintz in which, *inter alia,* it is argued that mouse teratocarcinomas are an important model for the study of cancer since they provide a case in which malignant stem cells give rise to benign progeny by differentiation. It is implied that many other cancers arise by a disruption in normal cellular interactions which reduce the probability that the progeny of stem cells will differentiate, and that this non-genetic malignant change should be reversible if only the correct environmental signals could be imposed. 'Malignant', however, is never clearly defined and the relevance of mouse teratocarcinomas, which seem rarely to metastasise or invade, to the corresponding human tumour, to non-malignant hyperplasia or to chemical carcinogenesis, is not discussed.

Murine terato(carcino)mas arise spontaneously either in the gonads or from early embryos implanted into extrauterine sites. The comparative development of these tumours is clearly described by Leroy Stevens, who argues that the pluripotent stem cells are equivalent to the cells of the inner cell mass of the normal blastocyst Evidence in favour of this view comes from the pioneering work of the laboratories of Dorothea Bennett and Francois Jacob, which has shown that teratoma cells, sperm, morulae and blastocysts have in common a surface antigen which is probably coded for by one of the genes of the T locus. This work is the first step towards understanding the way in which early embryo cells may recognise each other by their surface properties.

Other exciting contributions are those of Gail Martin and Martin Evans on an *in vitro* method for obtaining relatively rapid and synchronous differentiation of homogeneous stem cells into endoderm, which in turn seems to trigger the next stages of embryogenesis, and the highlight of the meeting, which was the report by Beatrice Mintz that teratoma cells injected into normal embryos are able to participate in the formation of a normal, chimaeric mouse. The evidence for integration of teratoma cells into a wide variety of tissues, including germ cells of the testis, is impressive and the finding rich in biological implications. The book is worth reading for this paper alone.

Brigid Hogan

Iron transport and storage

Proteins of Iron Storage and Transport in Biochemistry and Medicine. (Proceedings of EMBO Workshop Conference on Proteins of Iron Storage and Transport.) Edited by R R. Crichton. Pp. x+454. (North Holland: Amsterdam and Oxford; American Elsevier: New York, 1975.) Dfl.88; $36.75.

THIS book contains the proceedings of the Workshop Conference on Proteins of Iron Storage and Transport held by the European Molecular Biology Organisation in Louvain-la-Neuve in April, 1975. The main themes presented in the book are the molecular biology of transferrin and ferritin, iron transport and storage proteins, respectively, and the subcellular transfer of iron by the intestinal mucosal cell during iron absorption There is a total of 56 communications by contributors from Europe, the US and Australia.

In the section of the book devoted to transferrin all the outstanding problems related to its structure and function are brought to light and discussed. Two independent groups of workers presented almost the entire amino acid sequence of transferrin Several papers deal with the interaction of the metal and anion at the binding site, and demonstrate how iron and a ligand (with a carboxylic group) fit snugly into the receptor pocket on the protein surface. In addition, the distances between the iron, carbon and nitrogen (of the nitroxyl group) within the binding site have been measured using nuclear magnetic resonance and found to be about 1 nm. I find, however, that the most interesting investigations are not related to transferrin but to its specific receptor site on the surface of the immature red cell. The isolation and analysis of the transferrin receptor, a protein patch on the reticulocyte surface, initiated by Jack Fielding and Barbara Speyer, are bound to provide a solution to the biochemical basis of transferrin uptake and release by reticulocytes.

The contributions on the iron storage protein, ferritin, can be roughly divided according to their aim into the following groups. First, there are reports on the primary structure of this large molecule (molecular weight 450,000) composed of 24 subunits which form a shell enclosing a core of iron hyroxide and phosphate. In these reports the structure of subunits and their amino acid sequence are also described. Second, investigations on apoferritin subunit–subunit ineraction and assembly are presented These are followed by communications on identification of isoferritin in normal man and animals The significance of isoferritins in malignant diseases is then discussed Also, an atempt to determine the intracellular site of apoferritin synthesis and its turnover is described. Finally, but not least impressive, there is the work on iron uptake and release by ferritin carried out independently by Pauline Harrison *et al* and by two groups of investigators led by Robert Crichton and S Stefanini.

In the last section of the book several communications on the mechanism of iron handling by the intestinal mucosal cell during iron absorption are presented. The picture of subcellular iron pathways is not yet complete but intensive investigation under way in this field will no doubt bear fruitful results.

This book represents a faithful picture of the currents of research on iron metabolism carried out by investigators in many laboratories all over the world The book is published within a few months of the Conference and thus it has a rare quality of freshness. The editor's skill in balancing finely the material presented makes it an exciting book to read The reader with only a superficial interest in iron metabolism cannot easily appreciate the value of many hints so useful for bench work and may find many arguments too difficult to follow. For the iron enthusiast, however, this book is a 'must' and it certainly deserves space on a shelf of every reference library

B. Brozovic

Most studied single cell

Biochemistry and Pharmacology of Platelets. (Ciba Foundation Symposium 35, New Series.) Pp. viii+352. (Elsevier/Exerpta Medica/North-Holland: Amsterdam, Oxford and New York, 1975.) $23.95; Dfl. 59.50.

YET one more book on platelets! So prestigious a gathering as a Ciba Symposium, however, can be relied on to produce an authoritative book. What is the fascination that is fast making the platelet the most studied single cell? Partly, it is easily isolated yet more complex and interesting than the red cell: an understanding of it may contribute incalculably to the prevention of thrombosis. In addition, it is studied almost as a type cell The actin and mysin are similar to that found in muscle. Dr Cohen exclaims "the amazing thing is that fibroblasts respond to exactly the same stimuli as platelets do". Biological amines and monoamine oxidase drugs often have analogous effects on platelets and on the central nervous system. Another reason for the fascination is the close link of platelet biochemistry and pharmacology to platelet physiology. Indeed the contributors are as interested in pseudopod formation and sticky membranes as in the metabolic pathways involved: in fact large areas of platelet physiology are covered.

The basic membrane change involved in platelet 'stickiness' remains elusive but the membrane response to stimuli and the part played by the adenine nucleotides among many others, are presented in detail. The interrelationships between actin and myosin and the kinase of platelets and other cells are discussed. The pharmacology of platelet aggregation induction, its many inhibitors and the prostaglandins and aspirin effects are all well covered. The 'Platelet Release Reaction' has now become two: I from dense granules: II from α granules. Glycolysis, mineral elements, the part played by calcium and the gangliosides—it is all here including receptor action and bioamine storage.

Although not wishing to detract from the interest of the many detailed studies presented, one questions the relevance of some to intact platelets *in vivo*. They are so sensitive that demonstrable alterations occur, for example, with a poor venepuncture or after a fatty meal. Although the effect of prostaglandins on the biochemistry is extensively considered, I would have liked more space devoted to the prostaglandin E_1 precursors and platelet inhibition—that elusive therapeutic goal.

As usual the standard of production is excellent Professor Born and Ciba are to be congratulated, particularly on the editing of the discussion. But even so I don't find this nearly so rewarding as the papers themselves. This book is not easy going but is a recommended and masterly survey up to mid-1975 for physiologists and haematologists as well as biochemists and pharmacologists.

J. R. O'Brien

Learning theory

Elements of a Two-Process Theory of Learning. By J. A. Gray. Pp. x+423. (Academic: London, New York and San Francisco, 1975.) £6.60; $16.50.

IN the past twenty years the study of animal learning has suffered a sharp loss in prestige; in the 1950s it was seen as the most developed and 'scientific' topic within experimental psychology; and great, although perhaps unrealistic, hopes were held out that it would illuminate our understanding of human behaviour and personality. These hopes have not been realised and, with the development of the cognitive and information-processing approaches to human behaviour, animal psychology is often seen as an unattractive and somewhat stagnant backwater with few connections with the wider currents of psychological thought. Dr Gray has argued that the study of animal learning cannot be divorced from human psychology, and that it has much to tell us about human personality. In this book he still sees learning theory as providing a "scaffolding for a theory of the physiological basis of personality".

It is a pleasure to read a book which conveys such enthusiasm for the subject particularly when it is written with style and clarity; it is by no means an elementary book and makes considerable demands on the reader, but no-one who reads it could doubt that learning theory remains an interesting and challenging study, or that recent work on animal learning is providing valuable information about behaviour.

In his attempt to provide a unified account of a wide range of animal behaviour, however, there is a strong tendency to rely on a small number of 'crucial' experiments to support a particular line of argument; in some cases this may be justified, but in others there are a variety of other experiments, which pass unreferenced, that do not support the author's point of view. For example, the evidence on the effects of superimposing an appetitive conditioned stimulus on instrumental behaviour maintained by an appetitive reinforcer is confused and conflicting; there is at least as much reason to suppose that it suppresses instrumental responding as that it increases it as Dr Gray maintains. Rescorla is cited as supporting the idea of backward conditioning, where the experiments in question were concerned with simultaneous not backward conditioning. These are not isolated examples, but rather illustrate a weakness present throughout the book; the unwary reader may easily be misled in such cases. The author also has a tendency to attempt to resolve issues by definition or logic. Thus it is argued that the word drive is used to describe three rather different concepts which are logically and operationally distinct; it is then claimed that in the light of these distinctions the classical questions about the role of drive reduction in reinforcement largely disappear This logical coup, however, is achieved by making use of the concept of 'goal-directed drive', which is foreign to most forms of learning theory, and which, although undefined, seems to subsume all the goal-directed aspects of motivation. The subsequent logical argument merely spells out the consequences of the author's definitional decisions and takes our understanding of motivation little further.

The whole book is an attempt to provide a unified account of learning which the author describes as a two-process theory. It is curious therefore that the theory proposed relies very heavily on the classical conditioning component and, as the author admits, is very similar to Mowrer's 1960 theory, which Mowrer himself described as a one-factor theory. In Gray's, as in Mowrer's, model the instrumental component serves only to direct the animal towards or away from stimuli which possess positive reinforcing properties; and in spite of the earlier discussion of 'goal-directed drive', the way in which goal directedness enters into these relationships is not discussed. What we seem to have is a series of taxes, rather than an integrated goal-directed response. In short, the author provides a plausible account of how stimuli becomes attractive or aversive, but very little insight about instrumental behaviour.

I feel that these shortcomings make the book unsuitable for undergraduate reading; but this is a book which research workers in the field will find sometimes illuminating, sometimes irritating but always interesting

M. S. Halliday

obituary

Ben Dawes died at the age of 73 at his Burnley home on 3 March. He was formerly Professor of Parasitology at the University of London King's College, where he gave forty-two years of devoted service to the training of students and to research.

His first scientific appointment, after a hard-won start from being a weaver and then a tram cleaner, was to the Plymouth Marine Biological Station. Here he undertook research on plaice growth in relation to the availability of food, and his published papers on this continue to be standard references in fish feeding studies. In his early days at King's College he taught a wide spectrum of zoological subjects and in particular developed physiology and parasitology as final year undergraduate courses. His drive and enthusiasm were in no small measure responsible for establishing King's College as a centre of excellence in parasitology. His many students in this branch of study will remember his stimulating lectures and his well organised practicals, with an array of excellently prepared material from all parts of the world. Perhaps, too, his postgraduate students will have cause to recall his insistence on accurate compilation of data, on precision in presenting and writing up results and also his considerable disdain for the use of scientific jargon.

Professor Dawes was recognised internationally for his investigations into many aspects of the biology and physiology of the sheep liver fluke, and of particular significance were his studies into the penetration of host tissues, migratory routes, feeding, growth and drug effects on the immature stages in mammals and in snails. All this work was carried out with infinite patience, dedication and meticulous care: he drove himself very hard. His world-wide status as a helminthologist was enhanced with the publication of his book on *'The Trematoda'*, first published in 1946, reprinted in 1956, before being updated and re-issued in 1968. It still continues to stand the test of time as does his Ray Society Monograph on the trematodes of fishes. On assuming the editorship of the *'Advances in Parasitology'* series in 1963, Professor Dawes was insistent that it should reflect the progress in all areas of parasitology and the contents of the large number of volumes he edited demonstrate this resolve. He applied the same zeal, thoroughness and editorial criteria to each paper, irrespective of its specialisation, as he had to the work of his students, and always the advice and the criticism were intended to be helpful, a feature generally recognised by students and experienced workers alike. The 'cause' of parasitology was always near to his heart—a cause in which he lectured all over the world and in which he responded willingly to global requests for guidance and assistance. His demise leaves a gap in the ranks of world parasitologists.

announcements

Appointments

Dr Peter Ayscough has been awarded a personal professorship in Physical Chemistry at Leeds University.

Professor George F. Mitchell has been elected President of the Royal Irish Academy.

The Royal Society has elected the following as fellows: Professor Geoffrey Allen, Mr Sydney P. Smith, Professor Peter F. Baker, Dr Peter M. Biggs, Professor James Whyte Black, Professor Roger J. Blin-Stoyle, Professor Daniel J. Bradley, Professor John I. G. Cadogan, Professor William G. Chaloner, Professor H Charnock, Professor Patricia H. Clarke, Professor Geoffrey Eglinton, Professor Roger J. Elliott, Dr Lloyd T. Evans, Professor Albrecht Fröhlich, Professor Frank W. E Gibson, Dr Leonard G. Goodwin, Professor Edward G. Gray, Sir Ludwig Guttmann, Dr John M. Hammersley, Sir William MacGregor Henderson, Dr Robin Holliday, Dr John H. Horlock, Dr George B. Mackaness, Dr Dan P. McKenzie, Professor John F Nye, Dr Thomas G. Pickavance, Professor Hubert Rees, Professor Joseph M. Ritchie, Mr Stephen J. Robinson, Professor Howard H. Rosenbrock, Dr John D. Smith, Professor Stanley D. Smith, Professor Francis G. A. Stone, Dr Brian A. Thrush, Sir Frederick E. Warner, Mr William Watt, Dr Michael J. Whelan, Dr Elsie M. Widdowson, Professor Ronald K. S. Wood.

Awards

Dr E. F. Hartree of the ARC Unit of Reproductive Physiology and Biochemistry, Cambridge, has been awarded the CIBA Medal and Prize for 1975.

The Zoological Society of London has awarded **The Scientific Medal** for 1975 to **Dr W. D. Hamilton**, Imperial College of Science and Technology for his work on evolutionary biology and to **Dr S. H. P. Maddrell**, University of Cambridge, for his work on secretory mechanisms in insects.

Professor Arthur Kornberg of the Department of Biochemistry, Stanford University School of Medicine, has been chosen as the 1976 Jubilee Lecturer and recipient of the Jubilee Award of the Biochemical Society. Professor Kornberg has devoted much of his career to the study of enzymes involved in the replication of DNA. He was awarded the Nobel Prize in 1959.

The William Hopkins Prize of the Cambridge Philosophical Society has been awarded to **Dr S. W. Hawking** for his work on general relativity.

The Max Born Medal and Prize for 1976 has been awarded to **Hermann Haken,** Professor of Theoretical Physics of the University of Stuttgart for his work on the theory of lasers and also excited states in solids.

Academician **Ya B. Zeldovich** of the Space Research Institute Moscow has been awarded an Honorary D.Sc. by Sussex University. Amongst other topics, Dr Zeldovich has worked on Conserved Vector Currents, Relativistic Astrophysics, Shock Waves, High Temperature Hydrodynamics and Ultra-Cold Neutrons.

The Indian National Science Academy has announced the following awards for 1976: the Professor T. R. Seshadri 70th Birthday Meday to Professor R. C. Mehrotra of the University of Delhi, and the Silver Jubilee Commemoration Medal to Professor A. K. Sharma of the University of Calcutta.

International Meetings

May 12–13, **The Granulocyte: Function and Clinical Utilisation** (The Research Director, The American National Red Cross, Blood Research Laboratory, 9312 Old Georgetown Road, Bethesda, Maryland 20014).

May 19, **Scientific Research in Antarctica,** London (The Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG)

May 27, **The Biology of Chemical Carcinogenesis,** London (The Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG).

June 2–4, **Ozone Disinfection,** Chicago (Edward G. Fochtman, IIT Research Institute, 10 West 35th Street, Chicago, Illinois 60616).

June 4–5, **Isotope Effects on Enzyme-Catalysed Reactions,** Madison, Wisconsin (Dr W W. Cleland, Dept of Biochemistry, University of Wisconsin, Madison, Wi 53706).

June 6–9, **59th Canadian Chemical Conference,** London, Ontario (CIC, 151 Slater St, Ottawa, Ontario, Canada K1P 5H3)

June 6–13, **Zeolite '76,** Tucson, Arizona (F. A Mumpton, Chairman Zeolite '76, Dept of Earth Sciences, State University College, Brockport, New York 14420).

June 7–8, **Biological Monitoring of Water Quality,** Helsinki (EIFAC Secretariat, Food and Agriculture Organisation of the United Nations, Via delle Terme, 00100 Rome, Italy).

June 8–10, **Trace Substances in Environmental Health,** Columbia, Missouri (Dr D D Hemphill, Chairman, 411 Clark Hall, University of Missouri-Columbia, Missouri 65201).

June 8–19, **COSPAR Meeting,** Philadelphia (Dean P. Kastel, Space Science Board, NRC, 2101 Constitution Av., Washington, D.C 20418)

June 13–16, **Annual Meeting of the Society for Economic Botany,** Urbana, Illinois (Dr David S. Seigler, Dept. of Botany, 289 Morrill Hall, University of Illinois, Urbana, Illinois 61801).

June 21–23, **Mass Spectrometry in Drug Metabolism,** Milan (Dr A. Frigerio, Istituto di Richerche Farmacologiche 'Mario Negre', Via Eritrea 62, 20157 Milan, Italy).

June 26, **The Early Years of the Edinburgh Medical School,** Edinburgh (A. D. C. Simpson, Royal Scottish Museum, Chambers Street, Edinburgh EH1 1JF).

June 29–July 1, **Tropical Conference on the Weak Interactions,** Falmer Sussex (Conference Secretary, Dr E. A. Sanderson, M A.P.S., University of Sussex, Falmer, Brighton, Sussex BN1 9QH).

August 29–September 3, **Photobiology,** Rome (Deadline for abstracts: April 30) (Dr A. Castellani, Secretary-General, 7th International Congress on Photobiology, c/o Istituto Superiore di Sanita, Viale Regina Elena, 299, 00161-Rome, Italy).

September 7–10, **Meeting of the European Geophysical Society,** Amsterdam (Deadline for abstracts: June 15) (Mr C. R. Argent, EGS General Secretary, 6 Carlton House Terrace, London SW1Y 5AG, UK).

September 10–14, **Chapman Conference on Partial Melting in the Earth's Upper Mantle,** Southwestern Oregon (Deadline for abstracts: June 7) (AGU, 1909 K street, N.W., Washington, D.C. 20006).

September 27–29, **Pulmonary Macrophage and Epithelial Cells,** Richland, Washington (Deadline for abstracts: June 7) (Mrs. Judith A. Rising, Secretary to the 16th Annual Hanford Biology Symposium, Biology Dept., Battelle–Northwest, Richland, WA 99352).

October 21–23, **Annual meeting of the AGU Midwestern region–Eastern Section of the Seismological Society of America,** Ann Arbor, Michigan (Deadline for abstracts: July 27) (Meetings, AGU, Suite 1000, 1909 K street, N.W., Washington, D C. 20006).

October 30–November 5, **1st Panamerican Congress and 2nd International Cinematographic Review of Orthopaedics and Traumatology,** Mexico City (Deadline: July 31) (Paseo de la Reforma No. 445, 4th floor, Mexico 5, D.F.).

November 22–26, **Radiobiological Research Needed for the Improvement of Radiotherapy,** Vienna (Deadline for Papers: June 1) (Dr B. B Singh, Division of Life Sciences, International Atomic Energy Agency, Kärntner Ring 11, PO Box 590, A-1011 Vienna, Austria).

December 6–10, **Biological Applications of Stable Isotopes,** Leipzig (Deadline for papers: June 1) (Dr J. L. Servian, IAEA, P.O Box 590, Kärntner Ring 11, A-1011 Vienna, Austria).

Superstar technology monitored...or throttled?

SUPERSTAR technology is the name given by a working party of the Council for Science and Society to highly innovatory, large scale technical projects. A report just issued (*Superstar Technologies*, 66pp, £2.00) looks at "the social mechanisms by which critical expertise can be concentrated on [such technologies], so that grave defects and dangers, technical, environmental and social can be anticipated and minimised". The problem is said to be that there are inadequate mechanisms, particularly at the conception stage of superstar technologies, to monitor possibly disastrous consequences; this is partly because the technology may practically monopolise the employment and commitment of relevant experts, thus weakening the forces of criticism or even commercial competition, and partly because these relevant experts will, being only human, suffer from occasional frailties of intellect, conscience and vision. How, asks the council, can we spot any weaknesses before the project is irresistible?

The answer, with a certain amount of hand-wringing about yet another public institution, is a Technology Implications Commission (TIC) which would "foster the discovery, assessment and diffusion of reliable information about proposed advanced technical projects, so as to provide conditions for effective monitoring, with appropriate public participation at all stages of development". The TIC would neither replace nor interfere with present monitoring facilities further down the line such as select committees or inspectorates. Information would come to it by way of scrutiny of the technical press, patents and so on, "on the lookout for items whose significance might easily be ignored". It would also use independent consultants, and would be a place to which a 'whistle-blower' could turn. The TIC would, if there seemed to be a *prima facie* case for a possible danger, pursue its own independent research and could follow this up, if necessary, either by publicising its findings or holding a conference to generate public debate. The TIC would not have legal power to force the adoption of any policy or the abandonment of any project.

It would be pleasing to be able to give such a modest and mild proposal a wholehearted welcome, firm in the knowledge that it had been hammered out by a representative group after extensive international inquiries. Careful reading of the report suggests otherwise and casts some doubts that the council put together the right sort of mixture. The working party comprised a lawyer, an architect, a professor of physics, a physics research student, a professor of materials science and two science writers. A curious group, markedly, maybe fatally, deficient in practising technologists who might be presumed to know superstar technology from the inside.

It is sad also to relate that the concept of a superstar technology never really comes into focus. Various apparent candidates put in anecdotal appearances—Flixborough chemical works, the DC-10, Ronan Point (a high-rise block of flats that was severely damaged by a gas explosion), high alumina cement, the Comet, natural gas, supertankers, motor cars, large electrical generating sets, organic chemicals, Browns Ferry, Concorde, boxgirder bridges, thalidomide, Windscale and even groundnuts. All of these are, of course, coupled with disasters, and a mood of disaster informs much of the report. We are told that "the personal safety of thousands . . . and the prosperity of millions may depend upon the engineering success and environmental acceptability of a single enormous project". But the real superstar technologies, on this reckoning, are probably things of the past—railways, electricity and gas distribution, tunnels, sewers, steamships, telephones and transatlantic flight.

The working party claim that changes in the social and financial organisation of industry have weakened some of the forces controlling innovation; Brunel or Edison, for instance, carried heavy personal responsibility for safety and success, which was a continual check on their projects. This is a doubtful argument; Brunel and indeed all Victorian engineers lived with disaster and failure on a scale unknown these days. Society has since then gradually deemed human life less expendable and commercial failure more ignominious. But there has to be a limit to the amount of restraint (even if only moral) on a technologist's freedom of action or else he will give up practising or emigrate. The TIC might come dangerously near to snuffing out what enthusiasm a technologist has.

It is asserted that the control of advanced projects on behalf of society "must depend on the same principle as does science"; this means peer-review and mutual criticism. However well this has served science, it is doubtful whether scientists should go round trying to impose their way of reaching decisions on another community, where decision making is not just a matter of establishing the facts but also of assessing political, social and economic factors. And even 'the facts' are of a different order in technology—the report acknowledges as much when it speaks of the almost impossible task of judging the real weight of innumerable, often contradictory, warnings.

The real danger in all this is, first, that a monitoring agency be generated with which technologists cannot live and, second, that the institutionalising of monitoring may actually create a false public impression that everyone else can relax a little.

There are lots of good intentions behind the council's initiative, and few would quarrel with a call for more open decision making. But the TIC, for all its worthy beavering, might just prove the last straw that broke the not-entirely-wicked camel's back. □

Time for a reappraisal at the Select Committee

THE House of Commons Select Committee on Science and Technology is always an easy target for criticism. It has little money, limited time, few administrative resources. It possesses no legislative power, and shows a frustrating inability to influence intractable government departments.

This bleak picture is made worse by the committee's history of ill-prepared reports and badly formulated proposals, themselves often the product of seemingly sloppy if not uncaring hit-and-miss investigations unbecoming of serious parliamentary procedure. (Remember how the committee championed the ill-fated proposal to appoint a Minister of Research and Development?)

To cap it all, the committee last week published its report on a visit recently made to the Gulf states of Abu Dhabi and Kuwait to investigate "matters of oil policy and related energy questions". The somewhat inappropriate main recommendation was that more effort should go into the export of Range Rover automobiles to Arab countries. But more disturbing was its remark (an attempt at vindication?) concerning the British-built Steam Generating Heavy Water Reactor (SGHWR): "We were puzzled by reports that the . . . SGHWR cannot be submitted to overseas buyers until a commercial size reactor has been successfully constructed at home."

The committee should be familiar with the problems that have arisen with the Advance Gas Cooled Reactor because of premature scaling-up, and should know that present policy consequently demands stringent, highly detailed design specifications, still not achieved with the SGHWR. The chairman of the committee attempted to justify its thinking with the observation that Britain should not worry if other states are prepared to accept safety standards less stringent that its own.

The committee's approach suggests that it has become as disillusioned with its own role as everybody else has; an attitude of cynical self-disdain does disservice to British science and technology. The need for well informed, disinterested guidance is perhaps greater now than ever before.

Nobody can be expected to take this committee more seriously than it will take itself. It is time for a reappraisal, a move towards the professionalism and rigour customarily associated with the (admittedly better off) Congressional committees on the other side of the Atlantic. It does not require bottomless coffers and endless time to stop and consider the difference between disinterested and uninterested. □

Seeking sense about scientists in government

The debate over Civil Service scientists in the UK continues. Harold Turner of the National Physical Laboratory gives his view and takes up some of the issues raised in Nature's *columns by Cyril Cooper last November and David Budworth in February.*

CIVIL SERVICE baiting has become a popular national pastime. The points raised in relation to the science aspects of the sport fall into two main categories: first, those which question the role of the Scientific Civil Service (SCS) within British science and the British economy generally; and, second, those that are concerned with the organisation, structure and competence of the SCS itself. Any evaluation of the criticisms of the SCS must first look at the broader, overwhelmingly more important issues in the former category.

The growth of the SCS arose, not from a doctrinaire belief in Government science, but from the need to provide national scientific services, such as standards and geological surveys, and, in particular, from a desire to compensate for the failure of industry to undertake and apply its own research and development. The beginnings of the decline of investment in British manufacturing industry, and its replacement by the more immediately profitable alternative of investment abroad, had been perceived by some as early as the 1860s, and the First World War finally brought home to Government that much of British industry was so backward as to bring national survival into question.

The steps thus set in motion—to encourage research in industry, to set up Research Associations and Government research establishments—have led to the pattern we see today. In a very few areas, notably chemicals, industry itself now mounts a research and development effort comparable with that of our major competitors. In a few others, contributing only a small part of our industrial output, there is (for reasons linked with present or past defence policy) an overwhelming concentration of government support. For the rest, representing some 85% of our industrial output, there is an effort which is inadequate by any standards. This maldistribution of effort has persisted for a considerable time, through many successive governments. The failure of our large research and development expenditure (about 2.3% of GNP) to produce any comparable improvement in economic performance, can be seen to be due to an excessive concentration on high technology, to a general failure on the part of industry to undertake and apply its own research and development, and to a failure of both Government and industry to secure the application in industry of research and development carried out in the public sector and the universities.

In the late 1940s many people, including myself, believed that the technological and competitive weakness of much of British industry could be overcome through a research effort in which Government research establishments played an important part: that the successes of wartime research could be repeated in peacetime conditions. We believed that if we provided research and perhaps some of the development, industry would provide the production and marketing expertise, and investment and economic growth would follow. We thought that our contacts with industry and the involvement of industrialists in the work would ultimately ensure its relevance.

Now, sadly, nearly 30 years later, after passing through phases in which science has been alternately oversold ("the white-hot technological revolution") and undersold (as in the present phase of disillusion), we are wiser and sadder. We know now that the problems of industry are not primarily technological, but economic and managerial, and that we as scientists can have little influence upon them. Many of us now feel that when management and direction in industry is effectual, science will be undertaken or commissioned and applied, but that when management is ineffectual it will not.

The years since 1965 have seen an agonising reappraisal of the role of Government science and particularly of industrial research. There is now probably a reasonable consensus on the rightness of a Government presence in some research and development areas. Thus the provision of certain services, such as standards and specification, would scarcely be questioned. Similarly with work *for* Government, to provide advice as a basis for statutory or regulatory action (including taxation) and in connection with the procurement function of Government and public authorities generally. Most work for agriculture is welcomed.

But on the crucial question of innovation and growth in British industry there is still violent disagreement on what is the role of Government money and Government science. It is a matter for regret that the Confederation of British Industry (CBI), which could contribute so much, has so far treated these problems at such a superficial level. The SCS seems to have become the national scientific scapegoat. It is dissected and examined as if the solution of all our difficulties is to be found in its entrails. At the back of most official enquiries into the SCS is the feeling that something must be wrong with the organisation and the people if so much expenditure in the end produces so little economic growth. This is not only unjust to the able and dedicated people who constitute the great majority of the staff, but dangerous in that it poses a false and facile solution to a complex national problem.

Take the argument that the SCS is overstaffed and deprives industry and education of much needed scientific manpower. The CBI has campaigned for cuts in the SCS. But it is difficult at this time to take seriously the suggestion that the recruitment of scientists into industry and the schools is limited only or even mainly by the insatiable designs of the SCS. SCS recruitment has been at a low ebb for years, but even so the uncertainty about the future of the service has resulted in a considerable shortfall on advertised vacancies. If industry is not recruiting it is either by intention or because many young people find industry unattractive, making the issue one on which the CBI might take useful action, for the fault is unlikely to be wholly on the students' side. The problem of science teachers is quite separate: the financial rewards compared with either the SCS or industry must be an important factor.

The suggestion that the SCS is overstaffed is less a valid statement about the staff required for current programmes than an argument for the reduction of the scope of the Service. Sixty per cent of government scientists are employed on defence. Their work is closely related to the Government's procurement function in this area. Staff cuts have already been made and much larger ones seem likely in the next few years. The remaining civil areas have also been cut. Some areas of 'interventionist' work have already been dropped. Attempts to pin down the CBI to say exactly where the line should be drawn between government and industrial research and development have often brought a disappointingly vague response.

Then there is the argument that the SCS as a career service brings seclusion, stagnation, immobility and excessive security. The SCS is a career service because it was created within the Civil Service. The suitability of this form of organisation has often been considered, but the CBI (in evidence to the Fulton Committee) did not advocate the abolition of the career SCS, merely the greater use of short term appointments within it. A proposal to recruit all CS scientists to short term contract posts, with the retention of about 20% after 5 years, came from one individual, Sir Frank Turnbull, a former career administrator at the Department of Education and Science. This proposal was conscientiously considered but rejected by the Fulton Committee. The dangers of stagnation in a career service such as the SCS, though often talked about, have never been investigated "on the ground". There is little to suggest that unproductive scientific civil servants are more prevalent or more of a problem than their counterparts in other walks of life. Where they do exist they are all too often the end product of a chain of management blunders.

This is not to argue that the age structure of the SCS is ideal. However, the crucial factor is not that the numbers have been static for twenty-five years, but that the rapid recruitment in the 1940s and 1950s, falling away in the 1960s and 1970s, has led to an age distribution in which the proportion of older staff is higher than one would choose if there were no constraints. Too many able and effective senior men are inadequately supported. Retirement and movement are already tending to restore the balance, but in the long run the only satisfactory solution will be consciously to relate recruitment to the long term need for staff at the various levels. Once a long-term view of Government science is evolved this will not be difficult. At the moment, actual interchangeability with industry is still limited and movement out of the SCS is still relatively infrequent. But it may be questioned whether movement does have the unique importance so far attached to it when in some countries, such as Italy and Germany, more successful than we in applying science, it is even less prevalent than here. Movement of scientists in industry to non-research activities is common, but the analogous movement within the Civil Service remains at a very low level despite the recommendations of the Fulton Committee.

Finally, the argument that the SCS is overpaid and provides careers far more favourable than industry. It has been claimed that the typical graduate entrant to the SCS reaches Principal Scientific Officer, and by his late 30s at that. In fact, only around 50% achieve this grade before retirement (a sore point with many SCS graduates), and not all even reach the next lower grade of Senior Scientific Officer. Scientific civil servants are not life-long bench workers; in the defence area particularly, large numbers are occupied in the management of projects funded by government but carried out elsewhere. The role of these members of the Science Group and the nature of their responsibilities has no exact counterpart in industry. It is of course legitimate to compare the SCS with industry, but the chief difficulty in doing so is that while SCS pay and career details are fully accessible to the public, those of industry are not. Information is supplied by industry to the Civil Service Pay Research Unit, but only in the strictest confidence. Comparisons are further complicated by the major differences in the structure of careers between the SCS and scientific employment in industry. In addition there is evidence of a wide scatter of industrial rates. Recent surveys of the remuneration of Chartered members of professional institutions show great differences *within* industry, between different sections of industry, between different locations of employment and between different functions, notably between the scientific worker and the manager of scientific work. An informed discussion of the pay and careers of scientists in all sectors of employment would be welcome, but it ill-becomes the spokesmen of industry to attack the SCS while withholding information on which this discussion alone can be based. □

Rediscovering Islamic Science

An exhibition of Islamic Science opens this week in London—one of many displays, concerts and meetings organised by the Festival of Islam to give a perspective on the Islamic world. **David Davies** reports

It is very easy to view the historical development of science in terms of the contributions that separate nations or civilisations have made to what we now regard as real, successful, all-encompassing Western science. We get decimals from one place, the lodestone from another, paper from a third and so on. But knowing the history of science only in terms of what we got out of where is like knowing world geography only in terms of what different countries export—a common feature, it used to seem, of school textbooks. In order to understand Islamic science properly, one has to try and identify with Islamic needs and beliefs, and if one is thereby led into alchemy and astrology as well as water-engineering and mathematics, this was no less science in the Islamic world. "We have tried," say Francis Maddison and Anthony Turner in the introduction to their catalogue of the exhibition, "in all modesty, and albeit imperfectly as non-Muslims, to picture Islamic science and technology from within, that is, as part of the intellectual and everyday life of a widely heterogeneous community founded on a common faith."

Wide indeed; the Islam world stretches from Spain to Indonesia, from Samarkand to central Africa. And in time the exhibition, at London's Science Museum, covers nearly a millennium from the first infusion of Hellenic knowledge in the eighth century to the fading away of a specifically Islamic science in the sixteenth and seventeenth centuries. The word science in the exhibition does not, of course, have its present professional connotations of making hypotheses, verifying or falsifying them. It is much more the science-museum/popular view of science as a body of knowledge about things. As far as we know, the doing of experiments in a systematic way was as unknown in the Islam world of the middle ages as it was in the western world of the same period.

Two things cemented the Islam world: the dominance of two main languages, Arabic and Persian, and the importance of religion in everyday life. From religious needs sprang much of the science that will be on show. The great eleventh century philosopher al-Biruni commented rather tartly that people were paying more attention to their food, which was a twice-daily concern, than to their prayers, which occurred five times a day. It was in the correct ordering of these prayers that science had a major part to play, both in the accurate measurement of time and in determination of the direction of Mecca so that the prayer mat should be correctly aligned. Thus flourished clocks, sandglasses, astrolabes, astronomical tables, spherical trigonometry and so on. But at the same time there is astrology which was, at a later date in Western science, practised by some but which scandalised others.

The Islamic world stretched east to Indonesia but there is little evidence remaining beyond India of scientific achievements. But Muslims were great travellers, and Egypt and Syria in particular managed at the crossroads to hear about everything.

The exhibition has posed particular problems of what to display. To the scholar the most important sources are the manuscripts, of which there are large numbers. But in planning the exhibition Maddison and Turner have had to keep manuscripts to a minimum simply because they would be generally incomprehensible to a London public. Astrolabes were relatively easy to accumulate for most periods, but the difficulty has been in putting together a representative sample of other objects to exemplify the extent of knowledge. It has turned out that the richest sources of exhibits have been Paris, London and Oxford museums, rather than the Islamic countries themselves. A major disappointment, however, has been that Turkish law forbids even the temporary export of materials from particularly fine collections.

Prosperity in the Islamic world was largely determined by the availability of water, and so the exhibition has had to take note of water technology. But some of the most fascinating examples only existed in manuscript form—notably in al-Jazari's thirteenth century *Book of Knowledge of Ingenious Mechanical Devices*. No one, as far as is known, has constructed any of these devices for seven hundred years, but the recent publication of Donald Hill's splendid translation (Reidel, 1973) has awakened a wide interest in them. A huge water-clock built specially for the exhibition according to al-Jazari's specifications will undoubtedly be the central attraction for most people. Equally noteworthy, however, will be the half-size model of a water pump driven by a water wheel, also described by al-Jazari. The original was the first recorded pump to be powered other than by human or animal-power.

Modern alchemist's still (above) and (below) the model of a water pump driven by a water wheel

It is difficult to date the decline of a specifically Islamic science. The growth of the Ottoman Empire in Turkey helped to extend the period, and, both through Turkey and Spain, aspects of Islamic science were siphoned into Western civilisation.

There seems little doubt that the Islamic exhibits being brought together in London, not only of science, but of art, architecture, musical instruments and books, represent a unique occasion. And few believe there will ever in the foreseeable future be another occasion on which so much of the Islamic world can be seen in one city. □

The exhibition at the Science Museum is open daily until August 29. Admission 30p; children, students and pensioners 15p.

From embargo to control

A committee which has been striving for the past year to draft guidelines to control the use of a revolutionary, but currently embargoed, genetic engineering technique, last week paved the way for many uses of the technique to be resumed in the United States. Colin Norman reports from Washington

FOR nearly two years, many experiments involving the use of a newly-discovered method of manipulating genes in living organisms have been under an embargo because of potential hazards associated with the research. But scientists in the United States who have been itching to use the technique may not have much longer to wait, for it now seems almost certain that the embargo will be lifted in the next few weeks and be replaced with controls designed to minimise the hazards.

The latest step in the tortuous process of developing those controls occurred last week when a committee of the National Institutes of Health (NIH) met to consider criticisms and proposed revisions of a set of detailed guidelines it drafted last December.

The committee stood solidly behind its work, resisting most suggestions that its draft guidelines should be made more restrictive, and it also gave its approval for one particular biological safety system to be used for some of the more hazardous genetic manipulation experiments.

The matter is now firmly in the hands of NIH Director Donald S. Fredrickson, who last week promised to issue a final set of guidelines within a month. Though Fredrickson will probably amend the draft guidelines, a statement he sent to the committee last week indicates that he has accepted the principles embodied in the draft and that any revisions he may make will be relatively minor.

The draft US guidelines seek to contain bacteria or viruses bearing transplanted genes by two methods. First, they spell out four levels of physical containment, ranging from the use of standard microbiological practice to the use of specially designed laboratories (such as biological warfare establishments) capable of handling the most virulent pathogens, and second, they specify that experiments with high potential risk should use viruses or bacteria genetically crippled so as to be virtually incapable of surviving outside the laboratory. The central, and most controversial, portion of the guidelines attempts to assign specific experiments to specific safety levels.

After the committee finally hammered out those guidelines at a meeting last December, Fredrickson sent them out to several scientists for review, and he also called a public meeting to solicit the views of outside groups. The result is a stack of comments more than a foot thick, on the basis of which Fredrickson last week suggested some specific revisions in the draft guidelines and asked the committee for its reactions.

Many of Fredrickson's suggestions simply removed inconsistencies in the draft, and were readily accepted by the committee. But in several instances where Fredrickson proposed changes which would have made the guidelines more restrictive, the committee demurred, arguing that its draft guidelines would provide ample protection against the potential hazards. Specifically, Fredrickson suggested that experiments involving the insertion into bacteria of uncharacterised genes from cold-blooded vertebrates should be placed in the same category as experiments with genes from higher animals (next to the highest level of physical containment, coupled with the use of crippled micro-organisms); he asked the committee to consider the suggestion that genes from other cold-blooded animals and lower eukaryotes should only be transplanted into crippled bacteria; and he also asked the committee for its views on placing all genetic manipulation experiments with the monkey virus SV40 in the highest level of physical containment. Though the committee turned down all those suggestions, it remains to be seen whether Fredrickson will accept its views.

Whatever decisions Fredrickson makes on the fine details of the guidelines, it is clear that many genetic manipulation experiments will require the use of crippled viruses or bacteria before they are allowed to go ahead. In that regard, the committee last week took one important decision and came close to making a bad political blunder on a second.

At its meeting last December, the committee agreed that it should certify whether or not specific strains of viruses or bacteria have been sufficiently crippled to provide the degree of containment spelled out in the guidelines (it took on that assignment largely because no other competent national body is available). At last week's meeting, it was asked to certify two such crippled strains. If it approved them, the effect would be to give the green light to many experiments as soon as guidelines are published; if it turned them down, the embargo on experiments requiring crippled strains would effectively be maintained because no such strains would be available.

The first strain considered by the committee was a bacteriophage lambda, rendered incapable of surviving at body temperature and carrying three other genetic mutations which limit its infectivity and prevent it from surviving outside an artificial laboratory environment. Developed by Dr Philip Leder and his colleagues at NIH, details of the strain have already been published in *Nature*, and the committee members were provided with test data several weeks before their meeting. They certified the strain as being sufficiently weakened to provide an adequate biological safety barrier.

The second crippled micro-organism under consideration was a strain of the human gut bacterium *E. coli*, developed by Dr Roy Curtiss at the University of Alabama. Curtiss has been working on the strain for more than a year, and he has built a number of ingenious mutations into the organism to reduce its ability to survive outside the laboratory. He has also conducted exhaustive tests to measure the bacterium's chances of surviving. His test data were presented to the committee on the first day of the meeting in the form of a 147-page set of figures, graphs, tables and text. Though few members of the committee had the chance to go through Curtiss's data, they came close to voting on whether or not to approve the strain. Fortunately, however, it was decided—much to Curtiss's relief, it should be noted—to defer a decision for a month to allow committee members to consider the data and confer with other experts.

Though many members of the committee have been keeping in close touch with Curtiss's experiments over the past year, and were therefore well versed in his overall results, if the committee had certified his strain on the basis of such a cursory examination of the data, it would have laid itself wide open to criticism. Biological containment, after all, is a central feature of the safety guidelines. Nevertheless, Curtiss's data is so extensive and by all accounts it provides such convincing evidence for the feebleness of his bacterial strain that the committee is very likely to approve the strain for use in genetic manipulation experiments.

Within the next few weeks, guidelines will thus be issued by NIH to govern that agency's support of genetic manipulation experiments, and the committee's certification of at least one crippled micro-organism has paved the way for a lifting of the embargo in the United States. □

CANADA

Mercury poisoning in Ontario

Are Canada's Indians now victims of Minamata disease? David Spurgeon reports from Ottawa

IN THE spring of 1970, the minister of energy and resources management of the province of Ontario announced that the fish in the English-Wabigoon river system contained high levels of methylmercury and were unfit for human consumption. The sequence of events since then has seen the disruption of the way of life of hundreds of Indians in the area, the closure of a prosperous recreational fishing lodge there, serious doubt cast on the capacity of governments to deal with such issues, and a human tragedy recalling the mercury poisonings at Minamata, Japan.

Dr Masazumi Harada of Kumamoto University in Japan, a neuropsychiatrist and expert on Minamata disease, noted neurological symptoms in many Indians he examined in the area. "There were 37 cases in which some type of sensory disturbance was found," he reported. *"Impairment of the visual field was found in 16 cases. Seven of these cases had asymmetric constriction and tunnel vision. This is very significant in Minamata disease."* (Harada's italics). He was a member of a Japanese delegation that included victims of Minamata disease which last September visited the Canadian settlements affected at White Dog and Grassy Narrows Reserves, near Kenora, in northern Ontario.

The energy and resources minister singled out a paper company's chemical manufacturing plant as the cause of the mercury contamination in the area. Over the previous eight years it was said to have dumped eight tons of methyl mercury into the river system seventy miles upstream.

The process in which the mercury was used has now been replaced, but the advice given by the Ontario government to anglers is to fish for fun only. All commercial fishing licences held by the Indians were revoked in 1970 by the government, which has since supplied them fish to eat from other lakes. This removed a major source of income for the Indians, but it did not stop them eating contaminated fish. And in Grassy Narrows Reserve, where there had never been much reliance on government welfare support, welfare payments are now the principal source of income.

On the government's role, the Canadian Broadcasting Corporation has referred in its programmes to reports that were ignored or never came to light. Newspapers point to a conflict of jurisdiction between federal and provincial governments.

The line taken by government medical men is revealed by Dr James Stopps, senior consultant on environmental health for the Ontario government, who says "to date no Indian has been diagnosed as having mercury poisoning. That doesn't mean no cases exist; it does mean that after five years we haven't been able to find one." Dr Harada, however, says "even a conservative estimate is that the effect of methylmercury among seven cases cannot be denied." Critics further maintain that the Government's tests were carried out during the mid-winter rather than at the height of the fish-eating season; that it did not test some of the people who ate the most fish (the guides); and that it noted only the mercury levels of the individuals, not their symptoms.

The latest chapter in the story is found in an interim report, published by the federal health department, on a survey of residents of the White Dog and Grassy Narrows Reserves. The purpose of the survey was to determine the extent of exposure to mercury and whether such exposure is causing adverse effects on health; the report which deals with samples of hair and blood obtained at the reserves last August, was written by Dr T. W. Clarkson, professor and director of the Centre in Environmental Health Sciences of the University of Rochester's medical school and a consultant to the Research Institute of the Hospital for Sick Children in Toronto.

"The results obtained to date (December 1975) indicate a wide range of mercury levels—from less than 5 parts per 10^9 to 330 parts per 10^9 in blood," the report said. "The exposure to mercury usually follows a yearly cycle with the highest intake in the summer. Adult males acting as guides at fishing camps have the highest intake of mercury. Five guides out of eleven that were sampled had blood levels in the range of 100 to 330 parts per 10^9. Analysis of hair samples from the guide having the highest blood concentration (330 parts per 10^9) revealed that the peak mercury concentration had occurred two months prior to the collection of the blood sample. This peak value in hair was close to 150 parts per million, equivalent to a blood concentration of approximately 500 parts per 10^9".

The report also revealed that wives of guides tended to have higher blood levels of mercury than other females on the reserve. Children usually had lower levels than their parents, but younger children tended to have higher levels than older ones. "A matter of serious concern is the continued exposure of pregnant women to methylmercury," it said. By contrast, analyses of blood samples received from women (mostly non-Indians) living in or around nearby Kenora, and received from the Lake of the Woods Hospital, Kenora, revealed no significant exposure to methylmercury at the time of the delivery of their babies.

Picture: Mansell Collection

A thorough clinical evaluation of the health of those sampled will not appear until phase two of the study. But the report "tentatively" concluded that "several individuals in both reserves still have unacceptably high blood levels of methylmercury . . . very high exposure to methylmercury continues to be a serious problem with guides working at fishing camps." It noted that the highest concentrations reported occurred in the summer of 1975 "despite the fact that warnings against eating contaminated fish have been in effect for several years and that an intensive health education campaign has been in effect during the past year."

The report recommended further action by the guides' employers and health authorities to reduce exposure, and high priority for the planned expansion of a clinical programme. It recommended continuation of the health education programme and—because "the mercury problem may continue for some time"—establishment of a National Centre in Environmental Health. Such a centre, the report said, could deal with other environmental pollutants as well as methylmercury, and "would help detect and deal with potential threats long before they emerged as a national problem." ☐

SOLAR ENERGY

Power from the sun

Pierre Langereux of La Recherche *reports from France following an international symposium on solar electricity held last month in Toulouse*

"BEFORE solar energy becomes a major energy source for the 21st century, its development will require financial expenditure of the same order of magnitude as that needed for the development of nuclear energy." So said the scientific director of the National Scientific Research Centre (CNRS), which, together with the National Space Research Centre (CNES), organised the first international colloquium on solar electricity. He was speaking at the end of the meeting, which was attended by about 300 scientists from over 30 countries and produced an agreement on scientific and technical collaboration in developing solar energy through photovoltaic and thermodynamic conversion.

Photovoltaic conversion, perfected 20 years ago by Bell Laboratories and in general use since then to feed man-made satellites, is based on the capacity of certain semi-conductors (silicon, cadmium suphide, cadmium telluride, gallium arsenide) to transform light energy directly into electricity. Photopiles were developed for use in space exploration, where cost is of comparatively little importance, but they are still much too expensive to be widely used on earth. Silicon photopiles—the only ones currently in commercial use—have been used on earth for about fifteen years already, but for a few limited and highly specialised uses only.

In spite of the promising beginnings, there is still much to be done to make solar energy competitive with the other energy sources already in use. World production of photopiles for terrestrial application is currently equivalent to about 150 KW per year—100 KW in the USA, 30 KW in France, and the rest in Japan and Germany. But the market is expanding. In 1980 the production of silicon photopiles is expected to be of the order of about 10 MW: the price per watt of solar cells (currently \$21) may have been reduced by then to \$5 or \$10 through improvements in the manufacturing process, while in ten years the price could have fallen by a factor of 100 if current research on silicon cells in thin layers bears fruit. The most interesting prospects, however, seem to lie in the development of photopiles using other materials such as cadmium sulphide and cadmium telluride, which were prematurely abandoned for space projects several years ago.

What of thermodynamic conversion? This uses solar ray collectors to heat water which, when transformed into steam, activates an alternator or turbine after passing through a heat exchanger. To reach high power levels, solar towers are needed; heliostats receive solar rays and concentrate them onto a steam generator placed at the top of a concrete tower. The higher the tower, the greater is the capacity of the power station.

Thermodynamic power stations have evolved rapidly, especially in France, and the Sofretes company has recently installed the first solar thermodynamic power station at La Pas (Mexico). Other projects will follow, with more powerful experimental power stations—one of 1 MW at Odeillo (France), for example, and another of 5 MW in the USA. Both countries also have projects for building 10 MW solar power stations, while in Japan, Mitsubishi Heavy Industries has announced a plan for a 1000 MW solar power station.

Whichever of the two methods is envisaged for the future, however, the most difficult (and perhaps obvious) problem is yet to be resolved: how to store the energy produced by solar power stations, for they can only function when the weather is clear and sunny. In the photovoltaic system, electrochemical storage is expensive; with thermodynamic power stations, on the other hand, one can more easily use thermal storage. Material costs, which have already been studied for nuclear programmes, would be relatively acceptable, and three materials are being considered: oils, rocks and dissolved salts. Great hopes are based also on the possibility of stock-piling hydrogen, obtained as a by-product in the photodissociation of water.

The USA has embarked on a very ambitious programme, with the objective of supplying 5–7% of its energy needs from solar energy in the year 2000, and 25% in the year 2025. The Energy Research and Development Agency (ERDA) will assign \$120 million to the development of solar energy this year, and \$160 million in 1977. France, coming second, has set aside for this year a sum of the same proportionate size relative to the GNP—60–70 million francs, twice as much as in 1975. In comparison, Germany plans to spend only 36 million francs this year, and Japan slightly less. ☐

INFLUENZA

How it should work

THE House Appropriations Committee has unanimously approved the \$135 million requested by President Ford to inoculate the American public against a possible epidemic of 'swine' influenza next winter. The first batches of vaccine against this new strain should be ready in mid-April for clinical trials of its protective value.

If these are successful vaccination of those most at risk should begin in late summer. Representatives of the drug industry and government health officials testified before Congress this week that they hope to have the whole population inoculated by Christmas.

Rapid production of the vaccine can be achieved by an ingenious trick devised in the late 1960s. A quick-growing "master" strain of flu virus is hybridised with the swine flu to produce a recombinant bearing key characteristics of the swine flu virus. This recombinant can grow rapidly in fertilised hen's eggs, allowing vaccine production in 6-8 weeks rather than several months. The virus is then collected, killed and packaged into vaccine. It is reckoned that 50 to 100 million hen's eggs will be needed to produce the 200 million shots needed to vaccinate Americans. The protection expected with this vaccine will be between 70 and 80%.

The \$135 million will cover the costs of production and distribution of vaccine only. Vaccination will be voluntary and those who can will have to pay for their flu shots, but President Ford has stated that nobody will be denied vaccination if he cannot pay for it. The high-risk groups in the population will also automatically receive inoculation against the A and B strains which have been around this winter. But the emergency vaccine itself will only confer protection against the swine flu virus, which on its present showing in the one outbreak so far appears to produce generally less severe illness than the other strains prevalent this winter.

Meanwhile the Canadian government has also decided to approve a mass inoculation programme with swine flu vaccine. It plans to produce about 12 million doses, enough for about half the population, with preference to be given to high-risk groups.

IN BRIEF

Safeguards surface

A few days before taking office as Britain's new Prime Minister, Mr James Callaghan, speaking as Foreign Secretary, revealed in reply to a question in the House of Commons details of the safeguards Britain would apply in deals involving the transfer of sensitive nuclear technology. The safeguards, agreed among the (soon to be enlarged) Group of Seven nuclear exporting countries, demand assurances that the exported technology will not be used to make nuclear explosives for any purpose, that there is sufficient protection against the risk of theft or sabotage and that similar safeguards will apply both to re-export of the technology by the recipient and, for twenty years, to independent replication of nuclear plant by the recipient.

Deadline passed

The United States and the Soviet Union are to continue discussions which might yield a bilateral treaty on nuclear explosions even though they failed last week to meet the March 31 deadline originally set for agreement. The talks began in July 1974, when Mr Brezhnev and President Nixon agreed in principle that peaceful and military explosions should be limited to 150 kilotons and that there should be some on-site inspection. The remaining difficulty chiefly concerns monitoring multiple peaceful explosions which together exceed 150 kilotons that the USSR might wish to use in civilian projects.

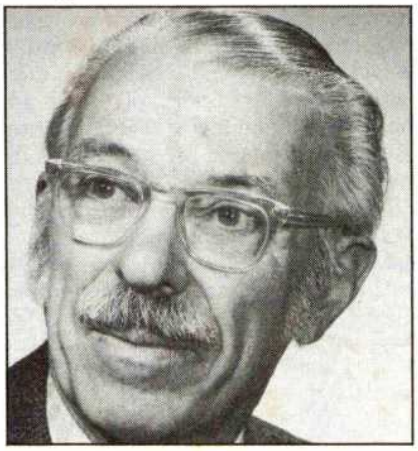
Asbestos inquiry

The renewed controversy in Britain over the health risks of asbestos to the public at large as well as to employees in the industry itself has led to the appointment of a government committee to make a wide-ranging review of the hazards involved and of the safeguards in use. The formation of the committee, to be headed by the chairman of the Health and Safety Commission, has been welcomed by the industry's Asbestos Information Council, and follows the publication of a report by the Ombudsman criticising the Factory Inspectorate's policing of a plant where 40 people died from asbestosis between 1939 and 1970.

UNEP plea

The annual governing council of the United Nations Environment Programme (UNEP), on which 58 states are represented, opened in Nairobi last week with a plea from its executive director, the biologist Dr Mustafa Tolba, that member states fulfil their pledges in order to resolve UNEP's financial crisis and so prevent it curtailing its plans. Only a small proportion of the money pledged has actually been received, with the big countries proving to be the most reluctant contributors.

Apricot retaliation



THOMAS H. JUKES

SPRING in California used to be signalled by a procession of fruit blossoms in the well-kept orchards: almonds in February, then apricots, sweet cherries, peaches, and, finally, the miles of prune trees in the Santa Clara valley that have now been displaced by houses. Most orchards have retreated into the background of the concrete invasion. In a few months, the fruit harvest will start with the sweet cherries, and later the wooden lugs of golden apricots will be loaded for shipment.

As a good Darwinian, I feel sure that the sweet and delectable flavour of apricots, enhanced by plant breeding, is meant to encourage me to pick the fruit and walk away with it. Then I shall devour it, and drop the stony pit on the ground so that the apricot will extend its territory when the seed germinates. But the seed doesn't want to be eaten, for this will destroy the embryo. So, in the seed, there is a substance called amygdalin that decomposes when the seed is macerated. This process liberates an enzyme, beta glycosidase, that hydrolyzes amygdalin to glucose and mandelonitrile, a compound of cyanide and benzaldehyde which breaks down to set free HCN. Death to eaters of apricot seeds! Having summarily disposed of its enemies, the apricot will take over the landscape.

The same game-plan is a hallmark of other members of the rose family, and, indeed, of many other plants—sorghums, lima beans, cassava, clovers and acacias. Almonds and beans have been selected by plant breeders for low content of cyanide. Cassava is soaked, fermented and leached to remove HCN. Until recently apricot pits were discarded, except occasionally the seeds were crushed and added to preserves to impart the almond flavour of benzaldehyde. The HCN presumably diffused away during cooking.

A new interest in apricot pits has come about as a result of the "health food" sponsorship of "Laetrile" (amygdalin) for the ineffective treatment of cancer. Dressed up as vitamin B_{17}, which is a completely unjustified soubriquet, Laetrile has become the darling of the diet stores. As a result, the apricot has struck back. Last October, a 34-year-old man residing in San Diego, California, developed symptoms of cyanide poisoning after eating apricot kernels. A package of the raw kernels was bought at a health food store and made into milk shakes, following a recipe in an "organic food" publication. The man's wife didn't like the taste, so her husband greedily downed both portions, and, one hour later, "developed forceful vomiting, headache, flushing, heavy perspiration, dizziness and faintness". He was rushed to the emergency room of the local hospital, and rescued by a stiff dose of ipecac. Once again, the process of natural selection was thwarted by human intervention.

The state health department drily states in its report "the minimal number of apricot kernels necessary to cause symptoms or death in humans is not known. Since this and similar products are widely distributed in health food stores for reputed nutritional and medicinal value, the possibility of disease from a large number of kernels should be recognised".

As you can guess, my apparently inhuman sympathies are with the plant world. I treat stinging nettles with respect, and I delight in the blue flowers of larkspur and monkshood. Unlike Bret Harte's "mliss", I do not plan to eat the leaves thereof. I disagree with D. H. Lawrence's idea that the devil himself must have conceived the spines of cacti in a moment of sheer ecstasy. Framed in thorns the exquisite blossoms of the cactus are to look at, not to touch. Plants have every right to tell us to keep our distance. *Hommage à Darwin!*

Genetics at the OU

SIR,—The letter by Kacser *et al.* (April 1, page 386) concerning the Joint Universities Genetics Course, raises issues on which formal consultations between the Open University and the Nuffield Foundation are taking place. It contains statements that are false, misleading, and prejudicial to Open University students and it is my duty to comment.

Firstly it should be understood that the grant from the foundation is less than half of the costs of production of a half-credit second-level course, the rest being met by the Open University. Nuffield support, whilst generous, was essentially given to carry through a project devised and planned by the participating universities.

We have always had draft material assessed for its academic validity by independent experts before final publication; the genetics course is no exception; all its units have been independently assessed and developmentally tested with volunteer student panels.

Relatively late in the planning of the course, the Nuffield Foundation proposed, and collaborating universities agreed on, a Consultative Committee to aid in course development. The Committee's unanimously agreed rôle was "to advise and comment on the general course outline, aims and objectives" and "to provide a group of geneticists willing to serve as academic referees for particular detailed portions of the course". It had neither control of nor responsibility for the course or the use made of it in individual institutions. In the main this is how the committee has interpreted its rôle and this has been of great assistance to the course team. Inter-university collaboration is a delicate and difficult plant to nurture, and it is a pity that the harmony between different universities reflected in the work of the team has not carried through to all the members of the consultative committee.

Kacser *et al.* state that "the Committee informed the Foundation that it was dissatisfied with the outcome of the previous three years' work and asked that the course should not be published, or even used by Open University students, without further consideration, restructuring and amendment". This is untrue. A document signed by some members of the Committee (whose membership is incorrectly given in the letter), which was neither seen nor discussed at any meeting of the committee, and whose very existence was unknown to some of its members, was passed to the Director of the Nuffield Foundation.

Kacser *et al.* imply that the committee thought that the length and depth of the course was far beyond the capacities of the intended students. They state (as if they had only just discovered the fact) that, for Open University students, the study time for the average "Unit" is 12 hours, and that this work must be completed, on average, in a week. All this is, of course, perfectly true. But they then go on to assert that "it was the Committee's considered opinion" (though the Committee has never considered such an opinion) "that this is an impossible task if understanding at a University level is aimed at".

This workload is normal for all Open University courses. If the opinion of Kacser *et al.* is correct, the fact that many thousand students have successfully performed this "impossible task" over the past five years could only mean that these students did not achieve "understanding at a University level". This is a gratuitous insult to students and graduates and a grave reflection on our academic staff and external examiners.

Further, as Kacser *et al.* know full well, developmental testing of the course's components has continued this year with actual students. To pronounce upon the alleged difficulty and overloading of the course in advance of the completion of this evaluation seems to indicate prejudice rather than a spirit of objective criticism. To do so publicly seems to me to be irresponsible. Based on the first returns we have had from students, the average times taken to study Units 1 and 2 were 7 hours and 10 hours respectively, 99% of students reported on Unit 1 as being "OK" to "Very Interesting" and 98% found it "OK" to "Very Easy" to understand. The comparable figures for Unit 2 were 78% in each case. It would be premature to generalise from the first two units, but the facts so far contradict Kacser *et al's* mere opinion. I am confident that when the evaluation of the remaining Units—and the examiners' assessment of students' performance—has been completed, Kacser *et al.* will be shown to have been wrong.

Kacser *et al.* further suggest that the use of this course by other institutions "has not been seriously considered". Quite the contrary: the other participating universities have, I believe, already made plans to use sections of it in their own teaching programmes and several other institutions have already let us know of their plans to do the same. It is also misleading to claim that an "obvious deficiency" of the course is that it has no "practical manual". At an early stage the team discussed practical work and decided that because of the widely differing circumstances of the different institutions that might use the course, no attempt should be made at present to prepare a manual except for OU students.

Kacser *et al.* assert that "the Consultative Committee jointly with the Nuffield Foundation suggested a number of changes which would have gone some way to meet these criticisms, but they were not accepted by Professor Rose". This is false in one respect and misleading in another. At no time has the "Consultative Committee jointly with the Nuffield Foundation" suggested these changes. Of course, in the design and development of the course, comments from members of the committee have been submitted to the team; many of these were accepted, with appreciation. The statement misleadingly suggests that acceptance or otherwise of comments was the prerogative of Professor Rose. In fact, all such decisions were taken by the full course team.

I very much regret the inaccuracy and tone of the letter, and wish to reiterate my belief that this course is academically and educationally on a par with other second-level Open University science courses, the value and success of which is already well established. Because of the wide interest in the subject and the way in which the course is constructed, the course will be of use in many other teaching contexts than the Open University.

Yours faithfully,

M. J. PENTZ

Ectopic production of HCG subunits

from a Correspondent

THE synthesis of a particular hormone or hormone subunit by tumours derived from a tissue not normally engaged in its production (ectopic production) is now a familiar observation. Endocrine abnormalities in patients can often be traced to the presence of a tumour in non-endocrine tissue. Measurement of raised levels of some hormones circulating in the blood is often used as a biochemical marker of malignancy and to monitor the success of surgery, analogous for example to the use of chorionic gonadotropin assays in women with choriocarcinoma. Human chorionic gonadotropin (choriogonadotropin) (HCG) is synthesised by the trophoblast at a very early stage of pregnancy—within a few days of fertilisation. It provides a critical support to the corpus luteum, which decays in its absence with resulting menstruation, and so is crucial in establishing and maintaining pregnancy. HCG is not normally present in the circulation of non-pregnant females, the only exceptions being patients with choriocarcinoma (Vaitukaitis *et al.*, *Ann J. Obstet. Gynecol*, **113**, 751–758; 1972), hydatidiform mole (Crawford, *Brit. Med J.*, **4**, 715–719; 1972) and patients with cancers that ectopically synthesise the hormone (Braunstein *et al*, *J. clin. Endocrinol. Metab.*, **35**, 857–862; 1972; Braunstein *et al.*, *Ann intern. Med.*, **78**, 39–45; 1973). HCG can also be detected in normal testis (Braunstein *et al.*, *New Engl J. Med.*, **293**, 1339; 1975).

The ectopic production of chorionic gonadotropin in cell lines was first described in Gha-Go cells isolated from a bronchogenic carcinoma (Rabson *et al*, *J. natn. Cancer Inst.*, **50**, 669–674; 1973; Tashjian *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 1419–1422; 1973). Both subunits of HCG were identified. The α subunit of HCG (HCG-α) is nearly identical to the α subunits of thyroid-stimulating hormone (thyrotropin), follicle-stimulating hormone (follitropin) and luteinising hormone (lutropin) whereas the β subunit (HCG-β) is different from the β subunits of the other glycoprotein hormones. The α and β subunits are glycoproteins containing moderate amounts (10–20%) of carbohydrate. Two papers in *Nature* have now shown that these subunits are synthesised and secreted by HeLa cells in culture.

A hundred years ago

ON the 31st ult. a meeting, at which several well-known English biologists were present, took place at the house of Dr. Burdon-Sanderson, at which the advisability of establishing a society or association for the purpose of promoting the progress of physiological research in England, was considered and discussed.

from *Nature*, **13**, April 6, 455; 1876

Ghosh and Cox (*Nature*, **259**, 416–417; 1976) used the HeLa 65 and HeLa 71 sublines. They showed by radioimmunoassay with β subunit antiserum that the secretion of small but significant amounts (~ 0.0024 ng per 10^6 cells over 5 d) of immunologically reactive material occurs during culture. It is not clear from the results of Ghosh and Cox whether β subunit production, secretion of the complete hormone or both processes takes place. Furthermore, there is a crucial question of the degree of specificity of antiserum for β subunit, as considered later. Perhaps the most striking result reported by Ghosh and Cox is the greatly increased (1,000-fold or more) secretion of immunologically reactive material when HeLa cells were grown in medium supplemented with 1–5 mM butyrate. The response of the cells to butyrate varied almost linearly up to 20 ng per 10^6 cells over 5 d with butyrate concentration over the range 0–5 mM. This intriguing finding is apparently not specific to HCG production. The levels of activity of placental alkaline phosphatase, which like HCG is produced ectopically by HeLa cells (Elson and Cox, *Biochem. Genet.*, **3**, 549–561; 1969) are also markedly increased by butyrate (Griffin *et al.*, *Arch. Biochem. Biophys.*, **164**, 619–623; 1974) The mechanism of action of butyrate in augmenting synthesis of two glycoproteins is unknown. It may be significant that short chain fatty acids including butyrate, were shown to increase the activity of a sialyl transferase in HeLa cells (Fishman *et al.*, *Biochim. biophys. Acta*, **59**, 292–299; 1974), since sialylation of at least one glycoprotein, thyroglobulin, seems to be obligatory for its secretion (Monaco and Robbins, *J. biol. Chem.*, **248**, 2328–2336; 1973). The substrate specificity of the HeLa cell sialyl transferase(s) responding to butyrate may therefore be of interest in considering its possible role in controlling HCG secretion.

Although the Ghosh and Cox experiments do not distinguish between secretion of β subunit or completed HCG molecules, Lieblich *et al.* (this issue of *Nature*, page 530) show unequivocally that at least some sublines of HeLa secrete relatively massive quantities of α subunit ectopically (about 75 ng per 10^6 cells per day). Unfortunately the HeLa sublines (CCL 2, 2.1 and 2.2) used by Lieblich *et al.*, do not include those studied by Ghosh and Cox. Since the rate of secretion of α subunit varies about 50-fold among the various sublines studied by Lieblich *et al.*, it is possible that HeLa 65 in fact secretes only the β subunit. Alternatively these cells may carry out a balanced synthesis of α and β subunits with secretion of the completed hormone.

The relatively massive secretion of free α subunit by the HeLa sublines studied by Lieblich *et al.*, does however raise the question of what Ghosh and Cox were measuring in their basal system or even in the stimulated cultures. The antiserum used by the latter workers, raised against purified β subunit, is stated to show less than 1% cross reactivity with luteinising hormone indicating even less than this degree of cross reactivity with the common subunit. But such contamination could conceivably account for the small reactivity obtained in the medium of cells grown in the absence of butyrate. It is of course less likely to complicate the measurement of the much larger quantities of immunologically reactive material produced by HeLa 65 cells in butyrate medium although this cannot be entirely ruled out.

The α subunit secreted in such large amounts by HeLa cells is immunologically indistinguishable from α subunit isolated from pregnancy urine. The tumour α subunit is apparently not structurally identical however, since Lieblich *et al.*, found a small but definite difference in elution of the tumour α subunit during gel filtration compared with the pregnancy subunit. A slightly increased molecular weight could account for this discrepancy, although glycoproteins often behave abnormally during gel filtration chromatography. Weintraub *et al.* (*J. clin. Invest.*, **56**, 1043–1052; 1975) showed similar abnormal properties for α subunits secreted by the Gha-Go cell line. In gel chromatography the Gha-Go subunit behaved as a protein of 27,000–30,000 apparent molecular weight, significantly higher than the α subunit found in pregnancy (23,000–24,000 apparent molecular weight). Thus, there seems to be an increase in the size of α subunit made by tumours. It may be that this material represents a precursor form present only transiently in the production of normal α subunit and HCG by placental cells. Interestingly, the Gha-Go tumour α subunit could not form biologically active HCG when incubated with HCG β subunit and tested in a rat testis radioreceptor assay. By contrast HCG α subunit from pregnancy urine combined efficiently with HCG β subunit to reconstitute 95% or more of the expected HCG activity under the same conditions. It seems therefore that tumour α subunits may be defective in a stage leading to functional HCG molecules. The molecular basis for the difference is presently unknown. It is possible that the α-subunits are degraded in some way by tumour-specific proteases, although this seems unlikely from their apparently greater molecular size compared with the subunit of pregnancy urine. Their amino acid compositions are also very similar to pregnancy α subunit except for small differences in some residues, particularly valine, phenylalanine and half cystine. Perhaps further analysis by peptide mapping or comparison of carbohydrate contents might suggest the structural differences between biologically active α subunit and the apparently inactive product of tumour cells. □

Why don't animals cheat?

from John Krebs

As a general rule, animals settle disputes with other members of the species by means of ritualised displays rather than by physical violence. In contests for food, territories and mates, raised crests and songs serve as substitutes for teeth and claws, and the loser retreats unscathed. This much is well known, but it is less clear why the ritualised communication system does not break down because of cheating. It is easy to imagine that the winner of a ritualised fight could save itself the risk of future harassment by killing the loser, yet even animals with powerful jaws or horns rarely do this; instead they play by the rules. Similarly, if a dominant individual claims a territory by, for example, loud song, why do submissive individuals not bluff their way to success by singing?

The first attempt at a formal theoretical analysis of these problems was made a few years ago by John Maynard Smith (*Nature*, **246**, 15; 1973; *On Evolution*, Oliver and Boyd, 1972). Using game theory, Maynard Smith was able to analyse why physical violence (which he calls escalated fighting) does not replace the 'conventional' system of ritualised signals. His method of analysis was to look for an evolutionarily stable strategy, or ESS. An ESS is defined as a strategy which, when it is used by the majority of individuals in a population cannot be bettered by any alternative rare 'mutant' strategy. The 'strategies' which Maynard Smith considered included such alternatives as 'hawk'—an individual which always escalates—and 'mouse', which only plays the conventional game and retreats at the first sign of violence. He then assigned payoffs for winning, losing, getting injured in an escalated fight and so on, and used these values to construct a payoff matrix for each strategy against all others, including itself. It is intuitively clear that the hawk strategy does very well against a mouse; but does poorly in a population made up mainly of other hawks, because the risk of injury is high, so it is not an ESS. Only in the extreme case where losing a contest means certain death, say from starvation, will hawk persist as the best strategy. Otherwise the most likely ESS, for a wide variety of payoff values, was a mixed strategy of mainly ritualised display, but with escalation in retaliation to violence by an opponent. Fortunately, this seems to be the common pattern of contest in real animals. In another model Maynard Smith (*J. theor Biol.*, **47**, 209; 1974) showed that if a species has no method of escalating (because it does not possess dangerous weapons) so that the main cost involved in a contest is time, the ESS is again a mixed one with the distribution of persistence times given by the expression $(1/v)\exp(-x/v)$ where v is the value of winning and x the persistence time.

In a recent paper, Maynard Smith and Parker (*Anim. Behav.*, **24**, 159; 1976) have taken the analysis a step further by considering combats in which there is an asymmetry. In the real world two contestants will rarely be identical; one may be larger than the other, or may have more to lose, say because it has invested effort beforehand in establishing a territory.

In the latter case, where the payoffs are unequal, it is an ESS for the individual with more to lose (the territory holder for example) to invest more in the contest. Although there is a 'paradoxical' ESS in which the intruder invests more, Maynard Smith and Parker show that this ESS is unlikely to occur in nature, because, unlike the common sense ESS, the 'paradoxical' strategy cannot invade a hypothetical ancestral population which ignores the asymmetry. In the other type of asymmetry, where differences such as size give an indication of the probable outcome of an escalated fight, the ESS depends on how accurately each individual assesses its own size in relation to that of the opponent, and how good size is as an indicator of the outcome of a fight. It turns out that size, or some other such cue, will be used as a conventional means of settling a contest if the contestants estimate it with certainty, even if it is a poor predictor of the outcome of a fight. The ESS will be "always retreat if you think your opponent is larger, always escalate if you think he is smaller, and do something intermediate if he is the same size".

This automatically leads one to consider the question of bluffers. If it is an ESS for animals to use features such as size to settle asymmetric contests, can bluffers, individuals with the equivalent of padded shoulders, spread through the population? Maynard Smith and Parker conclude that bluff will always tend to spread but it is probably limited by the ability of other individuals to detect the difference between bluff and real fighting ability.

At the moment, this new approach to analysing ritualised contests is still in the theoretical stage, but some data seem to support the theory. Male dung flies (*Scatophaga stercoraria*) competing for females at newly deposited cowpats show the negative exponential distribution of persistence times predicted by the 'no escalation' model. Although this in itself is not a very surprising result, the fact that males with different persistence times have an equal chance of mating suggests that the distribution is in fact an ESS. •

Monocular deprivation and the input to the visual cortex

from A. M. Sillito

THE role of visual experience in establishing the functional properties of the developing mammalian visual system is a topic which has aroused considerable controversy and has been the subject of a recent review in *Nature* (Barlow, *Nature*, **258**, 199; 1975). There is however general agreement in this field that a normal input from the two eyes in early life is essential for maintaining an effective binocular input to visual cortical neurones. If monocular deprivation is produced in a kitten by suturing together the eye-lids of one eye at eye opening time for a period of two months or more it will be found that the majority of cortical neurones will be driven only by the non-deprived eye instead of both eyes as in a normal animal (Wiesel and Hubel, *J. Neurophysiol*, **26**, 1003; 1963). There is a critical period during which monocular deprivation is effective in producing these changes. In kittens it extends from some time in the third week of life to approximately three months and the effects of deprivation extending through the critical period seem to be irreversible despite subsequent long periods of normal binocular vision (Hubel and Wiesel, *J. Physiol.*, **206**, 419; 1970). Even quite brief periods of monocular deprivation during the first month of the critical period will result in the deprived eye's appearing to lose access to cortical cells and an essentially complete takeover by the non-deprived eye (Peck and Blakemore, *Expl Brain Res.*, **22**, 57; 1975). However, reverse suturing (opening deprived eye, suturing the normal) within the critical period can result in the previously deprived eye's regaining its ability to drive cortical cells and a complete reversal of the original situation can even occur in which all the cells are driven by the previously deprived eye (Blakemore and Van Sluyters, *J. Physiol.*, **237**, 195; 1974).

Of particular interest at present are the mechanisms contributing to the effects of monocular deprivation. Although there are morphological changes in the layers of the lateral geniculate body (the thalamic relay between the eye and visual cortex) receiving an input from the deprived eye the functional properties of these cells seem to be relatively unchanged (Wiesel and Hubel, *J. Neurophysiol.*, **26**, 987; 1963). In fact binocular deprivation produces similar morphological changes in the lateral geniculate body but does not result in a dramatic loss of binocularly-driven neurones (Hubel and Wiesel, *J Neurophysiol.*, **28**, 1029; 1965) This type of evidence together with the results of reverse suturing experiments carried out within the critical period have led to the view that there is a competitive interaction at the cortical level between the afferent terminals deriving from the respective eye inputs. It has been suggested that there may be an actual growth and reorganisation of afferent terminals (Movshon and Blakemore, *Nature*, **251**, 504; 1974) with the implication of a loss on cortical cells of some or all the terminals deriving from the deprived eye. Alternatively, it can be argued that during the critical period synapses that are used become 'more effective', whilst those that are not are in some way 'silenced' although still present, and that within the critical period this is a reversible process. A recent paper (Duffy, Snodgrass, Burchfiel and Conway, *Nature*, **260**, 256; 1976) has presented some important new evidence on this topic. They found, in cats monocularly deprived by lid suture from the fourth week of life to eight months, that intravenous injection of bicuculline revealed an input from the deprived eye to cells that were otherwise only driven by the normal eye. Thus they managed to reverse briefly the effects of monocular deprivation and furthermore they found that within this period, the receptive field properties in the two eyes were basically the same. The alkaloid bicuculline is an antagonist of γ-aminobutyric acid (GABA) in the central nervous system and GABA is a putative inhibitory transmitter in the retina, lateral geniculate body and visual cortex. Bicuculline applied iontophoretically to visual cortical neurones will produce changes in their receptive field properties that are consistent with a loss of an intracortical inhibitory input (Sillito, *J. Physiol.*, **250**, 305; 1975). Hence the results of Duffy *et al.* suggest that the deprived eye actually retains an input to cortical cells but that this is in some way suppressed by GABA-mediated inhibitory process. It is tempting to view this simply as a block of intracortical inhibition but the presence of GABA-mediated inhibition at other levels in the visual system means that intravenously injected bicuculline will produce changes in excitability throughout the system and this may contribute to the observed effect.

Whilst no one would dispute that monocular deprivation from the fourth week of life to the eighth month produces an irreversible loss of the ability to drive cortical cells from the deprived eye, it must be noted that in the experiments of Duffy *et al.* the deprivation started in the fourth week and not at eye-opening time. This means that the animals had approximately one week of binocular visual experience partially overlapping the beginning of the critical period. This is reflected by the similarity of the receptive fields in the deprived eye to those in the normal, an occurrence which if deprivation had been from eye-opening time might not be expected in so far as the receptive fields would be more likely to be of the immature type (Blakemore and Van Sluyters, *J. Physiol*, **237**, 195; 1975). It is important that the effects of intravenously injected bicuculline should be examined in a situation where monocular deprivation is started at eye-opening time, and hence where there will have been no opportunity for initial reinforcement of binocular input to cortical cells. Probably the most crucial experiment would be to examine the effects of iontophoretically applied bicuculline on visual cortical cells in monocularly deprived cats to see whether a local block of GABA-mediated intracortical inhibition can reveal an input from the deprived eye. With the present evidence in mind there seems little doubt that some type of inhibitory suppression of the input of the deprived eye, either with or without a concurrent loss of synapses or synaptic effectiveness, constitutes an important component of the cortical effect of monocular deprivation. ☐

T antigen and DNA synthesis

from Walter F. Mangel

POLYOMA and SV40 virus induce an intranuclear tumour (T) antigen early in lytic infection in transformed cells and in tumour-bearing animals. T antigen appears in lytically infected cells at the same time as the early virus-specific 19S mRNA and is followed by the induction of chromatin replication. This temporal sequence of events led to the hypothesis that T antigen is an early virus-coded protein which is responsible for the induction of cellular DNA synthesis that occurs after infection by papova viruses. In three recent articles from the laboratory of A. Graessmann in Berlin, direct experimental support consistent with this hypothesis is presented.

If T antigen is the early gene product

of polyoma, then microinjection of early polyoma RNA sequences into the cytoplasm of permissive cells might result in a positive immunofluorescence test for T antigen (Graessman *et al.*, *Nature*, **258**, 756; 1975). So polyoma DNA was symmetrically transcribed by the *Escherichia coli* DNA-dependent RNA polymerase. This complementary RNA (cRNA) contained both early and late viral sequences because the early virus-specific cytoplasmic RNA originates from 50% of the E strand of polyoma DNA and the late mRNA from 50% of the L strand (Kamen *et al.*, *Cold Spring Harb. Symp. quant. Biol.*, **39**, 187; 1974). On removing the DNA, the biological activity of the cRNA ($1\ \mathrm{mg\ ml^{-1}}$) was assayed after microinjection of about 10^{-11} ml into individual secondary mouse tissue culture cells Intranuclear T antigen was first detectable 6 h after cRNA microinjection in 6% of the cells Thereafter the number of T antigen-positive cells as well as the intensity of T antigen-specific fluorescence per cell increased, reaching a maximum of 70% of the cells between 20 and 24 h, before declining to undetectable levels 65 h after cRNA microinjection. V antigen (capsid protein) which is a late virus-coded protein (Mangel, Hewick and Smith, unpublished) appeared with the same kinetics as T antigen

Microinjection of asymmetrically transcribed SV40 cRNA which contains the early mRNA sequences not only results in T antigen formation but also in the induction of cellular DNA synthesis (Graessmann and Graessmann, *Proc natn. Acad. Sci. U.S.A.*, **73**, 366; 1976). Between 24 and 26 h after microinjection, 70–80% of the epithelioid cells of confluent primary mouse kidney cultures were T antigen positive. In pulse labelling experiments, the maximum proportion of cells synthesising DNA was reached between 15 and 20 h. During this time interval, 85% of the T antigen-positive cells were incorporating tritiated thymidine whereas only 3.2% of the mock injected cells in control experiments were synthesising DNA.

Important controls for these experiments included the demonstration that the biological activity of the cRNA was destroyed by RNase but not DNase. Although actinomycin D inhibited T antigen formation in mouse cells either infected with wild type polyoma virus or microinjected with polyoma DNA, it did not reduce the cRNA-induced T antigen formation within the first 15 h. Inhibition of protein synthesis by cycloheximide, added to the cells after cRNA injection, prevented T antigen formation Finally, neither total RNA nor polyadenylated RNA isolated from uninfected cells induced T antigen synthesis on microinjection.

In a series of preliminary experiments to confirm that the early genes induce T antigen the four fragments of SV40 DNA produced by the two restriction endonucleases *Hpa*I and *Hpa*II were individually microinjected into monkey cells (Graessmann *et al.*, *FEBS Lett.*, **61**, 81; 1976). Only one fragment induced T antigen synthesis and none induced V antigen synthesis. The fragment, which corresponds to 36% of the total genome, contains only 60% of the early region and thus could code for a protein with a molecular weight of up to 60,000. This is the size of the largest polypeptide immunoprecipitable by T antibody that is synthesised in the wheat germ cell-free system using asymmetrically transcribed SV40 cRNA as message (Roberts *et al.*, *Proc. natn. Acad. Sci U.S.A.*, **72**, 1922; 1975). But with early SV40 mRNA as message in the wheat germ system, the largest immunoprecipitable polypeptide synthesised has a molecular weight of about 90.000, which implies that the entire early region codes for T antigen (Smith *et al.*, and Prives *et al.*, in *In Vitro Transcription and Translation of Viral Genomes* (edit. by Haenni, A., and Beaud, G.,) **47**, 331 and 305, Editions INSERM, Paris, 1975) The results of Tegtmeyer (*Cold Spring Harb. Symp. quant. Biol.*, **39**, 9; 1974) indicate that the *in vivo* T antigen has a molecular weight of about 90,000. Thus the polypeptide induced by the *Hpa*I and *Hpa*II fragment may only contain some antigenic sites for T antibody and be biologically inactive. It would be interesting to know whether this fragment can induce DNA synthesis and transform cells.

The microinjection experiments support the hypothesis that T antigen formation requires early viral RNA sequences which must be translated and that all cells synthesising T antigen within the first 25 h of SV40 cRNA microinjection are also stimulated to synthesise DNA. The results are consistent with T antigen being the early virus-coded protein. They do not, however, exclude the possibility that T antigen is a cellular protein which is antigenically modified by the cRNA translation product. To show that T antigen is entirely a virus-coded protein, asymmetrically-transcribed SV40 cRNA must be translated *in vitro* and the product's tryptic peptides proved to be identical with those from T antigen isolated from transformed cells. Once T antigen is purified, the microinjection technique may be used to determine whether this protein is both necessary and sufficient for the induction of DNA synthesis as well as for transformation, an experiment whose results are eagerly awaited. □

Microtextures and rock deformation

from K. R. McClay

The rheology of rock masses in the Earth's crust and upper mantle has been the object of intensive study over the past decade, encompassing phenomena from the formation of slaty cleavage and mylonite genesis, to peridotite deformation. Results of research on these topics from schools in France, Germany, the Netherlands, Belgium, Great Britain, Australia, and America were presented at the recent conference on Fabrics, Microtextures, and Microtectonics, held on March 3–5, 1976, at Leiden, the Netherlands. The conference was organised by the Department of Tectonics, Leiden University, and papers arising will be published in a special issue of *Tectonophysics* later this year.

THE aim of the conference was an assessment of the role of fabric, microtextural and microtectonic information in the interpretation of geological processes. Microtextures (often called microstructures) are the morphological characteristics of rocks, embracing features from microfolding and cleavages to dislocation substructures The recognition of a particular microtexture as being characteristic of a certain deformational and thermal environment, is fundamental in structural geology. Relict microtextures, overprinting relationships and microtextural transisitions are all used in the estimation of temperature, pressure and rate of deformation for a geological event.

Fabrics are the distribution in space of discontinuities in rock masses, (that is, preferred crystallographic orientations). Increased application of X-ray texture goniometry and of metallurgical theories has generated a new impetus in fabric studies. Model studies of fabric development indicate that it may be possible to use fabrics as an aid in the determination of the deformation environment, strain history and the kinematics of deformation.

For a considerable time, the study of fabrics and microtextures was essentially the collection of data with little interpretation It now seems possible that a number of fabrics and microtextures may be understood in terms of the kinematics of deformation —particularly the evolution of foliations, mylonites, and sheared peridotites.

The first part of the conference dealt

with materials amenable to metallurgical techniques, and it became clear that research emphasis has changed from finite strain studies to kinematics, with the realisation that the kinematics of the deformation history have an important role (for example B. Hobbs (Monash University, Australia), and A. Nicholas (University of Nantes, France)). Crystallographic preferred orientations may reflect the influence of deformation paths as clearly documented in the field studies of quartz mylonites by J-L. Bouchez (University of Nantes) and by J. Carreras, A. Estrada (University of Barcelona), and S. White (Imperial College London). It was shown that the quartz *c*-axis fabric is dependent upon the deformation path of the mylonite. The experiments on marble by E. Rutter and M Rusbridge (Imperial College) support the theoretical predictions of the influence of the deformation path on the development of preferred orientations—particularly the predictions (G. Lister, Leiden University) that the new preferred orientations overprint the old fabric patterns after approximately 30% strain.

Theoretical fabric analysis using a metallurgical approach is a most exciting development. Using a Taylor-Bishop-Hill model, Lister has computed *c*-axis preferred orientations for quartz polycrystals utilising various combinations of slip systems. This allows simulations of deformations at a number of metamorphic grades to be made and the computed fabrics agree well with those found in naturally deformed quartzites. A. Etchecopar (Montpellier University) has used a different approach to fabric modelling with a two-dimensional single slip analysis which gives agreement with specific quartz and peridotite shear fabrics. These models allow postulates about the deformation mechanisms and the strain history of the rock to be made. For the first time a clearer understanding of fabric development and its complexities is at hand. In conjunction with fabric models, G. Davies (University of Cambridge) analysed the preferred orientation development in a deformed metal and demonstrated that, with the aid of orientation distribution functions, it is possible to assess the relative roles of various deformation elements such as glide, twinning and phase transformations during fabric development. Orientation distribution analysis, coupled with theoretical modelling is a potentially powerful tool in understanding rock fabrics.

Dealing with recrystallisation processes during or after deformation of a metal, J Jones (McGill University, Canada) pointed out that the differentiation between dynamic recovery, cyclic, continuous, or annealing recrystallisation was of fundamental importance in the development of fabrics and microtextures. A study of the deformation behaviour of single crystals of galena at various strain rates and temperatures (K. McClay and B. Atkinson, Imperial College) indicated that dynamic recovery and recrystallisation processes in galena occur at surprisingly low temperatures (for example migration of kink band boundaries at 200 °C).

Other important concepts brought out included the role of the yield surface both in single crystals and in polycrystals in determining the response of the material to an applied stress or to an imposed strain. In addition, Burgers vector and glide plane determinations seem critical in allowing further advance in theoretical models for deformation and fabric development. S. White (Imperial College) pointed out that subgrains may have a memory of deformation conditions and discussed in detail the problems associated with the use of dislocation substructures in rocks in which a substantial amount of recovery has occurred during or after deformation. This difficulty was also discussed in the light of an extremely interesting report on thermal decoration of dislocations in peridotite nodules (Y. Gueguen, University of Nantes).

In the second part of the conference, contributions on the formation of foliations in highly anisotropic minerals were discussed. P. Williams (Leiden University) reviewed foliation development, emphasising the role of initial kinking of phyllosilicate in producing foliations and indicating that the foliation will reflect the XY plane of the finite strain ellipsoid during all stages of development only in special cases. Experimental contributions to the study of foliated rocks since 1960 were reviewed by W Means (State University of New York). His experiments using salt/mica analogues produced very good approximations to natural crenulation cleavages and foliations as defined by mica films in deformed sandstones.

An extremely interesting contribution in this section on highly anisotropic minerals was that of A. Maltman (University College of Wales, Aberystwyth). His experiments on soft sediment deformation produced structures simulating those found in zones of incipient slaty cleavage formation. R Knipe and S. White (Imperial College) reported on a detailed high voltage electron microscopic study of slates showing the change from a crenulated fabric in the low strain zones around a fold to a well developed slaty cleavage at higher strains. Excellent high magnification micrographs give us our first good look at the fine structures which can be resolved optically only with great difficulty. Evidence for the growth of new phyllosilicates during the crenulation process was clear. A study of glacier deformation by M. Hambrey (Geological Institute, ETH, Zurich) illustrated the complexities of foliation development.

It can be concluded that the increasing application of metallurgical techniques and theories in a kinematic approach to rock rheology and microtextural problems is a promising direction for research. In particular, certain quartz fabrics can be explained using a kinematic approach. There are also important changes in the interpretation of foliations and cleavages. Initial crenulation of an already existing bedding plane fabric seems to have an important role in cleavage generation. The relationship between the cleavage plane and the finite strain ellipsoid may not be important. In all, the emphasis has changed from finite strain analysis to studies of deformation mechanisms and kinematics in order to understand both the strain paths and deformational processes in geology. □

Mobile spaghetti

from P. V. E. McClintock

One of the central assumptions of Vinen's 19-year-old theory of the supercritical state of superfluid ^{4}He has been challenged by Ashton and Northby in a recent issue of *Physical Review Letters* (**35**, 1714; 1975) on the basis of their experiments at the University of Rhode Island.

The superfluid properties which liquid ^{4}He displays below its transition temperature at 2.18 K can only be maintained if the liquid is treated fairly gently. Large fluxes of heat or high velocities of flow can cause the superfluidity to disappear abruptly, taking the liquid into a so-called supercritical state. The nature of the supercritical state which results when a large thermal current is passed through the liquid formed the subject of Vinen's historic series of papers in the *Proceedings of the Royal Society* (**A240**, 114 and 128, 1957; **A242**, 493; 1957; **243**, 400; 1958), and it is this topic which has again been under study, using a different experimental technique, at Rhode Island.

Below its transition temperature liquid ^{4}He behaves as though it were an intimate mixture of two interpenetrating fluids: a superfluid component, with zero viscosity, able to indulge in non-dissipative flow at low

SCIENCE COLLEGE
[illegible], Upper Circular Road
CALCUTTA

velocities; and a normal fluid component which has ordinary liquid properties and carries all the thermal energy. For small thermal fluxes, the liquid is almost a superconductor of heat, its being virtually impossible to set up a significant temperature gradient. This is because of a very efficient internal convection mechanism, whereby there is a flow of superfluid towards the heater, where it is converted into normal fluid and then flows away again through the oncoming superfluid, carrying heat towards the cold end of the apparatus. There is thus a counterflow of the two components without any net movement of the liquid. As the heat input is increased, however, a critical level is eventually reached at which the liquid undergoes a sudden transition to the supercritical state, and a finite temperature gradient spontaneously appears.

On the basis of a series of elegant experiments, Vinen was able to show that this discontinuous change in behaviour was a consequence of the appearance in the liquid of a tangled mass of vortex lines Just as in any other fluid, a vortex in helium consists of a narrow linear core region about which the fluid (for ^{4}He, only the superfluid component) rotates with a velocity inversely proportional to its radial distance from the centre: an interesting difference, however, is that the circulation, or "strength", of superfluid vortices in helium, being quantised, is always the same, which introduces enormous simplifications into any calculations of the supercritical state. According to Vinen, when the velocity of counterflow of the normal and superfluid components exceeds a certain critical value, vortex lines are generated and, by providing a dissipative mechanism, they enable a temperature gradient to be set up. In his model the vortex lines form an irregular tangle, with their cores being arranged somewhat like a bundle of spaghetti, but in continuous motion because each vortex exists in the flow patterns of all its neighbours and, indeed, of other parts of itself. It is assumed that vortex line is created at constant rate by the normal–superfluid counterflow, but that there also exists a mechanism by which the lines are destroyed. when two elements of line with opposite directions of circulation approach closely enough they can annihilate each other. Competition between the creation and annihilation mechanisms therefore results in an equilibrium length L_0 of vortex line per unit volume characterising the vorticity Vinen proposed that, in the equilibrium state, the tangle of lines was both homogenous and isotropic. The latter proposition also implied that the vorticity would, on average, be at rest relative to the superfluid so that, in a thermal counterflow experiment it would be moving towards the heater. What Ashton and Northby have now accomplished is the first satisfactory measurement of the direction and the velocity with which the equilibrium tangle of vortex lines moves relative to a laboratory frame of reference.

Their experimental apparatus, constructed from the insulating material Lucite, was in essence exceedingly simple. A heater was placed against the inside end wall of a 10 cm long channel of rectangular (0.5 cm × 1 cm) cross section, whose other end was left open to the helium bath in which the cell was immersed: by sufficiently energising the heater, the helium in the channel could thus be brought into the supercritical state, with a thermal counterflow of the normal and superfluid components occurring along the channel between heater and bath. At right angles to this counterflow, recessed in the side of the channel, was an arrangement for generating ions and directing them into the liquid, where some became attached to the vortex cores (there being an attractive force between an ion and a vortex arising from the kinetic energy of the rotating superfluid which the ion replaces). Any given ion, after being held like this for a while, was subsequently released as a result of the annihilation of the element of vortex line on which it had been trapped. An electric field was provided to draw freed ions to a pair of electrodes—one nearer the heater, the other nearer the bath—mounted on the opposite side of the channel from the ion generator. By noting whether trapped ions were being released upstream or downstream from the ion generator, it was possible to determine unambiguously in which direction the tangle of vortex lines was moving, and it was also possible to measure its drift velocity.

In the event, Ashton and Northby discovered that, quite contrary to the picture proposed by Vinen, the vorticity does not move with the superfluid component; furthermore, they have been able to show that it actually moves in the opposite direction, that is, in the same direction as the normal fluid component. The existence of a net relative velocity between superfluid and vortex lines implies that, to some extent at least, the vorticity is anisotropic.

These new results do not seem to be in conflict with other aspects of Vinen's model, but his theory is almost certainly going to need some significant modifications. The authors suggest a possible approach, but further experiments are clearly required before one can be sure they are right. □

No surprises for vitamin B_{12}

by Peter Newmark

It is always a bitter sweet experience when a highly sophisticated investigation does little more than confirm what lesser studies had already more or less demonstrated. The pleasure that is gained from confirming the predicted plot is countered by the disappointment at finding no unexpected twists, let alone a surprise ending. A good illustration of that principle is to be found in a recent study of transcobalamin II (TCII), the plasma protein that transports the cobalamins (vitamin B_{12}) between tissues (Schneider *et al.*, *J. clin. Invest*, **57**, 27; 1976).

For some years it has been known that most of the vitamin B_{12} in human blood is not attached to TCII but to the completely distinct transcobalamin I(TCI), one of a family of vitamin B_{12}-binding glycoproteins. Vitamin B_{12} attached to TCI is only slowly transferred into the tissues. If the vitamin is bound to TCII, however, it is rapidly cleared from the blood. This knowledge has been obtained with the aid of radioactive cobalt-labelled vitamin B_{12} and it has therefore been impossible to determine directly the fate of the transcobalamins, although tissue uptake of TCII has been indicated.

In 1972 Allen and Majerus succeeded in applying affinity chromatography to the isolation of the transcobalamins. As a consequence Allen and his colleagues have since been able to prepare radioactive iodine-labelled transcobalamins and to study their fate simultaneously with that of the labelled vitamin bound to them. When human TCI-vitamin B_{12} was injected intravenously into rabbits, clearance of both protein and vitamin was at about the same slow rate as that of labelled bovine serum albumin (Burger *et al.*, *J. biol. Chem.*, **250**, 7700 and 7707; 1975) unless the TCI was desialylated, when both protein and vitamin were extremely rapidly cleared into the liver in a manner remininscent of that described by Morell *et al.* (*J biol Chem.*, **246**, 1461; 1971) for various desialylated glycoproteins.

A different picture emerged when similar experiments were repeated with TCII-vitamin B_{12}'(Schneider *et al*, *J. clin. Invest*, **57**, 27; 1976). In the first place the native protein and its vitamin disappeared rapidly from circulation and second, their destination was widespread rather than being confined to the liver.

Since, initially at least, the transcobalamin moiety of the complexes always accompanied the vitamin, the information gleaned by having the protein independently labelled was not much more than had been known from studies of crude transcobalamins with labelled vitamin alone. A poor return, one might think, for having to produce, for labelling, transcobalamins purified several million-fold from several hundred litres of plasma.

More original, although also predicted, was the data obtained on the fate of the TCII following its uptake into tissues. After a 30-min time lag radioactive iodine appeared in the urine in rapidly increasing amounts and with a molecular weight of less than 1,000, indicating linkage to, at most, a small peptide. That can only mean that TCII had been rapidly degraded in the tissues. In contrast the vitamin was either retained in the tissues or returned to the blood stream, with little appearing in the urine.

Whereas it is easy to understand why the vitamin should be retained it is, as Schneider *et al.* point out, harder to explain the wasteful way in which TCII is destroyed in the process (compare transferrin). Various microorganisms appear to be able to release vitamin B$_{12}$ from TCII and it is difficult to see why cell surface enzymes could not have evolved to do the same.

Tissue uptake of transcobalamin–vitamin B$_{12}$ complexes probably involves pinocytosis, a process that threatens to come back into vogue in relation to receptor modulation (Raff, *Nature,* **259**, 265; 1976). Regardless of that there is little doubt that the transcobalamins are destined to receive more attention in the near future. In part that is thanks to the possibilities opened up by Allen's elegant techniques and in part it is motivated by despair. This year is the 50th anniversary of the discovery by Minot and Murphy (for which they were to share a Nobel prize with Whipple) that a diet of raw liver could control the previously fatal pernicious anaemia. But we are still at a loss to understand the biochemical basis for the prevention of that disease by vitamin B$_{12}$, the active component of liver. □

Central anomalies: why so strong?

from Peter J. Smith

WHEN marine magnetic anomalies were first analysed in detail in the early 1960s, it immediately became clear that their amplitudes decrease with distance from the corresponding oceanic ridge. Possible explanations for this phenomenon were not long in coming. For example, the magnetic constituents of the oceanic lithosphere newly formed along ridge axes may change chemically with time, giving rise to a gradual decrease of magnetisation. Another suggestion was that older igneous crust would be overlain by a thicker deposit of sediment, so the anomalies as measured at the ocean surface would be attenuated with respect to those observed above younger crust with less accumulated sediment.

But although these and some other processes, acting either individually or together, could possibly explain a gradual decrease in anomaly amplitude, they were apparently insufficient (at least in the form originally envisaged) to account for the precise form of decrease actually observed. For there is usually a particularly large reduction in amplitude immediately beyond the central anomaly followed by a much more gradual decrease outwards towards the continental margins. In the case of slow-spreading ridges (<30 mm yr^{-1} half-rate), for example, the central anomaly amplitude can be at least twice as high as those of near neighbours, although for faster-spreading ridges the difference is less marked.

More recently, near-bottom magnetic measurements have shown that not only does the central anomaly have a relatively high amplitude, there is often also a large-amplitude, short-wavelength (<15 km) anomaly within it. With slow-spreading ridges the latter is not generally observed separately at the water surface because of loss of resolution with distance from the ocean floor; the wider and narrower anomalies combine in such cases to give a very large central anomaly. Over fast-spreading ridges, on the other hand, the two anomalies can usually be clearly distinguished from each other.

One possible explanation of the relative strength of the wider central anomaly, first proposed by Matthews and Bath (*Geophys. J.*, **13**, 349; 1967), is that all magnetised oceanic crustal blocks except the central one are contaminated with material of opposing polarity, thereby reducing the strength of their respective anomalies. Harrison (*J. geophys Res.*, **73**, 2137; 1968), on the other hand, concluded that this phenomenon would be insufficient, suggesting that there must also be a 'demagnetising effect' outside the central region. Klitgord (*Earth planet. Sci. Lett*, **29**, 201; 1976) has now taken up the question of the demagnetising effect in the particular context of the narrower central anomaly. From a new analysis of both surface and near-bottom magnetic data from many different spreading ridges, she concludes that the narrower anomaly is due to a zone of high magnetisation coinciding with the region of most recent extrusion. The absolute strength of this magnetisation is regarded as that to be expected from newly-formed basalt recently quenched in seawater. Its large magnitude relative to that of the adjacent older basalt, however, is attributed to the fact that the latter rock has undergone low-temperature oxidation.

This is not the first time that oxidation has been seen as the cause of decreasing anomaly amplitudes. Klitgord's point, however, is that in the light of recent work oxidation can be invoked to explain not only the gradual reduction of anomaly amplitude away from a ridge but also the more sudden drop at the edge of the central anomaly. The recent work concerned is partly that of Butler (*J. geophys. Res.*, **78**, 6868; 1973) who concluded that small stable single-domain titanomagnetite grains become superparamagnetic when oxidised to titanomaghemite and thus lead to a greater reduction in magnetisation than the oxidation of pseudo-single-domain or multi-domain grains, and partly that of Watkins *et al.* (*Earth planet. Sci. Lett.*, **8**, 322; 1972) who found that fresh pillow basalt has a zone of fine grains immediately below the glassy outer rim.

The argument is that many of the fine grains in this zone will be single domains with high magnetisation, which means that they will contain a high percentage of a pillow's total magnetisation. A given amount of alteration in the zone will therefore have a much greater effect on the overall magnetisation than the same amount of alteration in the larger-grained pseudo-single-domain interior of the pillow. Moreover, being both fine-grained and close to the exterior, the zone will be much more susceptible than the interior to alteration in the first place. Rapid oxidation of the fine-grained zone is thus envisaged as the cause of the sudden amplitude drop outside the narrower central anomaly, whereas slower oxidation of the interior is seen as the cause of the more gradual amplitude decrease away from the ridge.

The widths of the narrow anomalies in the ridge systems studied by Klitgord range from 2 km to 10 km, which compare with several tens of kilometres for the main central anomalies. The magnetic relationship between the two anomalies never clearly emerges, however. At one stage Klitgord suggests that "the narrow magnetisation high probably does not account completely for the difference in amplitude between the central anomaly and the flanking anomalies", implying that it accounts for some, and perhaps even a high (but unspecified) proportion, of the difference. On the other hand, it is acknowledged that in some cases the narrow anomaly does not exist at all.

Effects of drugs on the processes regulating the functional activity of brain 5-hydroxytryptamine

A. Richard Green & David G. Grahame-Smith*

5-Hydroxytryptamine (5-HT), seems to be involved in depression and perhaps schizophrenia. A behavioural test of 5-HT action in animals has been used to clarify the mechanism of its action and the effects of various drugs used clinically in affective disorders.

5-HYDROXYTRYPTAMIME (5-HT) is present in the cell bodies and varicosities of neurones in specific tracts in the brain[1,2]. Much is bound to synaptic vesicles[3] and there is good evidence that it is synthesised at the sites at which it is found. In view of the circumstantial evidence, and in the absence of evidence to the contrary, it is assumed here that it acts as an orthodox neurotransmitter (see ref. 4). It has been suggested that 5-HT is involved in the hypothalamic control of body temperature[5], the sleep–waking cycle[6], pain sensation[7], and sexual behaviour[4]. There has been discussion about its role in schizophrenia[8], affective disorders[4], and morphine addiction[4].

To understand the physiological role of 5-HT and the effects of drugs on those systems in which it is involved, it is essential to consider the regulation of 5-HT synthesis and release and how both of these are concerned in its functional activity. There are probably four factors involved in presynaptic regulation: synthesis, compartmentation, intraneuronal metabolism and reuptake. These four processes are presumably integrated to control the release of appropriate amounts of 5-HT from the presynaptic nerve terminal, as well as the amount acting at the postsynaptic site and the termination of its action. The postsynaptic factors involved in the action of 5-HT may be considered at two levels: the postsynaptic receptor site itself and the total postsynaptic response, which depends on the activity of other neurones and may be influenced by other transmitters or drugs affecting them. These mechanisms will now be discussed.

Availability of the 5-HT precursor tryptophan

An important factor controlling how much 5-HT is made in the brain is the availability of its precursor tryptophan, because in physiological conditions tryptophan 5-hydroxylase, the enzyme limiting the rate of 5-HT synthesis, is not saturated with tryptophan (for review see ref. 4).

Administration or deprivation of tryptophan will raise or lower brain 5-HT[9–11] and small changes in plasma tryptophan alter brain 5-HT content[12]. After food deprivation[13,14] or immobilisation[13] there is an increase in brain tryptophan concentration and increased brain 5-HT turnover. The rise in brain tryptophan is not accompanied by changes in other amino acids[15] and correlates not with total plasma tryptophan[13] but with the fraction of tryptophan which is not protein bound[16] (free or ultrafilterable[17]). Tagliamonte and coworkers have also shown a relationship between free plasma tryptophan and brain tryptophan concentrations[18,19] and further demonstrated that salicylate, which displaces tryptophan from its plasma albumin binding sites, increases brain tryptophan and 5-HT synthesis[20].

The relationship between starvation and brain tryptophan may be due to the increase in plasma unesterified fatty acids brought about by food deprivation[16]. Curzon and colleagues have shown that addition of unesterified fatty acids increases free tryptophan in human plasma *in vitro*. *In vivo*, drugs which alter plasma unesterified fatty acid (UFA) concentrations alter plasma free tryptophan in the same direction[22]. Wurtman's group have found a similar relationship between plasma UFA and free tryptophan[23] but dispute the importance of free tryptophan in determining brain tryptophan concentrations and the rate of brain 5-HT synthesis. It is clear, however, that many factors influence the transport of tryptophan into the brain. Insulin release[24], ingestion of carbohydrates[25], the relative concentration of tryptophan to other plasma neutral amino acids which compete with tryptophan for uptake[26], and starvation[15], all affect the amount of tryptophan in the brain. Free tryptophan concentration is clearly therefore only one determinant of brain 5-HT turnover.

Recent work has now shown that hydrocortisone decreases brain tryptophan[27] and 5-HT concentrations[27,28]. This is due to increased activity of the heptatic enzyme tryptophan pyrrolase[27,28], which metabolises tryptophan and causes a decrease in the concentrations of free and total plasma tryptophan[29] and results in decreased concentrations of tryptophan not only in brain but in liver also[29]. This indicates another peripheral mechanism altering the availability of tryptophan and therefore brain 5-HT turnover.

Little is known of the processes by which tryptophan passes from plasma into the brain although it has been suggested that these are subject to diurnal rhythms which are accompanied by changes in brain 5-HT metabolism[30]. Tryptophan transport across synaptosomal membrane has been studied[31,32] and it has been shown that uptake is stereospecific, temperature dependent and inhibited by metabolic inhibitors, and that there are low and high affinity uptake systems. Several other amino acids compete for transport and exchange diffusion occurs.

Central control of 5-HT synthesis

Glowinski and colleagues reported that 5-HT synthesis was reduced when the intraneuronal concentrations of 5-HT were increased[33–35] by monoamine oxidase inhibition. These results and their interpretation are the matter of some dispute[36,37].

Chlorimipramine which inhibits the reuptake of 5-HT at the nerve ending[38,39] decreases the rate of 5-HT synthesis[40,41]. Since inhibition of reuptake potentiates the effect of 5-HT on 5-HT receptors[42,43] it may be that increased stimulation of 5-HT receptors causes inhibition of synthesis by a feedback mechanism. Modigh demonstrated that tryptophan hydroxylation was inhibited following chlorimipramine, possibly through an action on nerve impulse flow[44] in accord with observations that the hydroxylase is influenced by nerve impulse flow[45,46]. It has been shown that increased receptor stimulation does inhibit impulse flow in central 5-HT neurones[47]. Since imipramine

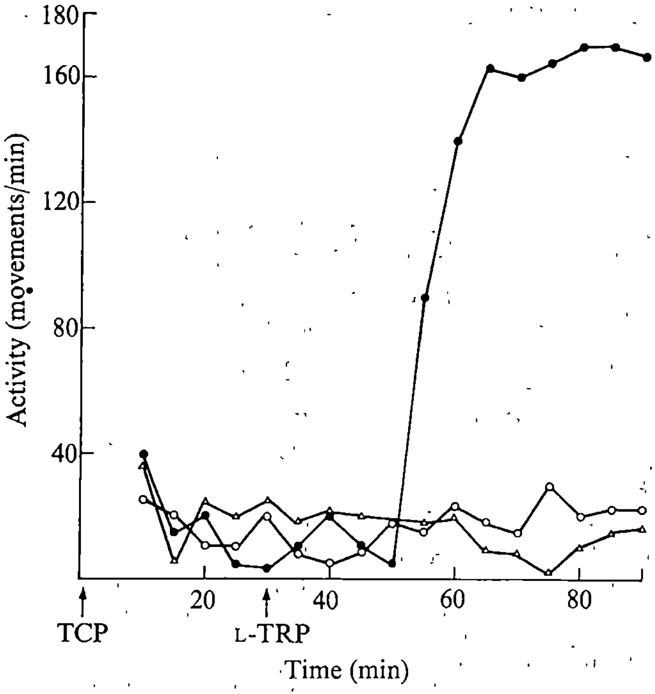

Fig. 1 Typical hyperactivity response in rats after administration of tranylcypromine (20 mg kg^{-1}) followed 30 min later by L-tryptophan (100 mg kg^{-1}) (●). Tranylcypromine administration only (○). Pretreatment with p-chlorophenylalanine (300 mg kg^{-1}) on two consecutive days before administration of tranylcypromine and tryptophan (△). Experimental details given in ref. 49.

inhibits tryptophan uptake by synaptosomes[48], however, some direct effects of chlorimipramine on 5-HT synthesis cannot be ruled out.

Functional activity of brain 5-HT

Our work was aimed at an understanding of how brain tryptophan concentration might control the rate of 5-HT synthesis and its functional activity. When L-tryptophan is administered to a rat there is a small increase in brain 5-HT concentration, but a large increase in the production of the 5-HT metabolite, 5-hydroxyindoleacetic acid (5-HIAA), indicating an increase in the rate of synthesis of 5-HT, which is then broken down by MAO. No gross behavioural changes occur. Administration of the same dose of tryptophan to rats pretreated with tranylcypromine, a MAO inhibitor, produces a large rise in brain 5-HT. This dependence of the rate of 5-HT synthesis on brain tryptophan concentrations is now well documented.

The increase in 5-HT is associated with characteristic behavioural changes, one of which is hyperactivity which can be measured on activity meters (Fig. 1)[49]. Appearance of the hyperactivity syndrome is dependent on MAO inhibition, tryptophan administration and tryptophan hydroxylase and 5-hydroxytryptophan decarboxylase activity (inhibition of either of these two enzymes with p-chlorophenylalanine and 4-bromo-3-hydroxybenzyloxyamine respectively, abolishes the hyperactivity (Fig. 1 and ref. 49)).

There is a positive correlation between the rate of accumulation of brain 5-HT and the rate of development of the hyperactivity, which suggests that the syndrome is produced by 5-HT[49]. Jacobs and colleagues have also demonstrated that the syndrome is the result of 5-HT stimulation[50,51]. Their studies[52] have shown that many of the behavioural aspects of the syndrome are present in the mesencephalic rat indicating that these behavioural changes are mediated by the B_1–B_6 group of neurones, which includes the pontine and medullary raphe nuclei and their synaptic contacts in the lower brainstem and spinal cord.

Our own recent biochemical studies[53] have strengthened the view that it is 5-HT and not a derivative that is responsible for the behavioural change, and we do not believe tryptamine is involved. The hyperactivity following tranylcypromine and tryptamine administration is inhibited by reserpine pretreatment[54], whereas that produced by tranylcypromine and L-tryptophan, far from being inhibited, has a more rapid onset following pretreatment with either reserpine or tetrabenazine, which block the storage or binding capacity of the synaptic vesicle[49].

The results of these experiments have been interpreted as follows (see also ref. 55). When tryptophan alone is given, the extra 5-HT synthesised is prevented from spilling-over into functional activity by intraneuronal binding and oxidative deamination. When MAO is inhibited the extra 5-HT accumulates at postsynaptic receptors, resulting in the hyperactivity syndrome. When intraneuronal binding is decreased by previous administration of reserpine or tetrabenazine and then MAO inhibited and tryptophan given, hyperactivity is enhanced because the "buffering" effect of vesicular binding against excess 5-HT production has been removed and more 5-HT "spills over" into functional activity.

This interpretation of the data has other implications. First, it suggests that the availability of tryptophan and the rate of 5-HT synthesis may not be very important in the fine regulation of the functional activity of 5-HT. Clearly the availability of tryptophan alters brain 5-HT metabolism but it seems unlikely that it is crucial in controlling the moment to moment functional activity of brain 5-HT. If synthesis were the only factor regulating the functional activity of 5-HT then it would follow that for each molecule of 5-HT released, a molecule would have to be synthesised and synthesis would therefore have to be critically and finely regulated from millisecond to millisecond to control synaptic events.

The second implication is that intraneuronal metabolism and binding of 5-HT are very important in controlling its functional activity. The third implication is that if a proportion of 5-HIAA is being produced intraneuronally from 5-HT which has not been functionally active then the measurement of 5-HIAA in the cerebrospinal fluid is likely to be of limited value as an index of the functional activity of 5-HT (see ref. 56 and later in the discussion of clinical implications).

Because 5-HT is stored in synaptic vesicles and decreasing this storage capacity alters the functional activity of 5-HT, compartmentation of 5-HT at the nerve ending might play an important role in regulating its functional activity and it has been suggested[49] that there is a prefunctional or reservoir pool, which nevertheless may be in equilibrium with the functional pool.

Unfortunately, at present the mechanisms involved in controlling the release of 5-HT are largely unknown so that fruitful discussion of this aspect is not possible.

To be able to investigate whether the drugs are acting on presynaptic mechanisms or postsynaptically the 5-HT agonist, 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) has been used. This compound causes a syndrome of hyperactivity qualitatively similar to that seen after tranylcypromine and tryptophan, but with a different time course[57]. It has therefore been used to bypass the effects of drugs on 5-HT synthesis, compartmentation or release and to investigate postsynaptic events.

Effects of lithium, diphenylhydantoin and chlorimipramine

Pretreatment of rats with one injection of either lithium[58] or diphenylhydantoin[41] causes the hyperactivity following tranylcypromine and L-tryptophan to begin earlier. There was no increase in 5-HT synthesis following one injection of either drug nor any change in response to 5-MeODMT indicating that postsynaptic responses were unaltered. Continued treatment with either of these two drugs caused an increase in 5-HT synthesis rate of 70% (lithium) and 100% (diphenylhydantoin).

It has been proposed that these two drugs may alter the compartmentation of 5-HT at nerve ending[58,59] thereby increasing the amount of 5-HT available for release and functional activity and that then leads to the increased rate of 5-HT synthesis. There is recent indirect evidence that diphenylhydantoin[60] (see also ref. 61) and lithium[62,63] increase brain 5-HT turnover in humans.

Inactivation of released monoamine by reuptake into the presynaptic nerve ending is well established[64,65]. We wished to see whether treatment with a known inhibitor of 5-HT reuptake would alter the hyperactivity syndrome. Pretreatment of rats with chlorimipramine before tranylcypromine and tryptophan caused the hyperactivity to begin earlier[41]. This may be because 5-HT cannot be inactivated by reuptake, and the concentration at the postsynaptic receptor site is therefore increased. One injection of chlorimipramine produced changes in the hyperactivity syndrome identical to those seen after one injection of diphenylhydantoin or lithium. But injection of chlorimipramine (25 mg kg^{-1}) twice daily for 2 d, with measurement of 5-HT synthesis on day 3 produced a 60% inhibition of 5-HT synthesis[41] in close agreement with a previous report[40], in contrast to the increased 5-HT synthesis seen after diphenylhydantoin or lithium. These findings suggest that diphenylhydantoin and lithium are not acting by inhibiting the reuptake of 5-HT.

Postsynaptic events

Finally we come to postsynaptic events as mechanisms for controlling 5-HT functional activity. Increasing the concentration of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) in the brain decreases the hyperactivity resulting from tranylcypromine and either tryptophan or 5-MeODMT administration[66].

Similarly, depletion of brain dopamine inhibited the hyperactivity from these two treatments[67]. Two interpretations can be made of this. Either a group of dopaminergic neurones lies between the 5-HT neurones responsible for initiating the hyperactivity response and those mechanisms responsible for its behavioural expression[67] or a group of dopaminergic neurones modulates the through-put from the activation of postsynaptic 5-HT receptors to the brain mechanisms responsible for the hyperactivity. It seems that this dopaminergic system may be involved in regulating the magnitude of the 5-HT behavioural response[68].

It had previously been shown that chlorpromazine inhibited the 5-HT induced hyperactivity without altering the rate of 5-HT accumulation[57]. It also inhibited the hyperactivity following 5-MeODMT. This suggested that it was acting at a postsynaptic site, probably by blocking 5-HT receptors[57]. Since there is good evidence that chlorpromazine blocks dopamine receptors[69,70] it now seems reasonable to suggest that it is inhibiting hyperactivity by interfering with the function of the dopaminergic mechanism, discussed above. Furthermore, recent studies (A. R. G. Heal, Boullin and D. G. G.-S., unpublished) have shown that other neuroleptic drugs, haloperidol, spiroperidol and α-flupenthixol (but not the clinically inactive isomer β-flupenthixol) also block 5-HT induced hyperactivity. All these drugs (except β-flupenthixol) also block the locomotor activity produced by a MAO inhibitor and L-dopa, strengthening the view that these drugs inhibit 5-HT responses by their action on dopaminergic neurones, though a direct effect to block 5-HT receptors has not been excluded.

Recently, we have found evidence that the sensitivity of the postsynaptic 5-HT receptor may be altered by electroconvulsive shock[71] While the short term changes of brain 5-HT metabolism seen in rats after a single electroconvulsive shock[71-73] cannot explain its therapeutic effect in humans, repeated electroconvulsive shock produces enhanced behavioural responses following 5-HT receptor stimulation. This may be because of a change in the sensitivity of the dopaminergic system involved in the 5-HT hyperactivity syndrome since postsynaptic dopaminergic responses are also enhanced by this treatment[71,74].

There is strong evidence that thyrotropin releasing hormone (TRH) over a restricted dose range, causes an enhancement of the hyperactivity that follows administration of tranylcypromine and L-tryptophan[75]. The effect was seen in hypophysectomised rats, and so could not have involved the pituitary–thyroid axis; nor did TRH alter the concentrations in the brain of 5-HT, dopamine or noradrenaline, or the rate of accumulation of 5-HT after administration of tranylcypromine and tryptophan. On the other hand, it did enhance hyperactivity after 5-MeODMT, which suggests a postsynaptic action on the response to 5-HT.

TRH has been shown not only to modulate several functions of dopaminergic systems[76-78] but to alter responses to several centrally acting drugs[75,79,81] and both in these and in the case of the hyperactivity syndrome, the administration of inhibitors of protein synthesis seems to act in a way that is generally "opposite" to that of TRH[80,81]. Since the synthesis of 5-HT itself was not inhibited by the drugs, it seems likely that this is another instance in which alterations in dopaminergic transmission influence the functional activity of 5-HT. Although it has yet to be demonstrated that TRH and the protein synthesis inhibitor cycloheximide act at the same site in the brain, both clinical and experimental evidence so far suggest that TRH may enhance[81-84], whereas cycloheximide inhibits, the release of dopamine in rat brain[81]. TRH is widespread in the brain[85-86] and unpublished observations (quoted in ref. 87) suggest that it is present in nerve endings along with a specific enzyme for degrading it, all of which is consistent with a modulatory role.

If polypeptides or proteins do mediate or modulate the actions of brain monoamines, then malfunction of such compounds might be confused with a primary abnormality in monoamine function. We found that although treatment with cycloheximide prevented the appearance of the hyperactivity syndrome after the usual doses of 5-MeODMT, increasing the dose of 5-MeODMT overcame this block[80]. It is just possible that in some psychiatric diseases attributed to primary abnormalities in monoaminergic function and which appear to respond to measures increasing or inhibiting monoaminergic activity, the abnormality lies with polypeptide or protein modulators.

In summary it is proposed that the functional activity of brain 5-HT is controlled predominantly by the following factors: (1) The availability of tryptophan to tryptophan 5-hydroxylase; (2) the regulation of the amount of 5-HT available for release by intraneuronal MAO activity and compartmentation such as vesicular storage mechanisms; (3) reuptake of 5-HT from the synaptic cleft; (4) sensitivity of the postsynaptic receptor; (5) regulation of the total postsynaptic neuronal responses through the influence of neuronal systems utilising other neurotransmitters such as dopamine. These processes are outlined in the hypothetical scheme presented in Fig. 2 with indications of the points at which various drugs are thought to act.

Clinical implications

The ethical problems posed by experimental psychopharmacology in humans are daunting. The introduction of really innovative drug therapy in psychiatric disease involves bridging the gap between experimental neuropharmacology and the manipulation of animal behaviour (which is fairly crude) and the manipulation of the neuropharmacology of the human brain to bring about subtle changes in the mind (which is likely to be a much finer process). What conclusions can be drawn from these studies of 5-HT function in rat brain, as mirrored by manipulation of the hyperactivity syndrome, which might help to bridge this gap?

Tryptophan alone produces an increase in the rate of 5-HT synthesis in both the rat brain and in the human brain (if 5-HIAA levels in cerebrospinal fluid can be relied on[56]), but neither hyperactivity in the rat nor, probably, relief of depression in the human results. A simple lack of brain 5-HT is therefore probably not responsible for the depressive state. Yet tryptophan plus a monoamine oxidase inhibitor produces hyperactivity in the rat and is an effective therapy for depres-

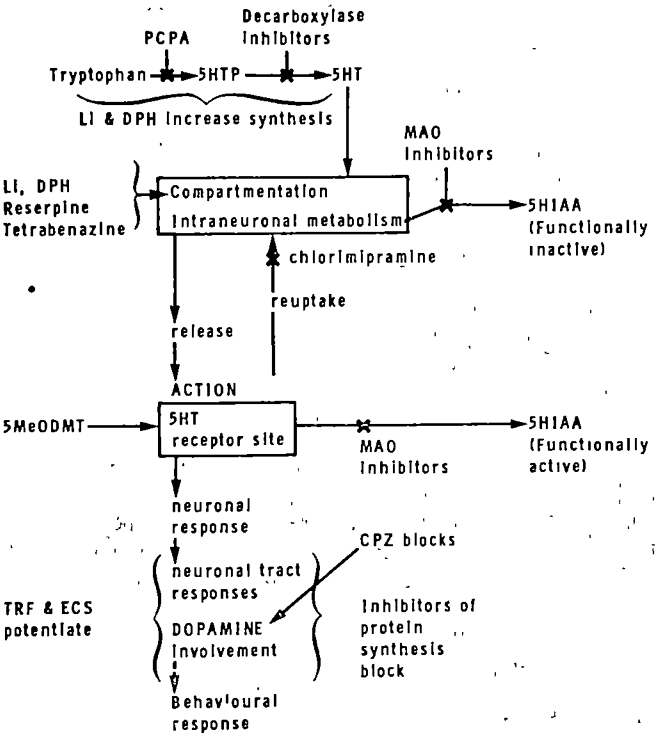

Fig. 2 Some postulated processes regulating 5-HT function and effects of drugs upon them. PCPA, *p*-chlorophenylalanine; 5-HTP, 5-hydroxytryptophan; 5-HT, 5-hydroxytryptamine; MAO, monoamine oxidase; 5-HIAA, 5-hydroxyindoleacetic acid; Li, lithium; DPH, diphenylhydantoin; 5-MeODMT, 5-methoxy-*N,N*-dimethyltryptamine; TRF, thyrotropin releasing factor; ECS, electroconvulsive shock; CPZ, chlorpromazine

sion[88]. In humans only relatively small doses of tryptophan can be used and MAO cannot be fully inhibited, so the problem is to find other mechanisms for increasing 5-HT function if indeed this is the mechanism by which tryptophan and a MAO inhibitor produce their therapeutic effect. For instance lithium or diphenylhydantoin might be used to render more 5-HT available for functional activity in combination with tryptophan and/or MAO inhibitors. Reserpine or tetrabenazine together with MAO inhibitors and tryptophan if carefully used may prove effective in retarded depression resistant to other forms of therapy[89]. Chlorimipramine, which blocks 5-HT reuptake, may in combination with MAO inhibitors and/or tryptophan also increase 5-HT function fairly selectively and might be used to chart those depressive states amenable to increasing 5-HT function. One might ask, why not just give a 5-HT agonist? 5-MeODMT and *N,N*-dimethyltryptamine while producing the hyperactivity syndrome are potent hallucinogens[90] but as far as we are aware small sub-hallucinogenic doses have not been tried in depressive states and perhaps the risk is too great. The possibility of more selective 5-HT agonists remains, however.

The similarity between the actions of lithium and diphenylhydantoin on brain 5-HT function prompts us to suggest the trial of diphenylhydantoin in the prevention of manic-depressive diseases. The adverse effects of diphenylhydantoin are well known through its long use in the treatment of epilepsy and they are certainly no worse than those already encountered with lithium. It should also be considered whether when a patient on "prophylactic" lithium for manic-depressive disease goes into a depressive state, MAO inhibitors given in conjunction with lithium might not be the best therapy.

For many years the presence of an endogenous psychotogen in schizophrenia has been sought, sometimes on the assumption that such an endogenous psychotogen could be produced by an abnormal metabolic pathway or by an abnormally functioning normal metabolic pathway. Because 5-MeODMT, itself an hallucinogen (and which has been invoked as an endogenous psychotogen in schizophrenia[91,92]), causes the same hyperactivity syndrome as is produced by raised 5-HT levels, we would suggest that abnormal functioning or increased activity of normal transmitters in their normal neuroanatomical pathways could equally be responsible for such changes. The worsening of the schizophrenic state reported after the administration of tryptophan and a MAO inhibitor[93] could be interpreted in this light. Since we have seen that postsynaptic mechanisms can change the behavioural response to brain 5-HT, schizophrenia could involve a change in the sensitivity of neuronal responses to "normal" stimuli.

The apparent interplay of dopamine and 5-HT in the production of the hyperactivity syndrome makes one wonder whether in psychiatric states some kind of imbalance occurs between neuronal systems containing 5-HT and dopamine, just as imbalances between cholinergic and dopaminergic systems seem to be involved in Parkinsonism[94]. These speculations are testable clinically using tryptophan, 5-HTP, and L-dopa, with or without (in the latter two cases) peripheral aromatic amino acid decarboxylase inhibitors.

The finding that chlorpromazine and some other neuroleptics, which it is generally agreed, block dopaminergic receptors in the brain, can probably by this action also block the sequences necessary for the production of the behavioural response to 5-HT, shows that these drugs may not be acting at a primary level, but rather at a secondary level in the therapy of schizophrenic illness. This has already been pointed out[8]. Nevertheless and in the loosest sense, perhaps the phenothiazines are capable of blocking the dopamine gates (and there may be several of them) through which several more primary stimuli may pass. There is no doubt that we need drugs which are not only pharmacologically more specific as agonist–antagonists but also show neuroanatomical specificity of function.

Finally, there is the controversy about the usefulness of 5-HIAA concentrations in the cerebrospinal fluid as an index of the functional activity of 5-HT in humans. This has been dealt with in a comprehensive review[56]. In animal studies 5-HIAA in the cerebrospinal fluid (CSF) does seem to reflect central 5-HT concentrations[95,96]. Furthermore, drugs affecting 5-HT turnover alter 5-HIAA in the lumbar CSF of human subjects[97-99]. Against this it has been shown that 5-HIAA injected into the cisterna magna of the cat does not change lumbar CSF 5-HIAA[99] although this is disputed[100]. Furthermore, patients with a spinal block at the thoracic level do not have decreased 5-HIAA[101,102]. Another study, however, showed substantially decreased CSF 5-HIAA in patients with an incomplete block[103].

Garelis and coworkers[56] argue convincingly that CSF 5-HIAA reflects central metabolic changes of 5-HT. If our earlier conclusions regarding the intraneuronal organisation of 5-HT synthesis, compartmentation and metabolism are correct, however, 5-HIAA comes not only from 5-HT that has been functionally active but from 5-HT synthesised in "excess of needs" which has been metabolised by monoamine oxidase intraneuronally. This means that CSF 5-HIAA concentrations include both of these "pools" of 5-HIAA and does not necessarily reflect the metabolism of 5-HT which has been released and has been functionally active.

Until we can measure that proportion of 5-HIAA resulting from the metabolism of functionally active 5-HT (and at present we have no idea under normal situations what this proportion might be) it is premature to conclude that changes in CSF 5-HIAA levels[56], or rates of rise of 5-HIAA in CSF after probenecid treatment with or without tryptophan loading[104], really indicate the functional activity of 5-HT in the brain. This is not to say that if consistent changes in CSF 5-HIAA are found to occur in certain affective disorders, the knowledge may not be empirically useful; but only to point out the hazards of interpreting the data in terms of the functional activity of 5-HT and its primary aetiological involvement in psychiatric disease.

The directional dependence of the primary cosmic rays of energies 10^{11} - 10^{12} eV

R. G. Marsden, H. Elliot, R. J. Hynds & T. Thambyahpillai

Blackett Laboratory, Imperial College, London SW7 2BZ, UK

The apparent sidereal variation in the intensity of muons generated by cosmic rays with energies greater than 10^{11} eV showed a marked change in phase at Northern Hemisphere stations at the time of the recent reversal in sign of the general solar magnetic field. No corresponding change was observed at rather lower energies at Hobart, Tasmania. By adopting a particular model of the large scale interplanetary field, it is possible to account for this behaviour of the sidereal variation in terms of a primary cosmic ray anisotropy which is related to the local direction of the galactic magnetic field.

SYSTEMATIC long term studies of the variations in intensity of muons deep underground have been carried out by a number of investigators to establish the existence of a variation over the sidereal day. The depths at which the observations relevant to this paper have been carried out lie in the range 30–80 m water equivalent (m.w.e.). At a depth of 60 m.w.e. most of the muons derive from primaries with an energy per nucleon of 10^{11}–10^{12} eV.

An experimental result that has become rather well established over the years is that in the Southern Hemisphere at Hobart (depth 32 m.w.e.) the sidereal variation has an amplitude of ~0.030% with a time of maximum close to 0600 LST whereas stations in the Northern Hemisphere, Budapest (40

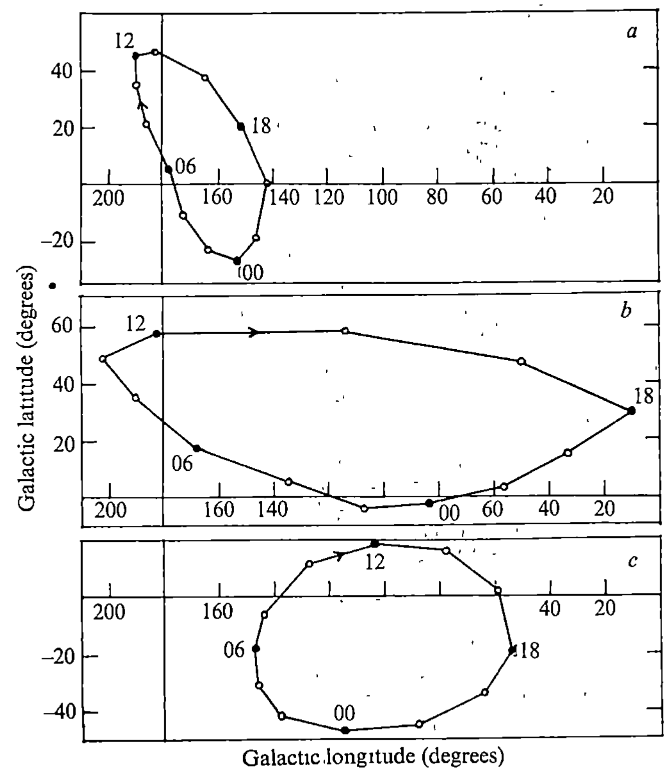

Fig. 1 Galactic scan directions for the vertical direction in London of the epoch 1 interplanetary field configuration. *a*, Average for October–February; *b*, for March–May; *c*, for June–September.

m.w.e.), London (60 m.w.e.), Socorro (80 m.w.e.) and Torino (80 m.w.e.), showed a rather smaller variation with a time of maximum displaced by almost 12 h from that in the Southern Hemisphere. Sekido[1], using a Cerenkov telescope to select high energy muons at ground level which are the progeny of primaries in the same primary energy band as those generating the underground muons, has obtained results which are in substantial agreement with the underground measurements.

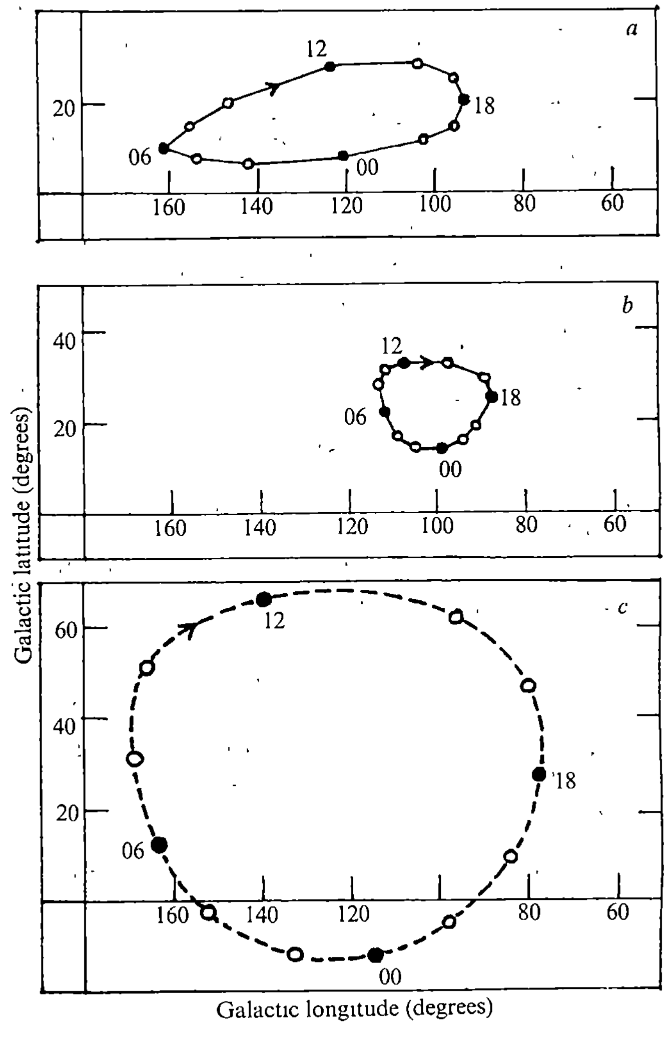
Jacklyn[2] and Sekido[1] have interpreted these experimental results in terms of a 'two-way' anisotropy of the primary cosmic rays in space. That is to say the intensity distribution has two maxima located on the celestial sphere in such a way as to be compatible with the observed times of maximum in the Northern and Southern Hemispheres. This assumes that the directions on the celestial sphere that are scanned by the underground cosmic ray detectors are not significantly affected by the interplanetary magnetic field. In other words the directions in space from which the primary cosmic rays arrive were taken to be those corresponding to the purely geometrical projection of the cone of acceptance of the telescopes on to the celestial sphere after allowing for the (small) deflection in the geomagnetic field. In fact we shall show that the presence of the interplanetary field changes very substantially the scanning directions of underground telescopes at the depths we are considering.

Speller *et al.*[3] and Barnden[4] have examined the effects of an interplanetary magnetic field model consisting of sectors in the meridian plane of alternate polarity on the trajectories of cosmic rays in the range of magnetic rigidities appropriate to muon detectors at 60 m.w.e. In particular Speller *et al.*[3] showed that the intensity variation over the sidereal day observed in the Northern Hemisphere could be accounted for by the motion of the solar system relative to the average rotation frame of the Galaxy in our neighbourhood. The cosmic rays are assumed to rotate with the Galaxy and the relative motion of an observer in the solar system then leads to a sidereal variation in close agreement with the observed amplitude and phase. The variation observed at Hobart could not, of course, be explained in this way since the time of maximum differs by 12 h from that expected for the solar motion effect, and in addition the amplitude is too large.

During the period after 1970 the sidereal variation observed at stations in the Northern Hemisphere changed markedly from that found in the earlier years. Data from the vertical recorders at the Holborn laboratory in London show that the sidereal wave has shifted in phase by ~180 ° so that the time of maximum is now ~0600 and has been for the past few years. Similar changes in phase have been observed at Torino by Cini-Castagnoli (personal communication) and by Swinson[5] for his Socorro station. This change in phase[6] seems to have taken place at the same time as the reversal of the large scale solar photospheric fields[7]. Neither the solar field nor the sidereal variation itself changed abruptly and, as far as can be seen, the change was spread over several years. For convenience, however, we assume here that the change took place at the end of 1969 and we shall refer to the period before the changeover as epoch 1 and the period from 1970 on, following the changeover, as epoch 2.

The change in phase of the sidereal wave is apparently confined to the Northern Hemisphere stations and has not occurred at Hobart[9]. As concluded by Cini-Castagnoli *et al.*[6] it is very likely connected with a change in the interplanetary field which is in turn related to the magnitude and sign of the photospheric fields. We have therefore been led to investigate

Fig. 2 Galactic scan directions for the vertical direction in London of the epoch 2 interplanetary field configuration. *a*, Average for April–July; *b*, for remaining months; *c*, scan for infinite energy particles.



the effects on cosmic ray trajectories of a rather different interplanetary field model from that used by Speller *et al.*[3] and by Barnden[4].

The interplanetary field model

It is clear that the changes in the large scale photospheric fields observed by Howard[7] must produce corresponding changes in the interplanetary magnetic field and evidence for such changes based on *in situ* spacecraft magnetometer measurements has been given by Rosenberg[9] and by Hedgecock[10]. There is no doubt that the presence of the interplanetary magnetic field affects the trajectories of primary cosmic rays of magnetic rigidity $\leqslant 10^{12}$ V which generate the bulk of the muons monitored at depths $<$ 80 m.w.e. and it is to be expected, therefore, that a substantial change in the field will in some measure influence the character of the sidereal variation.

As stated above the effect on such primaries of an interplanetary field with a 2- or 4-sector meridional structure has been investigated by Speller *et al.*[3] and by Barnden[4] and these authors have shown that this type of field does not scatter the relevant cosmic rays sufficiently to prevent the observation of a galactic anisotropy at the Earth although it does reduce the measured amplitude. It now seems possible, however, that the interplanetary magnetic field is not of this sectored form, but, instead, derives from a large scale solar dipole in which the field north of the solar equatorial field is predominantly of one sign while that south of the equatorial plane has the opposite sign[11,12]. The two-sector structure of the interplanetary field, which is the most frequently observed configuration, is then attributable to the tilt angle between the axis of the solar dipole and the Sun's rotational axis.

A field of this configuration has a much more serious perturbing effect on cosmic ray trajectories than one which is meridionally sectored, where the alternating sign of the field is to some extent self-cancelling so far as the particle deflections are concerned. Consequently there is good reason to suppose that the reversal of such a stretched dipole field would produce a significant change in the form of the cosmic ray anisotropy observed at the Earth.

In determining the directions on the celestial sphere scanned by an underground monitor in the course of the day it is necessary first to compute the trajectories of representative cosmic ray primaries which reach the Earth at the appropriate latitude and longitude for a variety of times of day throughout the year and then combine these with the response functions of the detector[13,14]. The interplanetary field model we have used is a simple idealised one of the form

$$B_r = B_0 \left(\frac{a}{r}\right)^2$$

$$B_\theta = 0$$

$$B_\varphi = B_0 \left(\frac{a}{r}\right) \sin\theta$$

where θ is the heliographic colatitude and B_0 is the radial component of the field at the Earth's orbit ($r = a$). Although, as stated above, the dipole axis must be inclined to the Sun's axis of rotation we do not know what this angle is, and for the purpose of the present calculation it has been taken to be zero. We have also assumed that to a sufficiently good approximation the radial and tangential components of the field at 1 AU can be taken as equal and written as $B_0 = 2.5$ nT. B_0 is positive in sign (the field is directed away from the Sun) everywhere north of the solar equatorial plane and negative everywhere to the south of it for epoch 2. The field in epoch 1 has been taken to be the exact reverse. These field directions correspond in sign to those measured in the photosphere. The trajectory integrations were terminated at a heliocentric distance of 30 AU, under the assumption that the field is ineffective at greater distances but extending the field model and the integration process to 100 AU does not significantly change the asymptotic directions of the trajectories.

Using these two field models, average viewing directions weighted according to the response function for a depth of 60 m.w.e. at London have been computed at 2-h intervals throughout the sidereal day for each month of the year for the two epochs. Certain months have very similar directional scans and to reduce the number of diagrams these have been combined together. Figures 1 and 2 show, in galatic coordinates, the effective 'direction of look' of the vertical underground telescopes as a function of sidereal time.

As Figs 1 and 2 show, reversal of a stretched dipolar field of the kind used in the trajectory computation has a significant effect on the directions scanned by the Holborn muon monitor in the course of the sidereal day. The corresponding purely geometric scan for infinite energy particles or zero interplanetary magnetic field is shown in Fig. 2 for comparison and it will be clearly evident that if the interplanetary field is of the form assumed it must be taken into account in interpreting the sidereal variation in terms of an anisotropic distribution of cosmic rays in space.

Cosmic ray intensity contours

The radius of curvature of the trajectory of a cosmic ray with magnetic rigidity 3×10^{11} V in the galatic magnetic field of ~ 0.3 nT is $\sim 3 \times 10^{14}$ cm which is very small compared with the dimensions of a spiral arm. It seems highly improbable that the transport mean free path in interstellar space can be much less than 1 pc, and consequently the motion of the primary cosmic rays we are concerned with can be considered to be nearly adiabatic in the galactic field. In these circumstances it is plausible to regard the cosmic ray directional distribution as essentially a pitch angle distribution having symmetry about the local direction of the magnetic field whatever that may be. If this picture is valid we would then expect the angular distribution of the cosmic rays to be symmetrical about the two points on the celestial sphere where it is intersected by the local field vector.

With this assumption of symmetry and the directional scans of Figs 1 and 2, the measured intensity variation over the sidereal day can be used to construct cosmic ray intensity contours for galactic longitudes in the range 0–200°. In doing so, it is necessary to correct the measured sidereal variation for two separate solar effects.

The first of these is the solar motion effect referred to above which can be calculated from the known solar velocity, the exponent of the cosmic ray spectrum in the relevant energy region and the directional scan diagrams. The second correction arises from the solar diurnal temperature wave in the terrestrial atmosphere which generates a spurious sidereal time variation of the muon intensity because of its seasonal dependence. The variation in the muon intensity underground which is generated in this way is a combination of pion and muon decay effects. The former leads to a positive temperature coefficient whereas the latter has the opposite sign. We have not attempted to calculate this correction from the (uncertain) atmospheric temperature variation but have instead made use of the spurious sidereal variation measured by inclined telescopes situated at the same depth in Holborn with their directions of maximum sensitivity directed along the Earth's axis of rotation. The 'sidereal variation' observed in this way arises entirely from atmospheric temperature variation, since such telescopes do not see any genuine variation from a primary cosmic ray anisotropy.

The intensity contours derived in this way are shown in Fig. 3, and Fig. 4 illustrates the degree of fit attained between the experimental data and these contours. In the latter diagram 2-h departures from the mean intensity over the sidereal day at Holborn averaged for the two epochs and corrected for the

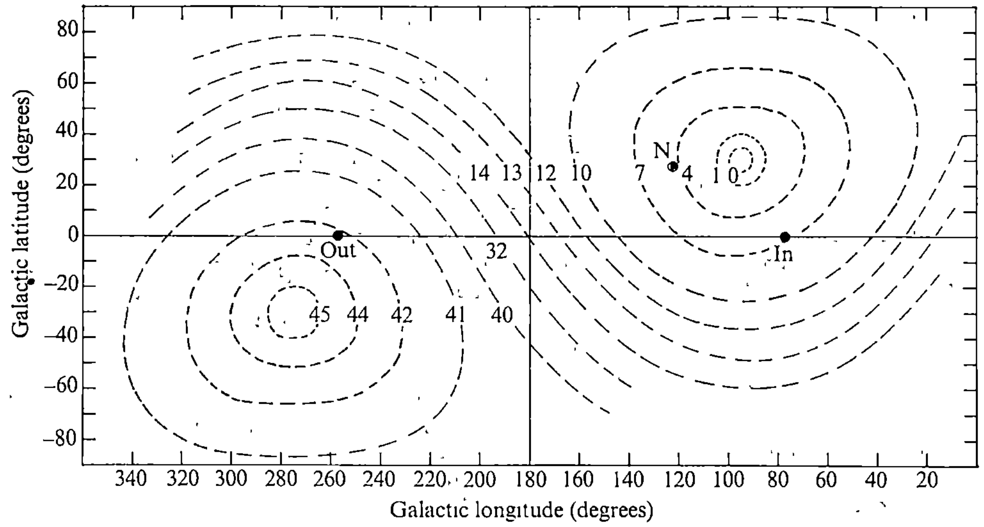


Fig. 3 Intensity contours in galactic coordinates inferred from the sidereal variation observed in London and Hobart. They are in units of 7.5 × 10^{-5}. 'In' and 'Out' correspond to the local spiral arm in and out directions. N is the direction corresponding to the Earth's North Pole.

two solar effects described above have been plotted together with the variation to be expected on the basis of Fig. 3.

To extend the contours derived from the London data to cover the complete range of galactic longitudes we have made use of observational data from Hobart together with galactic scan diagrams for that station, similar to those in Figs 1 and 2. It turns out that while the Hobart scans extend the range of longitudes covered beyond 200°, they also show considerable overlap with those for London, which permits a satisfactory patching together of the data. Figure 5 illustrates the degree of fit between the Hobart measured first harmonics and those deduced from the intensity contours of Fig. 3 for the two epochs. It is of particular interest to note that reversal of the interplanetary magnetic field does not reverse the phase of the sidereal variation in Hobart as it does in London.

Conclusions

In summary we believe that the observational data on the sidereal variation of cosmic rays in the energy range 10^{11}–10^{12} eV in both the Northern and Southern Hemispheres, including the phase reversal in the former, are all compatible with the intensity distribution shown in Fig. 3, provided that the field configuration in the interplanetary field model correctly describes the magnetic conditions in interplanetary space. The axis of symmetry of the cosmic ray distribution, which on this model should correspond to the local direction of the interstellar magnetic field, lies at ~25° to the Earth's axis of rotation. It is fortunate that the angle is not smaller, since the possibility of observing an anisotropy of the kind discussed here diminishes rapidly as this angle tends to zero, even for high energy particles where the effect of the interplanetary field is insignificant.

It has often been argued that the presence of the interplanetary magnetic field makes it impossible to observe any anisotropy for primary cosmic rays in this range, and that because of this, it is necessary to make such measurements at much higher energies, where the effect of the field on the particle trajectories is negligible. Our result is somewhat ironic in that the presence of the interplanetary magnetic field apparently results in a more favourable directional scan for the lower energy particles than for high energies because of the small angle between the Earth's axis and the axis of symmetry of the cosmic ray distribution.

Fig. 4. Corrected average 2-h departures of the cosmic ray intensity from the mean in London for epochs 1 (*a*) and 2 (*b*) together with the variation (dotted curves) expected from Fig. 3.

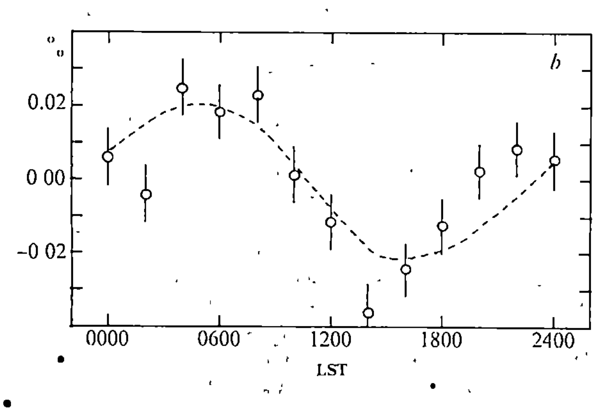

Fig. 5 Harmonic dials showing the 24-h sidereal waves to be expected from Fig. 3 (– – –) together with those measured in Hobart (——) for epochs 1 (*a*) and 2 (*b*).

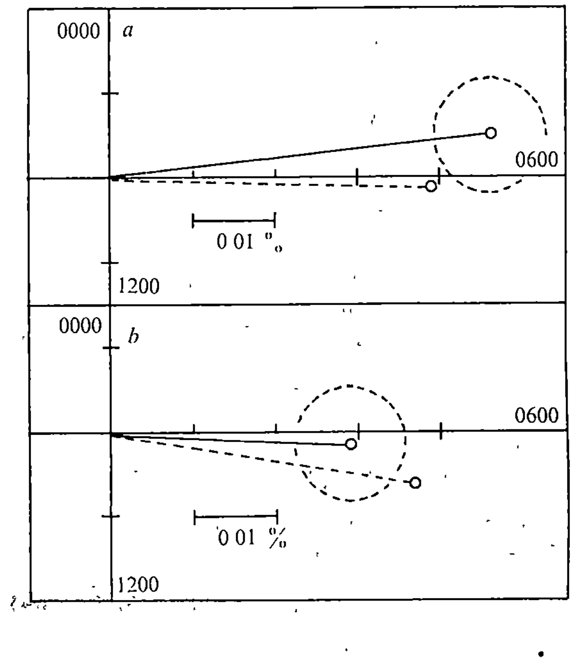

The question as to whether an apparent sidereal anisotropy can be simulated by purely local solar effects (see for example Swinson[16]) has often been discussed in the past and in this connection it should be borne in mind that the axis of symmetry of the distribution in Fig. 3 lies along the normal to the ecliptic, so that any preferential solar induced streaming of the cosmic rays perpendicular to the ecliptic plane could in principle produce an angular distribution similar to that described here. It does not, however, seem possible to reconcile other established characteristics of the sidereal variation with such a solar effect. In particular we are not aware of any solar process which is capable of explaining the change in phase of the siderial variation observed at Northern Hemisphere stations in 1969–70 together with the absence of any corresponding change at Hobart. In the absence of any satisfactory explanation based on solar processes alone it is our opinion that the angular distribution shown in Fig. 3 is most readily interpreted in terms of a galactic magnetic field pitch angle distribution.

Because of the low statistical accuracy of the measured sidereal variation, the uncertainty of the corrections applied, the relative insensitivity of the observational method which is a consequence of the small angle between the axis of symmetry of the intensity distribution and the Earth's rotational axis and, above all, the uncertainty in the interplanetary field model, the contours of Fig. 3 cannot be more than a very rough approximation to the truth.

Accepting, however, that within rather wide limits of uncertainty the intensity distribution is valid, a plausible explanation for such a distribution can be given. The intensity minimum of Fig. 3 is taken to correspond to the galactic magnetic field direction leading inwards towards the centre of the Galaxy, a not unreasonable assumption since it lies closest to the 'spiral in' direction of the local arm. If, then, cosmic rays of energy $> 3 \times 10^{11}$ eV are predominantly of extragalactic origin, this pitch angle distribution could be the result of the extra amount of galactic material traversed by particles whose trajectories are such that they arrive at the Earth after reflection at some point in the spiral arm closer to the galactic centre than the Solar System and where the magnetic field is stronger than it is in the neighbourhood of the Sun. An additional path length corresponding to the traversal of ~ 0.3 g cm^{-2} of interstellar matter would suffice to explain the observed departure from isotropy.

This work was carried out with the aid of an SRC grant and we are indebted to Dr C. J. Hatton for drawing our attention to an error in the interplanetary field model used in earlier calculations.

Genomic transcriptional activity and the structure of chromatin

Raymond Reeves & Alma Jones

Department of Zoology, University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5

Nucleic acid hybridisation has shown that micrococcal nuclease-derived chromatin subunits from the cells of Xenopus laevis *contain fragments of ribosomal 28S, 18S and 5S RNAs within the population of 200 base-pair pieces of DNA. Subunits from cultured embryonic cells actively transcribing ribosomal RNA contain only 70–74% of the cistrons present in undigested wild-type DNA, while subunits from adult erythrocytes not active in RNA transcription contain close to 90% of the ribosomal cistrons in native chromatin.*

CHROMATIN can be cleaved, either by endogenous nucleases[1] or by exogenously supplied micrococcal nuclease[2,3-7] into fragments containing discrete size classes of protected double-stranded DNA. Noll[2] has reported that about 85% of rat liver chromatin is susceptible to such digestion giving rise to a basic "chromatin subunit" with a sedimentation vale of 11.2S and containing about 205 base pairs of DNA associated with nucleoproteins. Kornberg[4] has proposed a model for chromatin structure based on such DNA subunits being associated on the outside of an octamer of histones[8,9] with the composition f2a1$_2$ f3$_2$ f2a2$_2$ f2b$_2$. Van Holde[10] has proposed a similar chromatin model. Histone f1 is not present in these subunits[3-7]. Electron microscopic[11-14] and neutron diffraction studies[15] have strongly supported such a beads-on-a-string model for chromatin. Little is known, however, about the functional significance of such a chromatin substructure. It is thus interesting to ask whether the areas of chromatin that are more accessible to various chemical probes, such as nucleases[16-21], are also the areas more active in genetic transcription. And, conversely, to query whether those areas of chromatin protected from ready nuclease digestion represent less active, or perhaps, repressed parts of the genome[22]. We present here results of nucleic acid hybridisation experiments in which purified ribosomal RNAs (rRNAs) have been annealed to the DNA from chromatin subunits prepared by micrococcal nuclease digestion of isolated nuclei. Nuclei were obtained from tissue culture cells actively transcribing the ribosomal genes and from mature erythrocytes, which are not active in transcription. By comparing the susceptibility to nuclease digestion of DNA in both transcriptionally active and inactive states we hoped to obtain information concerning the structure and function of native chromatin.

Isolation of chromatin DNA fragments

Nuclei isolated from embryonic *Xenopus laevis* tissue culture cells and treated with micrococcal nuclease (EC 3.1.4.7) for 4 min at 37 °C release, when lysed, pieces of chromatin that are integral multiples of a discrete particle size, the monomer

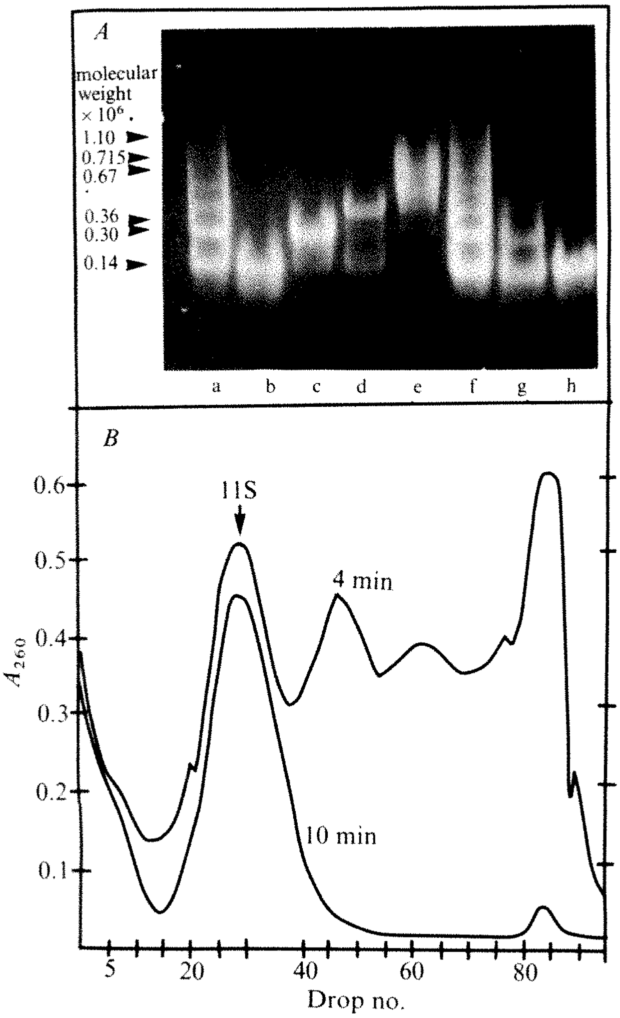

Fig. 1 *A*, Patterns obtained when DNA fragments were separated by electrophoresis on a 1.4% Agarose slab gel, stained with ethidium bromide and photographed under ultraviolet light using the methods of Sharp *et al.*[41]. The electrophoresis buffer contained 40 mM Tris base (*p*H 7.8), 5 mM sodium acetate and 1 mM EDTA. Electrophoresis towards the anode was for 2 h at room temperature on a Raven slab gel apparatus run at a constant 35 mA. Slot a: 15 μg of DNA fragments isolated from tissue culture cell nuclei that had been incubated with micrococcal nuclease (500 U ml^{-1}) for 4 min at 37 °C; Slots b–e: DNA fragments isolated from tissue culture cell monomer, dimer, trimer and tetramer (and larger) chromatin subunits separated by centrifugation on a 10–30% sucrose gradient run for 20 h at 30,000 r.p.m. in a Beckman ultracentrifuge using a SW 50.1 head; slots b–e contained, respectively, 10 μg, 10 μg, 5 μg, and 10 μg of DNA each. Slots f–h: sequence showing DNA fragments from timed nuclease digestions of tissue culture cell chromatin; slot f: 4-min digest of nuclei (30 μg DNA); slot g: 8-min digest (10 μg of DNA); slot h: 10-min digest (10 μg of DNA). *B*, Absorbance profile (at 260 nm) of chromatin subunits from actively growing tissue culture cells separated on a 10–30% sucrose gradient as described in (*A*). The sucrose solutions contained 0.2 mM EDTA and 2.85 mM phenylmethylsulphonylfluoride (PMSF). After centrifugation the gradients were pumped through a Uvicord II recording UV analyser and separated into fractions by drops. The upper curve gives the profile from a 4-min nuclease digest (at 37 °C) and the bottom curve the profile of a 10-min digest of tissue culture cell chromatin. Catalase, as a convenient marker for the 11S region, was run on a separate gradient. For preparation and micrococcal nuclease digestion of nuclei, exponentially growing tissue culture cells were collected by standard procedures[42] and washed in homogenisation solution (10 mM Tris-HCl, *p*H 7.8, 1 mM $MgCl_2$, 0.05 M $NaHSO_3$, 0.15 M sucrose) at 4 °C. The cells were then centrifuged at 250*g* for 10 min and the pellet was resuspended in hypotonic homogenisation solution (above buffer without sucrose) and swollen for 10 min at 4 °C. After further pelleting the swollen cells were resuspended in complete homogenisation solution containing 0.5% Triton X-100 and pipetted vigorously. After washing and pelleting the isolated nuclei were resuspended in homogenisation medium (without Triton X-100) containing 1 mM $CaCl_2$. Micrococcal nuclease was added to the solution (with concentrations of nuclei of up to 5×10⁸ per ml) to give a final nuclease concentration of 300–500 U ml^{-1} depending on the experiment. The nuclei were nuclease digested at 37 °C for the times indicated and then pelleted at 6,000*g* for 10 min. Erythrocyte nuclei were isolated by the procedures of Destree[43]. Chromatin particles were freed from the pelleted nuclei by homogenisation in the complete homogenisation solution containing 0.2 mM EDTA and 2.85 mM PMSF at *p*H 8.0 and 4 °C. Nuclear membranes and insoluble materials were removed by centrifugation. The chromatin-containing supernatant was then concentrated and dialysed against the appropriate buffer solutions for a particular experiment. Protein determinations were either by the method of Lowry[44] or by the use of the E_{280}/E_{260} ratio using appropriate standards. To isolate DNA, whole chromatin or chromatin subunits derived by nuclease digestion were dialysed against SSC (0.15 M NaCl, 0.015 M trisodium citrate, *p*H 7.8) before extraction of DNA by the technique of Brown and Weber[27,28].

subunit. The chromatin subunits have a sedimentation value of about 11S when run on a sucrose gradient (Fig. 1). The double-stranded DNA isolated from these monomers has a molecular weight of about 1.4×10⁵ as judged by its comigration during electrophoresis with marker viral SV40 DNA endonuclease restriction pieces of known molecular weight[23,24]. In Fig. 1*A*, columns a and f show the Agarose gel electrophoretic pattern of DNA fragments isolated from nuclei digested with nuclease for 4 min at 37 °C. On the left of the figure are the molecular weights of marker SV40 DNA pieces electrophoresed on the same slab gel. In the 4-min digest there are at least six DNA bands visible under ultraviolet light in this slab gel stained with ethidium bromide. These bands are, as shown by the molecular weight markers, integral multiples of the approximately 200 base pairs present in the monomer DNA. As columns g and h show, with increasing times of nuclease digestion, the larger multimeric DNA bands disappear from the profile so that by 10 min of incubation (column h) 70–75% of the bulk DNA in these tissue culture cells has been converted to the 140,000-dalton monomer DNA size. Such 10-min digests of culture cell chromatin were thus routinely used as a source of monomer DNA for most of the hybridisation studies reported here.

In all of these DNA preparations from nuclease-digested chromatin a slight smear of DNA fragments, with a few weak but distinct minor bands, electrophoresed faster than the major monomer DNA band. These bands do not show up very well on this photograph but were always a very minor fraction of the total DNA present in any preparation.

When the chromatin fragments from a 4-min digest of culture cell nuclei were centrifuged on a 10–30% sucrose gradient the absorbance profile of the gradient shown in Fig. 1*B* was obtained. As is evident, it is possible to separate the oligomeric chromatin fragments of the digest according to increasing size and weight on such gradients. The monomeric subunit migrates with a sedimentation velocity of about 11S as determined by using a catalase marker. Figure 1*B* also shows the absorbance profile of chromatin from a 10-min digest confirming that by this length of nuclease treatment virtually all the remaining DNA of the culture cells is of the monomer DNA size class. When the DNA from each of the gradient peaks from a 4-min chromatin digest are extracted and electrophoresed on an

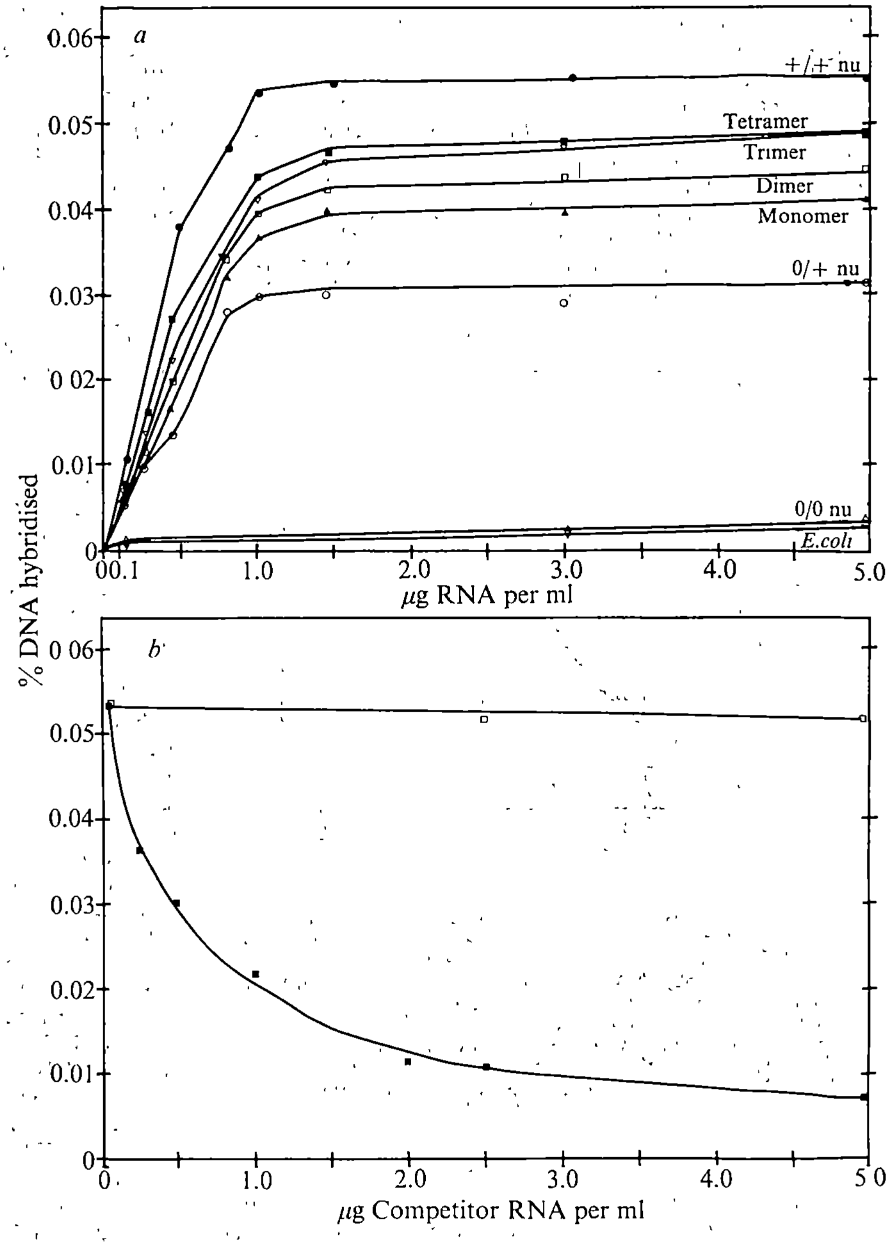

Fig. 2 *a*, Saturation profiles for hybridisations obtained from one experiment in which all DNA-containing filters were annealed in identical conditions with increasing concentrations of the same batch of purified ^{32}P-18S+28S RNA. The specific activity of the RNA was 728,000 c.p.m. per µg RNA. Monomer, dimer, trimer and tetramer (and larger) DNAs were isolated from logarithmically growing tissue culture cells as described in the legend to Fig. 1. Embryos of +/+ nu, 0/+ nu and 0/0 nu genotypes were obtained by mating two heterozygous anucleolate mutant frogs by standard techniques[45]; their DNAs were isolated as described. *E. coli* DNA was from Sigma. Curve codes as labelled. Each point is the average of the counts on two separate filters. Counts on filters were corrected for non-specific binding to blank filters (about 30 c.p.m.) and for loss of DNA from filters during the hybridisation. Each 6-mm filter initially contained 5–10 µg of immobilised DNA and during the annealing reaction no more than 10% of the DNA was lost from the filters. Loss was monitored by counting the radioactivity left after incubation on test filters to which high specific activity ^{14}C-DNA from *Xenopus* culture cells had been added. Hybridisation conditions were 2×SSC, 50% formamide, 45 °C, 16 h. *b*, Competition hybridisation curves obtained when increasing concentration of 'cold competitor rRNA' was added to an annealing mixture containing a constant amount (1.5 µg) of ^{32}P-18S+28S ribosomal RNA from *Xenopus* tissue culture cells. Conditions were as in (*a*) except that the specific activity of the ^{32}P-rRNA was 3.4×10^5 c.p.m. per µg RNA. ■, Unlabelled competitor *Xenopus* 18S+28S RNA; □, ^{32}P-18S +28S RNA. For hybridisation, whole or monomer DNA was prepared as described in the legend to Fig. 1. DNA determinations were by the method of Burton[46]. Whole, undigested DNA was sheared by either repeated passages through a 26 gauge needle or by homogenisation in a Virtis S23 homogeniser at full power for 1 min. Nuclease-derived DNA fragments were not sheared. For hybridisation experiments, the membrane filter technique described by Gillespie[34] was used. The purified DNA dissolved in 1/10×SSC at 100 µg per ml was heat denatured at 95 °C for 15 min. The denatured solution was cooled quickly in a dry-ice acetone bath and diluted with cold 6×SSC to a concentration of less than 10 µg per ml. The 6×SSC–DNA solution was made 0.05 M in KOH and 1 mM in MgCl$_2$ to increase the retention of small DNA fragments to nitrocellulose filters. Millipore HA filters (45 mm) were washed with hot (90 °C) 6×SSC, cooled and then loaded with the ice-cold single-stranded DNA solution by slow gravity filtration at 4 °C. Gravity filtration was repeated twice. The loaded filters were then treated for 1 h at room temperature with Denhardt's[47] preincubation mixture, dried and baked overnight at 60 °C. From each 45-mm HA filter, small 6-mm minifilters (each containing 5–10 µg of DNA) were cut. After annealing of DNA filters with radioactive RNA as described, the RNA–DNA hybrid-containing filters were washed extensively with 2×SSC followed by incubation for 15 min at 37 °C in 2×SSC containing boiled RNase (50 µg ml^{-1}). The filters were then dried and counted in an Isocap scintillation counter. All counts on filters were corrected for background and for channel spill over where two isotopes were used. To purify isotopically labelled RNAs, exponentially growing tissue culture cells in low phosphate medium were labelled for 3 d with ^{32}P as orthophosphate (New England Nuclear) and then chased for 48 h. Alternatively, cells in normal medium were labelled similarly with ^{3}H-uridine (New England Nuclear). Whole cell RNA was extracted and separated into fractions by polyacrylamide gel electrophoresis as described by Miller and Knowland[33]. Segments of the gels corresponding to either the 28S ribosomal RNA alone or to the 18S+28S rRNAs together were cut from the gels. The RNA was recovered from these gel fragments by electrophoresis against a dialysis membrane followed by ethanol precipitation. Radioactive 5S RNA, on the other hand, was recovered from the polysome fraction of ^{32}P-labelled tissue culture cells. RNA was extracted from polysomes and separated by gel electrophoresis as described above. The 5S RNA was further purified by chromatography on a Pasteur pipette column containing methylated albumin kieselguhr using a 0.2–1.5 M NaCl gradient for development[48].

Agarose slab gel the results shown in columns b–e of Fig. 1 are obtained. As expected, the peaks on the gradient correspond primarily to DNA fragments of increasing molecular weight. There is, however, always some minor cross contamination of all of the gradient-separated DNA bands. Nevertheless, by sucrose gradient separation it is possible to obtain greatly enriched populations of chromatin particles of a particular size class for extraction of DNA fragments for hybridisation experiments. The same experiments have also been done with DNA fragments of various sizes isolated by elution from Agarose gels after electrophoretic separation. The annealing results are similar in both cases.

Hybridisation with DNA from transcriptionally active cells

The reiterated ribosomal cistrons of *X. laevis* comprise about 0.2% of the nuclear DNA of diploid somatic cells[25,26]. This corresponds to 450–500 adjacent sets of ribosomal genes per haploid genome[25–27]. Each of these tandemly repeated gene sets, in turn, includes DNA which codes for a precursor to

18S and 28S ribosomal RNA as well as DNA for the untranscribed 'spacer' regions of high deoxyguanylic and deoxycytidylic acid (G+C) content[28,29]. Thus the DNA from wild-type animals contains about 1,000 sets of these ribosomal cistrons per diploid genome. Within the cell nucleus of such wild-type animals there are usually two nucleoli (hence they are +/+ nu) with each nucleolus containing about half of the total ribosomal cistron sets localised to a nucleolar organiser region of one of the chromosomes[30]. There is also a stable mutation, the anucleolate mutation[31] known in certain strains of these animals which involves the total deletion of the reiterated cistrons from the normal nucleolar organiser region of the chromosome[30]. Animals heterozygous for this mutation (+/0 nu) contain only half the normal complement of ribosomal cistron sets and have only one nucleolus per diploid somatic cell. Individuals homozygous for the anucleolate mutation (0/0 nu) have no detectable ribosomal 18S and 28S cistron sets[30] and die at an early larval stage. DNA isolated from either +/+ nu, +/0 nu or 0/0 nu embryos was used as reference standards for the nucleic acid hybridisation studies reported here.

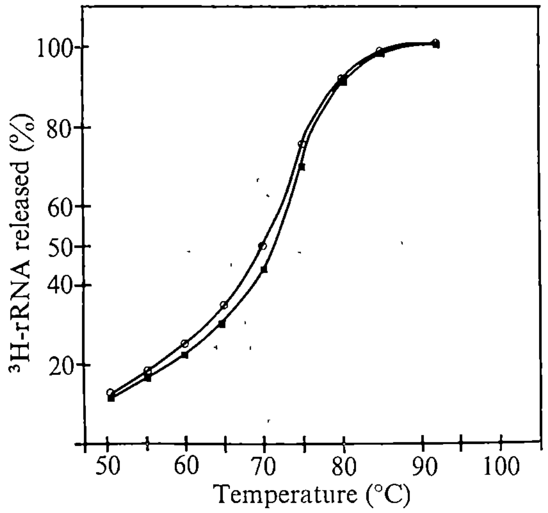

Fig. 3 Thermal dissociation profiles of rRNA–DNA hybrids of sheared whole DNA (○) and nuclease-derived monomer DNA (■) from actively growing tissue culture cells. Filters containing (28S+18S)RNA–DNA hybrids were heated in 1 ml of 0.1×SSC for 5 min at each temperature, and the radioactivity released was measured after precipitation with cold trichloroacetic acid. At no temperature were the ^{3}H counts released from the filters able to rebind to other membrane filters, showing that intact hybrids were not released[34]. Line codes as labelled.

Figure 2*a* gives the results of saturation hybridisation experiments with purified 18S + 28S ribosomal RNA annealed to DNA immobilised on nitrocellulose filters in the low temperature-formamide hybridisation conditions of McConaughy *et al.*[32]. Detailed hybridisation information is given in the legend to Fig. 2. The hybridisation conditions chosen (2×SSC, 50% formamide, 45 °C) correspond to incubation at 25 °C below the T_m of *Xenopus* rRNA–DNA hybrids and ensures both a high specificity of annealing and fast reaction rate[33].

The specificity of the hybridisation reactions reported on here are indicated by the following findings: (1) there is only a slight reduction in the number of RNA–DNA hybrids retained on a filter after RNase treatment to eliminate partially paired hybrids[34]; (2) reproducible saturation plateaux are attained after ribonuclease treatment of the hybrids; (3) unlabelled ribosomal RNA competes effectively with isotopically labelled rRNA in annealing experiments (Fig. 2*b*); (4) there is high thermostability of both sheared whole DNA–rRNA hybrids and chromatin monomer DNA–rRNA hybrids (Fig. 3) with T_m values in agreement with those reported by others[26,35,36] in the same salt conditions; and (5) the saturation plateaux obtained with hybridisation of 18S and 28S ribosomal RNAs to DNAs from +/+ nu, +/0 nu, and 0/0 nu animals are within the range of expectation[27,30,33].

Figure 2 shows the results from one hybridisation experiment in which all DNA filters were annealed with increasing concentrations of the same batch of ^{32}P-labelled RNA in identical hybridisation conditions. Figure 2*a* shows that undigested DNA isolated from wild-type (+/+ nu) embryonic tissue culture cells reaches a saturation plateau of about 0.056% of the DNA hybridised even at low concentrations of input ^{32}P-rRNA (that is, at about 1.5 μg per ml of RNA). On the other hand, DNA from 0/0 nu embryos homozygous for the anucleolate mutation does not hybridise above the level of heterologous *E. coli* DNA, confirming the absence of detectable ribosomal cistrons in these embryos. DNA from heterozygous +/0 nu embryos has an intermediate saturation level between these two at about 0.032% hybridised corresponding to about 550 copies of the 18S and 28S ribosomal cistrons per cell. As is evident, the saturation plateaux for monomer, dimer, trimer and tetramer (and larger) DNA fragments fall above this heterozygote level but do not reach the level of hybridisation of undigested wild-type DNA. In addition, the saturation plateaux for longer pieces of DNA (in dimers, trimers and so on) are seen to reach increasingly higher levels compared with that of the monomer DNA. The plateau level for 18S+28S rRNA annealed to monomer DNA from exponentially growing tissue culture cells averages about 0.043% of the DNA hybridised (from four experiments). This represents about 72% of the level of hybridisation for bulk undigested DNA from the same cells. A similar reduction in the number of ribosomal cistrons in monomer DNA is obtained if hybridisation experiments are done with purified 28S ribosomal RNA alone (Table 1). Again, only about 73% of the number of 28S ribosomal genes present in sheared whole DNA are found in monomer DNA. These results most probably indicate that 28S and 18S ribosomal DNAs are both equally accessible to nuclease digestion in these transcriptionally active tissue culture cells.

As Fig. 2*a* shows, larger pieces of nuclease-cleaved DNA seem to contain greater numbers of rDNA fragments than do smaller pieces. Exact quantitation of the relative numbers of cistrons present in these increasingly long oligomers is difficult,

Table 1 Saturation hybridisation of DNA from logarithmic phase embryonic tissue culture cells with purified 28S and 5S ^{32}P-RNA

RNA*	DNA	μg of RNA per μg of DNA ×100±s.d.§	Mean no. of gene† copies per genome	No. of genes‡ as % of wild type
28S	Undigested	0.041±0.002	982±48	100
28S	Monomer	0.030±0.003	718±72	73
5S	Undigested	0.055±0.005	56,485±5,130	100
5S	Monomer	0.040±0.008	45,170±8,200	80

*Specific activity of ^{32}P-28S RNA was 6.4×10^5 c p.m. per μg RNA; of ^{32}P-5S RNA, 1.1×10^6 c.p.m. per μg RNA

†Calculations based on assumption that each somatic diploid cell contains about 6 pg of DNA[26,29] and that 28S RNA has a molecular weight of 1.5×10^6 and 5S RNA a molecular weight of 35,000 (refs 26, 27, 35 and 36).

‡The assumption is made that a weight of monomer DNA equivalent to the weight of DNA in a normal somatic cell is a genome equivalent.

however, because of the limitations of sensitivity of nitrocellulose filter hybridisation reactions.

Hybridisation using transcriptionally inactive cells

The mature nucleated erythrocytes of *X. laevis* are, as are most vertebrate erythrocytes, transcriptionally quiescent and do not synthesise detectable amounts of rRNA[37].

Chromatin from adult red blood cells was thus chosen for comparison with the transcriptionally active culture cells to determine whether there are detectable differences, in terms of accessibility to nuclease digestion, between synthetically active and inactive genes. The results of hybridisation experiments using 18S+28S rRNA or 5S RNA to saturate either bulk or monomer DNA from adult erythrocytes are given in Table 2.

The saturation levels for hybridisation of both types of RNA to undigested bulk erythrocyte DNA are similar to the plateaux for the same types of RNAs annealed to bulk culture cell DNA (Fig. 1 and Table 1). Erythrocyte monomer DNA (either obtained from gradients or eluted from gels after electrophoretic separation), however, consistently gave higher annealing plateaux for both the 18S+28S and 5S RNA populations than did monomer DNA derived from the synthetically active culture cells (compare Fig. 1 and Table 1). Thus an average of 86% of the 18S+28S ribosomal cistron DNA was protected from degradation in the erythrocyte chromatin subunits compared with about 72% being protected in the culture cell monomers. Similarly, close to 90% of the DNA coding for 5S RNA was recovered in blood cell monomers compared with only about 80% from embryonic cell subunits.

Structure of chromatin

The hybridisation results reported here support the notion that there is no simple, straightforward relationship between chromatin accessibility to micrococcal nuclease digestion and the transcriptional activity of the chromatin itself[16–21]. Most reiterated ribosomal cistrons and 5S genes are associated with protective proteins in the form of subunit particles whether the genes are being actively transcribed or not (Fig. 1, Tables 1 and 2). On the other hand, even in the chromatin of transcriptionally quiescent erythrocytes there are regions or stretches of DNA comprising up to 10–15% of the total reiterated gene copies that can be cleaved by nuclease attack (Table 2). Whether these 'open' regions of DNA in the inactive red cell chromatin reflect the fact that 10–15% of each of the multiple gene copies present are accessible to digestion or simply mean that 85–90% of all of the ribosomal genes are completely protected by monomer proteins cannot be determined from the data.

A similar ambiguity exists when considering the data presented in Fig. 1 and Table 1, showing that there are fewer ribosomal gene sequences protected from nuclease digestion in the chromatin of transcriptionally active cells than in chromatin that is not active in synthesis of rRNA. These data could be construed to mean that transcriptionally active DNA is more 'free' or 'open' than inactive DNA. But there are several technical and theoretical uncertainties, perhaps the foremost being the difficulty of interpreting hybridisation data concerning the transcriptional activity of genes that are present in multiple copies within a genome. For instance, it is not known what fraction of the total number of reiterated genes is functional at any given time within a random population of growing cells. Even though RNA is synthesised continuously throughout the cell cycle (except in mitotic cells)[38], it is not at all clear that all of the genes coding for rRNA need be active in transcription at the same time.

An example of this latter problem for the somatic cells of *X. laevis* comes from the work of Knowland and Miller[33,39]. These investigators have demonstrated that the absolute rate of ribosomal RNA synthesis is the same in wild-type (+/+ nu) and 0/+ nu embryos even though the latter embryos had only half the normal complement of ribosomal cistrons. These results were interpreted to mean that either the 0/+ nu embryos had doubled their rate of transcription of ribosomal genes or that the same number of active rRNA genes were present in both wild-type and mutant animals.

This report thus lends experimental support to a model of chromatin structure in which most of the DNA within genes is associated with proteins to form a 'chromatin subunit' whether or not the genes are actively involved in transcription. The data can also be interpreted to support the view that, during active transcription, genes may have all or some parts of their DNA in a more open or free configuration so as to allow ready access to heterologous molecules, such as experimentally applied nucleases. As discussed, however, this latter interpretation is still a matter of speculation. A direct test of this hypothesis might be to determine the nuclease accessibility of +/0 nu embryo chromatin (in which all of the ribosomal genes must be active for survival) before and after the onset of ribosomal RNA synthesis at the gastrula stage of development[40]. Such experiments are in progress.

We thank Dr J. B. Gurdon for +/0 nu animals and Dr H. Boyer for restriction pieces of SV40 DNA. We also appreciate many helpful discussions of Drs D. Baillie, P. Candido, B. Honda, F. Wilt and H. Woodland. This work was supported by a grant from the National Research Council of Canada.

Complete nucleotide sequence of bacteriophage MS2 RNA: primary and secondary structure of the replicase gene

W. Fiers, R. Contreras, F. Duerinck, G. Haegeman, D. Iserentant, J. Merregaert, W. Min Jou, F. Molemans, A. Raeymaekers, A. Van den Berghe, G. Volckaert & M. Ysebaert

Laboratory of Molecular Biology, University of Ghent, 9000 Ghent, Belgium

Bacteriophage MS2 RNA is 3,569 nucleotides long. The nucleotide sequence has been established for the third and last gene, which codes for the replicase protein. A secondary structure model has also been proposed. Biological properties, such as ribosome binding and codon interactions can now be discussed on a molecular basis. As the sequences for the other regions of this RNA have been published already, the complete, primary chemical structure of a viral genome has now been established.

RNA BACTERIOPHAGES such as MS2 have been important in molecular biology not only because they provide a model system for investigating viral RNA replication and the physiology of the infected cell, but also in the study of fundamental processes such as translation[1]. MS2 RNA contains the genetic information to specify three viral polypeptides (Fig. 1). The first two genes code for the A protein and the coat protein, which are structural elements: the virus particle contains one A-protein molecule[2] and approximately 180 coat protein molecules. For practical reasons, most knowledge of the *in vitro* replication of phage RNA is based on work with a purified system derived from cells infected with the distantly related bacteriophage Qβ (reviewed in ref. 3), but the principal findings are presumably also valid for the MS2 phage group[4]. The enzyme complex responsible for viral RNA replication has been referred to variously as viral RNA-dependent RNA polymerase[5], RNA synthetase[6] and replicase[5]. As the latter name is simple and unambiguous we use it here. The replicase complex consists of four polypeptides, α, β, γ and δ[4,7,8]. β is specified by the third and last viral gene and has a molecular weight of approximately 63,000 (ref. 4). α has been identified as the 30S ribosomal subunit S1 (ref. 9) and γ–δ as the elongation factors Tu–Ts[1,3].

The expression of the three viral genes is strictly regulated. The A-protein gene is presumably only translated from chains in a nascent state[1,10,11]. The replicase gene is subject to a polar control by the coat gene; this means that the latter has to be translated to allow expression of the replicase gene[1,10]. Moreover, the coat protein represses the replicase gene[1,10] while the replicase complex in turn might be involved in shutting off coat gene expression[12]. Regulation of the frequency of gene expression by modulation has also been proposed[13,14].

We have shown that the MS2 genome starts from the 5′ end with a 129-nucleotide untranslated leader sequence (Fig. 1)[15]. Then follows the A-protein gene which starts with a G–U–G initiation codon and ends with a U–A–G codon[11,16], an intercistronic region of 26 nucleotides, the coat protein gene[14], an intercistronic region of 36 nucleotides[14,17], the replicase gene (see below) and finally a 174-nucleotide untranslated segment at the 3′ terminus[16,18]. The proposed secondary structure models provide a rational basis for explaining such biologically relevant phenomena as the autocontrol of A-protein gene expression[11], the polarity effect[14] and the location of easily mutable sites[11,14].

We now report the complete primary structure of the third and last MS2 gene, which codes for the replicase subunit. Some partial nucleotide sequences have been published before[13,19,20].

Nucleotide sequence and structure

Our methods, which have been described before[11,16,18], were briefly as follows. Uniformly ^{32}P-labelled MS2 RNA (2–8 mCi) was digested partially at 0 °C with the single-strand-specific ribonuclease T_1, and the digest was fractionated by electrophoresis on a polyacrylamide slab gel[15]. A series of bands was obtained, and the material in each band was separated further into individual fragments by two-dimensional gel electrophoresis[21]. The advantages of the latter method are that, in general, pure and unique fragments are obtained and that the procedure is applicable to virtually any chain length. These pure fragments were suitable for detailed sequence analysis, mainly according to the methodology described by Sanger and colleagues[22,23], or modifications thereof[15,24]. The structural determination of the longer oligonucleotides required various methods[25,26] and will be described in detail elsewhere.

Discrete fragments can be obtained reproducibly because of the specific three-dimensional conformation of the viral RNA; for example, a fragment may correspond to a hairpin. In milder conditions of partial enzymatic digestion, larger fragments are obtained, for example, several hairpins linked to each other or bound by secondary interactions. Although in this way several regions can often be ordered, this approach has practical limits. On the one hand, if a fragment becomes too large (for example, more than 300–400 nucleotides) its oligonucleotide composition can no longer be established accurately and on the other hand, some sites in the viral RNA are extremely sensitive to T_1 ribonuclease (see legend to Fig. 2). To solve this problem, we introduced the use of carboxymethylated ribonuclease (CM ribonuclease); this enzyme cleaves mainly between C and A

SCIENCE COLLEGE
92 Upper Circular Road
CALCUTTA

and between U and A residues[27]. Such partial digestion of MS2 RNA with CM ribonuclease identified a complete new set of fragments. These not only often constituted suitable material for solving nucleotide regions not well represented in T_1 fragments, but by and large provided all the essential overlaps, which have enabled us to reconstruct the entire sequence.

For identification of the fragments and for correlating the T_1 fragments with the CM ribonuclease fragments, we used a catalogue of all the unique oligonucleotides (mainly T_1 oligonucleotides). In this respect, an improved minifingerprinting system[28] has been very helpful in the last stages of this work.

The nucleotide sequence of the replicase gene is shown in the form of a secondary structure model in Fig. 2. It starts with the initiation codon A–U–G and ends with the termination codon U–A–G; these regions have been published before[14,16,18]. Figure 2 also shows sites which are sensitive to ribonuclease T_1, but which could be bridged by suitable CM-ribonuclease fragments, and vice versa for sensitive CM sites. For example, the T_1 fragment 2381–2532 was nearly always found in the same band of the primary gel separation system as the T_1 fragment 2533–2631, but no linkage in primary sequence could be demonstrated. Direct proof for the correct order, however, was provided by the characterisation of several CM fragments, such as 2500–2596.

Such fragments, clearly linked by secondary interactions and only separated in the denaturing conditions of the first dimension of the two-dimensional gel fractionation system[21], provided the primary basis for the construction of the secondary structure model. Sometimes a unique pairing scheme could be derived, but more often there were several alternatives (usually varying only in detail). On the basis of simplified rules for estimating thermodynamic stability[29,30], the most plausible configuration can be selected. After these hairpins have been fixed, additional, thermodynamically stable interactions can then be sought. The model shown in Fig. 2 is much more tentative as far as the latter aspects are concerned. But it is satisfying that by and large the feathered arrows, which are a measure of the sensitivity of the site towards nucleases, point to loops at the top of hairpins, or to discontinuities in the helical segments or to other single-stranded loci. Further study of the model by chemical modification is in progress.

Some of the segments, which remained single stranded in the model shown in Fig. 2, can be base paired to other regions of the molecule (Fig. 3). Such long distance interactions (that is, linkage of segments far apart in the primary sequence) certainly agree with hydrodynamic and other physical properties of MS2 RNA[31,32], but they are not supported by direct experimental evidence. Some of these interactions may have important functional roles, as in the control of the genetic expression or in encapsidation. For example, the coat protein gene must be translated before the ribosome-binding region of the replicase gene becomes accessible. This polar effect can be explained by the interaction of segment 1409–1433 with segment 1738–1769 (Fig. 3), as proposed in a slightly different form[14]. This does not exclude that rearrangements to other conformations may occur[14,33].

Little can be said about the tertiary interactions of the type found in tRNA[34], which almost certainly are also present in MS2 RNA. Yet they may influence profoundly the structure–function relationship. Moreover, some alternative conformations which have not been retained in the present model (Fig. 2) may be stabilised by such tertiary interactions and thus may represent the true conformation.

Sequence of replicase subunit

On the basis of the nucleotide sequence, we can deduce the whole amino acid sequence of the replicase gene product (Fig. 4); only the first three amino acids had been established previously by direct peptide analysis[35,36]. This is the first protein for which the primary structure has been solved entirely on the basis of the genetic information which encodes it.

The replicase subunit is a 544-amino acid polypeptide. Like the A protein, it ends with an arginine residue. It is even more rich in arginine than the A protein (some arginine residues may be involved in interactions with the RNA). But as the aspartic acid content is also high (6.0%), the polypeptide is slightly less basic than the A protein. Also noteworthy are a relatively high leucine content (9.0%; also high in the A protein) and phenylalanine content (6.9%). On the other hand, valine, alanine and glutamine are low, compared with the two other viral proteins.

At present no very meaningful deductions can be made from the amino acid sequence. With available procedures it is not possible to derive a plausible conformation and even less to interpret the structure–function relationship. But when more

Fig. 1 The genome of MS2 contains three genes, shown in blocks Untranslated regions are present at both ends of the viral RNA and between the genes. The length of the different regions, expressed in number of nucleotides, is shown on top. The nucleotides in the viral RNA are numbered from the 5′ end to the 3′ end and the positions of some important signals are indicated underneath (the initiation codon is considered part of the genes and the termination codon part of the untranslated region).

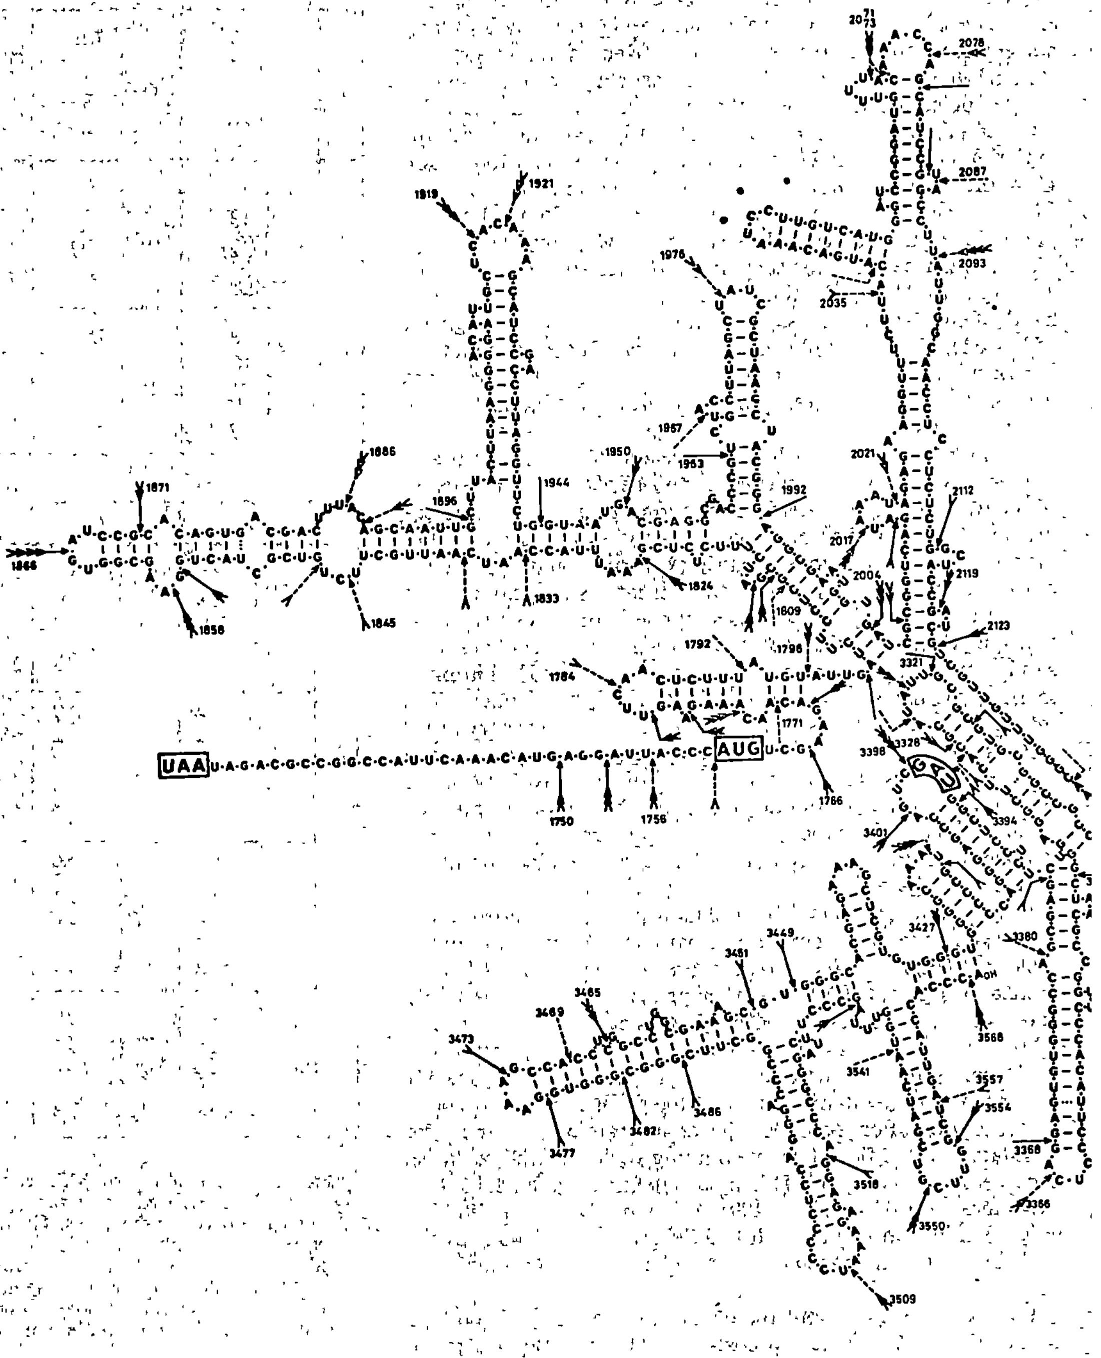

Fig. 2 Primary nucleotide sequence and secondary structure model of the replicase gene. The sequence is read from the 5′ to the 3′ end: U–A–A, termination signal of the preceding coat gene; an intergenic region of 33 nucleotides; A–U–G, the initiation codon of the replicase gene; the replicase gene (1,632 nucleotides); U–A–G, the termination signal; an untranslated, 171-nucleotide 3′-terminal sequence. Together with previous models for the 5′-leader sequence–A-protein gene[11] and the coat gene[14] this figure completes the chemical structure of the entire MS2 RNA. The numbering starts at the first (5′) nucleotide and ends at the 3′-terminal residue 3569. The primary structure has been established rigorously but the secondary structure is based in part on experimental evidence and theoretical predictions and in part on conjectures (see text). Arrows point to sites easily split by nucleases during partial digestion of complete MS2 RNA: solid arrows, T_1 ribonuclease; dashed arrows, CM ribonuclease. The feathers indicate the sensitivity of the bond in the conditions used: (0) split very seldom, (1) seldom, (2) rather often, (3) very often, (4) always.

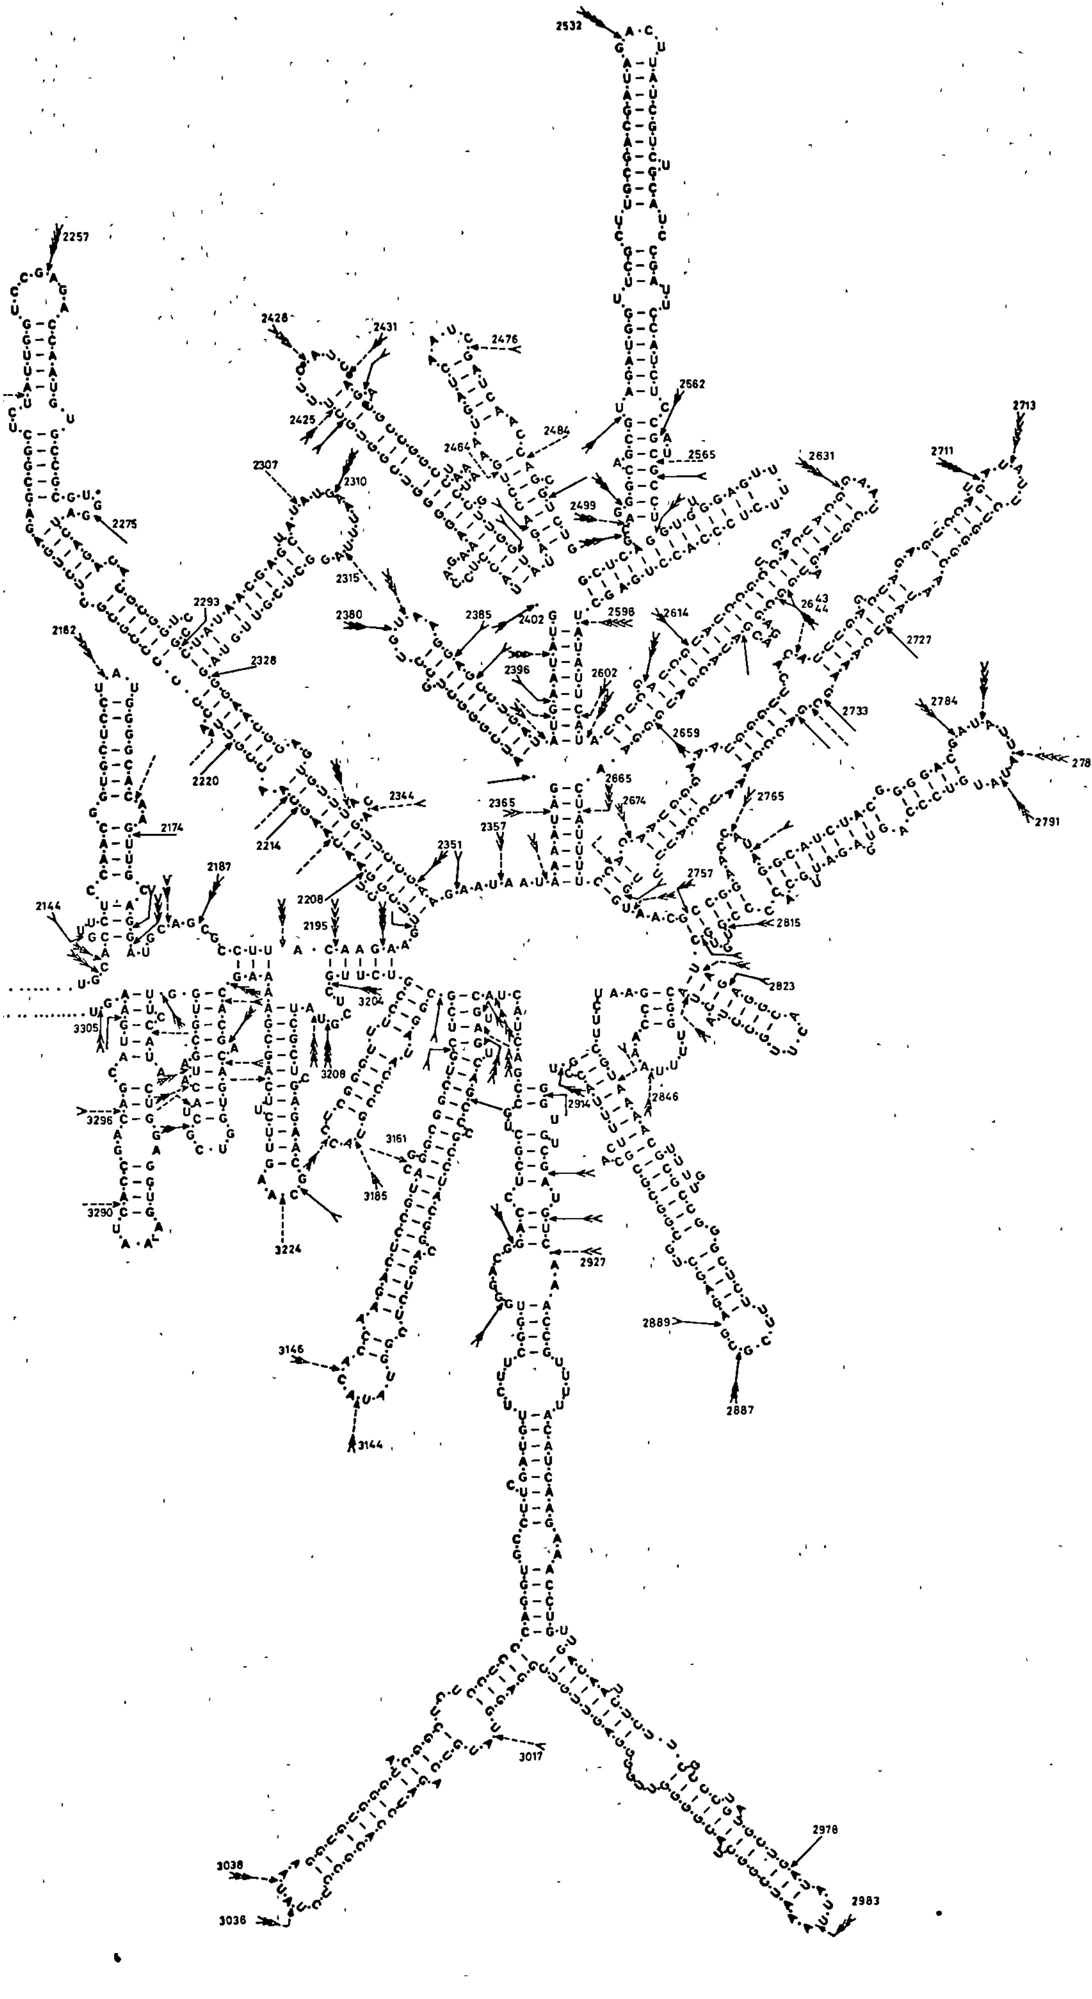

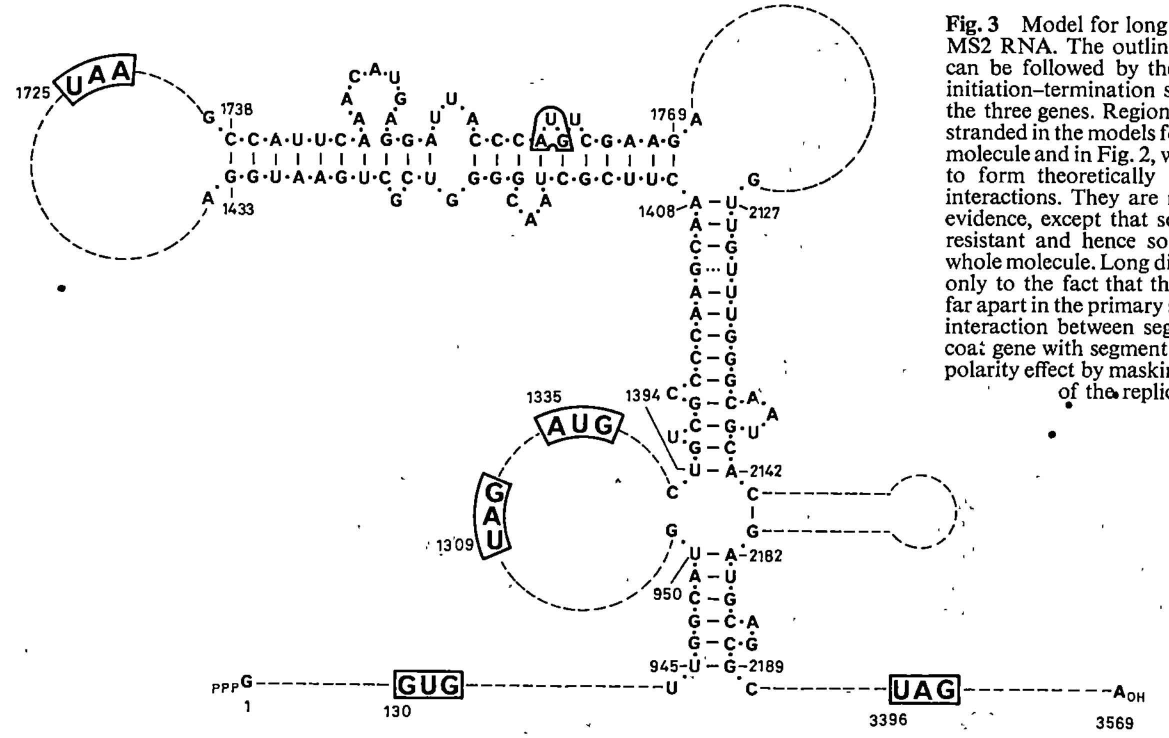

Fig. 3 Model for long distance interactions in MS2 RNA. The outline of the complete chain can be followed by the numbering and by the initiation–termination signals (in bold type) of the three genes. Regions which remained single stranded in the models for the other parts of the molecule and in Fig. 2, were screened for ability to form theoretically stable, complementary interactions. They are not supported by direct evidence, except that some are rather nuclease resistant and hence somehow protected in the whole molecule. Long distance interaction refers only to the fact that the segments involved are far apart in the primary sequence. Note that the interaction between segment 1409–1433 of the coat gene with segment 1738–1769 explains the polarity effect by masking the initiating A–U–G of the replicase gene.

Fig. 4 Nucleotide sequence of the replicase gene and amino acid sequence of the coded polypeptide. As in Figs 1–3, the nucleotides are numbered from the 5′ end of the viral RNA. The amino acid sequence is entirely deduced from the nucleotide sequence data. In analogy with the Qβ polypeptide it is assumed that the initiating formylmethionine has been eliminated in a post-translational process[55]. This polypeptide, together with three host components S1, Tu and Ts, forms a complex which is responsible for specific viral RNA replication.

data become available on viral and other RNA polymerases these amino acid sequences may reveal important clues on virus evolution and/or their origin.

Biological information content

The ribosome-binding region, including the initiating A–U–G of the replicase gene, was first identified by Argetsinger-Steitz[37]. Good yields were only obtained after partial unfolding of the viral RNA. It is still not clear which features constitute a ribosome-binding region, although progress has been made. Shine and Dalgarno[38] have proposed that a purine-rich sequence preceding the initiation codon is involved in an interaction with a complementary 3′-terminal segment of the ribosomal 16S RNA. Indeed, all genuine ribosome-binding sites characterised so far contain a sequence of three or more purine nucleotides complementary to the 3′ end of 16S RNA. Also, experimental evidence has been obtained for the direct complementary interaction between the ribosome-binding region and the 3′ end of the 16S rRNA[39]. But this cannot be the whole answer, because many regions in the viral RNA fulfil these criteria, yet are not bound. For example, the segment 2381–2396 is . . . U–A–A–G–G–A–G–C–C–U–G–A–U–A–U–G . . .; according to the criteria mentioned it should interact about as strongly as the A-protein initiation region with both *Escherichia coli* and *Bacillus stearothermophilus* 16S rRNA[38]. That this is not observed may mean that masking/accessibility by secondary and tertiary structure may be equally important. Such cryptic sites may be involved in the additional initiations observed after formaldehyde treatment[40], but these are very unnatural conditions. On the other hand, ribosome binding as tested by protection against nuclease may not be as specific as polypeptide chain initiation. In the original fingerprints of the protected regions of the *E. coli* ribosome there were additional, unexplained spots[37]; on the basis of preliminary identification (J. A. Steitz, personal communication) it seems likely that the main contaminating sequence contained the region 1965–1986. Likewise, in the experiment with *B. stearothermophilus* ribosomes at 49 °C (plate IV in ref. 41) a major contaminant must have been 2926–2967. In neither case is it immediately obvious why this anomalous binding reaction occurred.

Translation of the replicase gene is repressed by the coat protein, and the region to which the coat binds has been characterised[42]. The coat protein may interact with an alternative hairpin structure (Fig. 6 of ref. 14, and ref. 33).

Starting from the initiating A–U–G the nucleotides are read in triplets. For many regions the correct reading frame could be derived independently from the fact that the two illegitimate reading frames were blocked by nonsense code words[19]. The latter occur with a frequency not higher than expected for a random distribution. Finally the reading ends with the terminating U–A–G, as reported before[18]. This assignment is confirmed by studies of specific suppression in an *in vitro* translation system[43]. The replicase gene is followed by a 174-nucleotide untranslated, 3′-terminal segment (including U–A–G); this is shown in a more compact model in Fig. 2.

A heat stable host factor, HF (a hexamer of 72,000 daltons), is required in the Qβ-replicase reaction, but only when Qβ-RNA plus strand is the template[3]. HF binds to two regions in Qβ RNA, one of which is close to the 3′ end[44]. Although it is doubtful that HF is involved in the replication of the RNA of the MS2–R17–f2 group[45], it can nevertheless specifically bind to a single region in these viral RNAs. Senear and Steitz[44] found that HF protects a small segment in R17 RNA against nuclease, which has the following nucleotide sequence: . . . A–A–G–A–A–U–A–A–U–A–A–A–A–U–A–G . . .; undoubtedly this corresponds to the residues 2352–2367 which are located in the middle of the replicase gene. Presumably this interaction has no functional significance; HF is known to have a high affinity for poly(A)[46], and not only is the protected sequence A rich, but the T_1-oligonucleotide A–A–U–A–A–U–A–A–A–A–U–A–Gp has peculiar and very exceptional properties (strongly sticking to cellulose acetate and DEAE paper).

Use of code words

The code words used in the replicase gene are summarised in Fig. 5. On what basis is the choice made between degenerate codons for a given amino acid? In some cases it may be a historical accident, like the choice between a U–C–X or an A–G–Py codon for serine. It is unlikely that there are no constraints on the third letters. Indeed, although the mutation rate is very high (as evidenced by, for example, forward and backward mutation rates), we have been able to work for at least 6 yr with an essentially unaltered sequence. An obvious constraint is that third letters may be involved in optimising the secondary and tertiary structure. Secondary structure can be maximised by a proper choice of third letters and by bringing complementary segments into proper register[47]. Although some evidence in this direction was found[13,14,48,49] in the case of the coat gene, it could not be substantiated further as more data became available[11]. We believe that relatively few, selected third letters are sufficient to bring the molecule from a random secondary structure (50–60% base pairing[49,50]; but this random structure is less stable[51]) to the level of a stable conformation as observed in the viral RNAs (73%±5 base pairing[31]). Statistical methods may not be adequate to reveal these effects convincingly. Moreover, we have no way of assessing the role of third letters in tertiary structure interactions. Neither should we forget that selection may also operate at the level of the negative strand (again no regions should be created which may function in ribosome interaction, or as nuclease targets or as binding sites for encapsidation and so on).

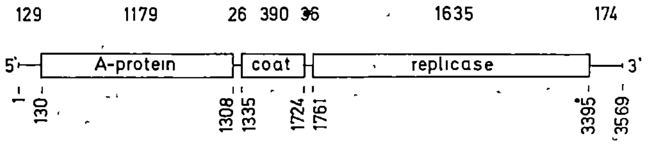

Fig. 5 Code words used in the replicase gene and in the whole genome. The numbers refer to the frequency with which each code word is used. *a*, Codewords used in the replicase gene. Circled numbers indicate codons not used in the coat gene. *b*, Summational table of codewords used in the three viral genes. The initiation codewords (one G–U–G and two A–U–Gs) are counted separately.

But it is very likely that at least for some amino acids other factors directly related to translation in *E. coli* have a predominant role in the choice of the third letter. For example, the code word G–G–U is definitely preferred for glycine and this is true for the whole genome (significant at the 0.1% level as tested by χ^2 analysis). This effect is specific and not due to a general preference for U in third positions, as found in the φX174 gene G[52].

We have suggested that isoleucine, tyrosine and/or arginine have modulating codons. Indeed, in the coat protein the codon U–A–U is not used for tyrosine, and we now conclude that for the whole genome U–A–C is definitely preferred (0.1% significance). Similarly, the code words C–G–Pu and A–G–Pu were not used for arginine in the coat gene, and it now seems that for the whole genome the preference is clearly C–G–Py > C–G–Pu > A–G–Pu (0.1% significance). These modulating triplets may be absolutely unacceptable in a gene like that for the coat, which is translated at high frequency, but can be tolerated in moderate numbers in genes whose elongation rate of translation is average. Isoleucine codons may constitute another class of modulating triplets. A–U–A is absent from the coat gene (5% significance; the coat contains only eight isoleucine residues), and is known to be recognised by a specific tRNA which is present in very small amounts in *E. coli*[53]. The A protein and the replicase genes contain several A–U–A codons, and these may very well modulate (brake) the speed of translation; in fact, in these two genes it seems that it is the A–U–U codon which is selected against (1% significance).

In summary, we have established the primary nucleotide sequence of bacteriophage MS2 RNA. The polynucleotide chain contains 3,569 residues, 10.2% of which constitute untranslated segments. As all the genetic information is derived from this RNA molecule, the primary structure of all the virus-specified products (A protein, coat protein and replicase subunit) has also been deduced. MS2 is therefore the first living organism for which the entire primary chemical structure has been elucidated. We propose tentative models for the secondary folding of the viral RNA; parts of these are based on experimental evidence, and some aspects provide plausible bases for the explanation of biological effects. The secondary structure of the coat gene resembles a flower[14], and there are similar foldings in other parts of the molecule; the secondary structure of the whole viral RNA therefore constitutes a bouquet.

letters to nature

Solar influence on galactic cosmic ray anistropy measurements

COSMIC ray particles of energies $\gtrsim 10^{12}$ eV are virtually unaffected by the interplanetary magnetic field, and thus any galactic anisotropy manifests itself in sidereal intensity variation in Earth-based measurements. Below 10^{11} eV, on the other hand, solar modulation is of importance. Galactic anisotropy would be smeared out at this energy, and an anisotropy is introduced by the solar modulation effects. In the intermediate 10^{11}–10^{12} eV region sidereal variation may originate either in genuine galactic anisotropy or in solar modulation[1]. The London–Torino groups found[2], in accordance with other measurements[3], that, in this intermediate energy range, the phase of the sidereal variation shifted from ~ 1800 to ~ 330 local sidereal time (LST) in 1969 when the polarity of the solar magnetic field reversed. The authors suggested that the change of phase was a result of the change of 'optics': different regions of the sky were scanned before and after 1969, respectively. Here we consider the alternative possibility—that the observed variation was a result of the electromagnetic field embedded in the solar wind.

At energies > 10^{11} eV, the effect of magnetic irregularities is small and particle propagation is governed by the large scale interplanetary magnetic field. Thus, instead of using the transport equations which work well at lower energies, one has to consider individual particle trajectories. Anisotropy at the Earth will be introduced by the energy loss suffered by the particles in the solar system from the electric force associated with the expanding solar wind. If particles lose energy then, at the Earth, we observe the galactic spectrum at higher energy, resulting in a lower flux. As in the London–Torino work[2], we take the magnetic field to be an Archimedean spiral directed away from the Sun everywhere north of the helioequator and towards the Sun south of it for the post-1969 epoch. The exact reverse field is assumed for the pre-1969 epoch. The electric field can be evaluated by requiring

$$0 = \mathbf{E} + 1/c\,(\mathbf{V}\times\mathbf{B}) \qquad (1)$$

for particles comoving with the solar wind velocity **V**. Thus we arrive at the following form of **B** and **E**

$$\begin{aligned} B_r &= B_0(a/r)^2 \quad &; E_r &= 0 \\ B_\theta &= 0 \quad &; E_\theta &= B_0(a/r)(a\Omega/c)\cos\theta \\ B_\varphi &= B_0(a/r)(a\Omega/v)\cos\theta \quad &; E_\varphi &= 0 \end{aligned} \qquad (2)$$

r being the radial distance from the sun, $a = 1$ AU and B_0 being the radial component of the magnetic field at the Earth (2.5 gamma (ref. 2)). θ represents heliolatitude while Ω is the angular velocity of the rotating Sun ($\Omega = 2.7\times10^{-6}\,\mathrm{s}^{-1}$).

There are two implications of equation (2): (1) The electric field is independent of the solar wind velocity; (2) an electric quasi-potential can be introduced with

$$\mathbf{E} = -\nabla\Phi;\ \Phi = aB_0\,(a\Omega/c)|\sin\theta| \simeq 150|\sin\theta|(\mathrm{MV}) \qquad (3)$$

The potential, Φ, exists only within the solar cavity. If the Earth had a well defined potential then the energy loss would be identical for each trajectory, resulting in no anisotropy[4].

In our model, however, the continuous injection of magnetic flux from the solar wind yields a $\nabla \times E$ term, and it is this term which enables cosmic rays of different trajectories to reach the Earth having suffered different energy changes.

Particle trajectories depend only on rigidity, P ($P = pc/Ze$, p being the momentum and Ze being the electric charge of the particle). In the Solar System a highly relativistic particle changes its rigidity by

$$\Delta P = (\mathrm{d}P/\mathrm{d}E)\Delta E = -\Delta\Phi \qquad (4)$$

where $\Delta\Phi$ is the potential difference between the Earth and the point where the particle entered the Solar System. Thus, for a fixed rigidity, P, the relative intensity variation follows as

$$\Delta I(P,t)/I(P) = -(\gamma+2)\,\Delta\Phi(P,t)/P \qquad (5)$$

where γ stands for the negative exponent of the differential rigidity spectrum of the galactic cosmic radiation. $\Delta\Phi(P,t)$ refers to the trajectory reaching the observation site vertically (most of the observed flux arrives nearly vertically). By taking the response function of the detector, $r(P)$, into account we obtain

$$\frac{\Delta I(t)}{I} = -\int_{P_0}^{\infty} (\gamma+2)\,\frac{\partial r(P)}{\partial P}\,\frac{\Delta\Phi(P,t)}{P}\,\mathrm{d}P$$

The detailed analysis of the trajectories carried out by the Imperial College group[5] showed that particles of rigidities $\lesssim$ 300 GV were considerably deflected, while > 300 GV the deflection was small. As a rough approximation, we take that rigidities < 300 GV do not contribute to the intensity variation. Above 300 GV, on the other hand, trajectories are assumed to be straight lines. Obviously the energy change is maximal for the trajectories nearest to the pole (Fig. 1) which results in a sidereal daily variation of 0.017% with times of maximum at 1904 and 0704 LST before and after 1969, respectively. This result is in accordance with the general character of the London–Torino measurement[2] (0.013±0.003%; 1800 for the pre-1969 epoch and 0.012±0.005%; 0330 for the post-1969 epoch).

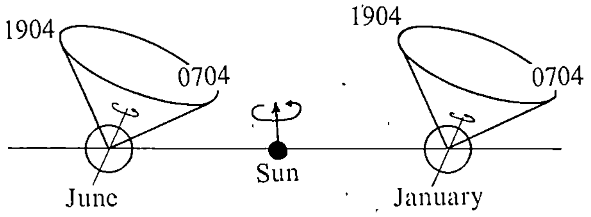

Fig. 1 The cone of the directions scanned for January and June. The maximal energy change occurs for the trajectory nearest to the pole, that is, for 1904 LST.

The model outlined here predicts opposite phases for measurements made on the Northern and Southern Hemispheres, respectively. In a measurement carried out at Hobart[6] between 1957 and 1974 (the pre-1969 interval being dominant) the phase of the sidereal daily wave was found to be 0700 LST, agreeing with this prediction. There was, however, no sign of a reversal of phase in 1969. A detailed investigation of trajectories may give firmer support to the model discussed here or may disprove it. At present, however, one cannot rule out that the sidereal daily variation of cosmic ray intensity in the 10^{11}–10^{12} eV region can be accounted for by solar influence.

I thank Professor H. Elliot and the referee for their remarks on the original manuscript.

Ionising flux of cosmic background radiation

THE intensity of the diffuse cosmic background radiation for photon energies of 13.6 to ~ 150 eV cannot be measured directly because of absorption by the neutral component of the interstellar medium. In the range 150–300 eV, there is considerable galactic emission within a few hundred parsecs of the Sun which places severe limitations on attempts to measure the intensity and spectrum of the metagalactic background radiation at these energies. An indirect means of estimating the diffuse metagalactic flux of ionising radiation was proposed by Sunyaev[1], who studied the interaction of this radiation with neutral hydrogen at the peripheries of galaxies. More locally, the intensity of this radiation within ~1 kpc of the Sun can be probed by studying the ionisation of heavy elements in the interstellar medium[2]. Here we re-examine Sunyaev's proposal in the context of more detailed studies of the interaction of metagalactic ionising radiation with galactic gas. We give a firm upper limit on the intensity of metagalactic ionising background radiation to which the neutral interstellar medium is exposed, and discuss some important consequences of this result. Our principal conclusion is that further than ~30 kpc from the centre of the Galaxy, self-shielding by H II[3,4] is possible only if the flux of ionising radiation is below a certain critical value[5–7].

Hill[6] used a self-gravitating galactic disk model of the galactic gas distribution that was exposed to an ionising photon flux calculated on a variety of possible extrapolations of the high latitude soft X-ray data to lower energies. Bochkarev and Sunyaev[7] used a variety of possible gas density distributions, including disk models without stellar halos, and also models appropriate to a disk embedded in a massive non-gaseous corona.

An important result can be inferred from their studies: there is a critical value of the metagalactic ionising flux; if this value (φ_c) is exceeded, there will be too little neutral hydrogen far from the centre of nearby spiral galaxies. The specific 21-cm observations that we use indicate that, after correcting for projection effects, the H I column density is ~(2–3)× 10^{19} cm^{-2} at ~30 kpc from the centre of M31 (refs 8–11). Now, the hydrogen ionisation rate from hydrogen-primary photo-ionisations at the periphery of the Galaxy is

$$\zeta = 4\pi \int_{\nu_H}^{\infty} \frac{\sigma\varphi}{h\nu}\mathrm{d}\nu \simeq 4\pi\sigma_0\varphi_0\left(\frac{\nu_H}{\nu_0}\right)^{3+\alpha} (3+\alpha)^{-1}\,\mathrm{h}^{-1}$$

where we have written the incident ionising radiation flux (erg cm^{-2} s^{-1} Hz^{-1}) as $\varphi = \varphi_0(\nu_0/\nu)^{\alpha}$. Here $\nu_0(\nu \geqslant \nu_0 \geqslant \nu_H)$ is a low energy cutoff, $\alpha \geqslant 0$, $\sigma_0 = 6.3\times10^{-18}$ cm^2, and ν_H is the frequency at the Lyman limit. It is important to also include the effects of helium recombination radiation and secondary electrons produced by both hydrogen and helium in the exact computations. This gives the critical value[6,7] of ζ as $\zeta_c = 2\times10^{-13}$ s^{-1}, and this in turn gives an upper limit on the metagalactic ionising photon flux > 13.6 eV of $\varphi_c = 5\times10^{-23}(\nu_0/\nu_H)^3$ erg (cm^2 s ster Hz)$^{-1}$ if $\alpha = 0$ (and is readily generalised if $\alpha \neq 0$). ν_0 and α are characteristic parameters of the incident ionising flux: an unattenuated thermal bremsstrahlung spectrum with temperature parameter $kT \gg h\nu_H$ corresponds approximately to $\alpha = 0$ and $\nu = \nu_H$.

This limit depends weakly on the gas distribution; here it is for the model of a self-gravitating infinite disk with surface density varying inversely as galactocentric distance. For other models, somewhat lower limits are obtained that are within a factor of three of this value, which also lies in the same range as Sunyaev's earlier estimate[1].

These results were obtained under the assumption that the gas is diffuse. If there is an intercloud medium which is ionised and heated to $\sim 10^4$ K by the metagalactic ionising radiation, clouds cannot exist in thermally stable pressure equilibrium (and would consequently not be replenished over the cloud dissipation time scale) unless the mean gas density exceeds $\sim 0.03\ \mathrm{cm}^{-3}$ (ref. 5). One remaining possibility would be for H I clouds at the periphery of the Galaxy to be maintained in pressure equilibrium with a tenuous, hot intercloud medium, for example at $T \simeq 10^6$ K and $n \simeq 10^{-3}\ \mathrm{cm}^{-3}$. The low column density of the clouds ($\sim 10^{19}\ \mathrm{cm}^{-2}$), however, renders them transparent to photons of energy $\gtrsim 50$ eV, and the clouds would evaporate over a time scale short compared with the relevant time scale for cloud formation, which we may identify with the cooling time of the ambient medium (particularly if the gas is depleted in heavy elements).

Note that the characteristic propagation time for the ionisation front in the diffuse medium is $\sim 1.7\times 10^7\ (\varphi_c/\varphi)(N/10^{20}\ \mathrm{cm}^{-2})$ yr, where N is the local column density of gas normal to the galactic plane. If φ is sufficiently small, this can exceed the dynamical time scale in the outer regions of the Galaxy; in this case, it is necessary to study the propagation of a non-stationary ionisation front[12].

This conclusion has some notable implications that we now mention. Recent work on the existence of massive galactic coronae[13,14] has indicated that such coronae may contain masses of $\gtrsim 10^{12}\ M_\odot$ within $\lesssim 100$ kpc of the Galaxy. Such coronae could be gaseous and unobservable if the gas temperature were in the range 10^5–10^6 K. Our limit on the ionising radiation flux, however, enables us to impose a severe restriction on the emission from a galactic corona containing gas in this temperature range, and we find that the maximum mass of a gaseous galactic corona (compare ref. 15) is

$$M_{\mathrm{max}} \simeq 1\times 10^{11}(\varphi/\varphi_c)^{1/2}(100\ \mathrm{kpc}/R)^{5/2}(10^{-23}\mathrm{erg\ cm^3\ s^{-1}}/\Lambda^{1/2} M_\odot$$

for a uniform density model, where R is the radius of the corona and $\Lambda(T)$ is the cooling function ($\sim 10^{-21}$–10^{-22} erg cm^3 s^{-1} for $T = 10^5$–10^6 K if the heavy element abundance, Z, is solar; $\Lambda \propto Z$). Consideration of a non-uniform gas distribution only strengthens this limit.

A second result is that we can give an upper limit on the mean luminosity, F, radiated by a QSO in the energy band 40–170 eV. Adopting Schmidt's[16] QSO density distribution function and assuming a non-thermal continuum spectral energy distribution $\propto \nu^{-1}$ (ref. 17), we find from the background limit (in a $\Omega = 1$ cosmological model) that $F \lesssim 10^{29\ 2}$ erg s^{-1} Hz^{-1}; this estimate takes into account the absorption of ultraviolet photons in the neighbourhood of the quasars. Since QSO optical luminosities (at 2,500 Å in the rest frame of the QSO) are in the range 10^{29}–10^{31} erg s^{-1} Hz^{-1} (ref. 16) and several at high redshift are found to be transparent to Lyman continuum photons, we infer that QSO may be expected to make an appreciable contribution to the metagalactic ionising background radiation.

Finally we mention an upper limit on the mean density of intergalactic gas obtained by considering its radiation[1]; the critical flux is exceeded only if the mean density of matter exceeds the value for closure of the Universe when a Hubble constant of 100 km s^{-1} Mpc^{-1} is adopted (note that the radiation of the gas is proportional to $H_0{}^3$).

We realise that this discussion has hitherto been entirely devoted to the astronomy of upper limits. An important observational implication for 21-cm studies of external galaxies is that the presence of a metagalactic ionising background radiation field will affect the distribution of H I in the outer regions of galaxies. The transition between H I and H II occurs over a dimension short compared with the galactocentric distance and with low spatial resolution should be detectable as an abrupt change in H I surface density (compare refs 4 and 5). Because of the hardness of the spectrum of ionising photons, however, the transition zone, in the case of a bremsstrahlung or power-law incident spectrum, can be appreciable, amounting to[4] $\sim 2(\varphi/\varphi_0)\ (0.01\ \mathrm{cm}^{-3}/n)^2\ (T/10^4\ \mathrm{K})^{1/2}$ kpc.

Thus the transition region may be detectable when high resolution 21-cm studies of the outlying parts of external galaxies are available, and would provide useful information on the nature of the ionising photon spectrum.

New theory of the Great Red Spot from solitary waves in the Jovian atmosphere

THE nature and stability of the Great Red Spot (GRS) on Jupiter have been persistent problems. We show here that solitary waves on a horizontally sheared zonal flow in a rotating, stratified atmosphere can explain many of the GRS characteristics known at present and numerous other features that have been observed on Jupiter (see also ref. 1).

Solitary waves have a number of attractive properties: they are isolated, permanent waves in which nonlinear steepening balances dispersive, spreading effects[2]. They can arise from arbitrary initial disturbances and interact nonlinearly without changing their shape[2]. The only memory of an interaction is a finite spatial phase shift between the post- and the pre-interaction trajectories[2,3], an interaction which looks like a rapid acceleration of one wave through the other.

Their simplest mathematical basis is the quasi-geostrophic potential vorticity equation for an incompressible fluid[4] which, when made suitably non-dimensional and when one assumes a flow composed of a mean zonal shear flow $U(y)$ and a superimposed disturbance $\varepsilon\psi(x,y,z,t)$, has the form

$$[\partial_t + U\partial_x + \varepsilon(\psi_y\partial_x - \psi_x\partial_y)] \times$$
$$\times [\partial^2{}_{xx} + \partial^2{}_{yy} + (f_o l/Nd)^2\partial^2{}_{zz}]\psi + (\beta - U'')\psi_x = 0 \qquad (1)$$

The east–west, north–south and vertical coordinates are x,y,z; t is the time; $f = f_o + (U_o/l)\beta y$ is the local Coriolis parameter;

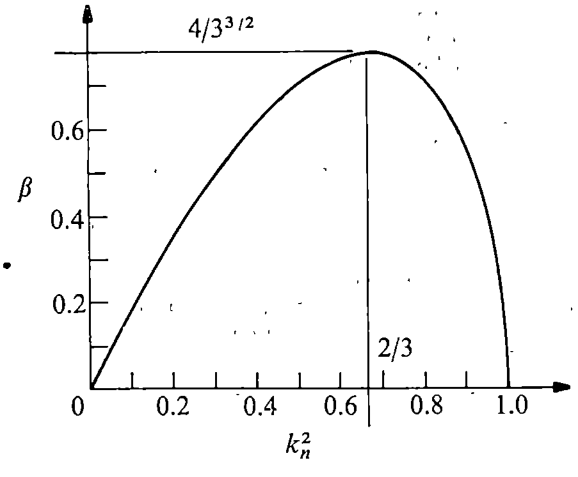

Fig. 1 Eigenvalue relationship for $U=\tanh(y)$; $\beta=2k_n^2(1-k_n^2)^{\frac{1}{2}}$ for $0<k_n^2<1$.

N is the Brunt–Vaisala frequency (assumed constant) and $\mu=d/l$ the ratio of the atmospheric depth to the characteristic zonal wavelength.

Restricting our discussion to a single vertical wave mode, this equation admits a solution of the form

$$\psi=A(\xi,\tau)\varphi(y)\cos(n\pi z)+O(\varepsilon)$$

if $A(\xi,\tau)$ satisfies the modified Korteweg–DeVries equation

$$A_\tau+\alpha A^2A_\xi+\gamma A_{\xi\xi\xi}=0 \tag{2}$$

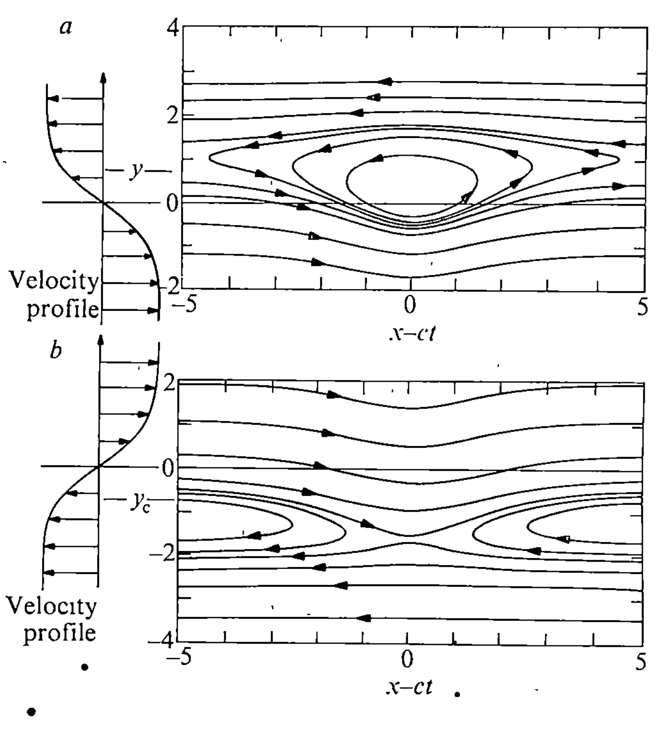
where

$$\xi=\varepsilon(x-c_o t),\quad \tau=\varepsilon^3 t$$

The quantities α and γ are numbers that depend on certain integral properties of φ, its derivatives and $U(y)$. Simultaneously, $\varphi(y)$ satisfies the barotropic stability equation

$$\begin{gathered}\varphi''-k_n^2\varphi+[(\beta-U'')/(U-c_o)]\varphi=0\\ k_n=n\pi(f_o l/Nd)\\ \varphi\to0 \text{ as } |y|\to\infty\end{gathered} \tag{3}$$

Fig. 2 *a*, An E soliton on an anticyclonic shear in the southern hemisphere ($C=-0.7$, $\varepsilon=0.7$). *b*, A D soliton on a cyclonic shear in the southern hemisphere ($C=-0.7$, $\varepsilon=0.7$).



For the shear profile, $U=\tanh(y)$, equation (3) has been solved by Lipps[5]. The appropriate eigenvalue curve for neutral solutions is shown in Fig. 1.

Figure 2*a* and *b* shows typical streamline patterns for waves corresponding to solitary waves of elevation (E solitons) and of depression (D solitons). The first has closed streamlines with pronounced cusps and the second has reversed flow fore and aft of the wave centre. The similarity of the flow shown in Fig. 2*a* to that found around the GRS[6] is obvious and hardly needs further comment. The picture is enhanced when one constructs possible extensions of this theory to the solitary waves one would expect on the asymmetric jet-like profile that exists in the vicinity and equatorward of the GRS. Figure 3 shows a combined D–E soliton that emerges from a combining of flows like those shown in Fig. 2*a* and *b* with distortions arising from their mutual interactions. This picture is even closer to the total flow near the GRS, as shows particularly clearly in Fig. 4

There is strong evidence, both from its morphology and flow pattern (the so-called Circulating Current (Fig. 7, Plate III, Figs 5–9 of ref. 7)) that the South Tropical Disturbance (STD) was a D soliton. When this feature interacted with the GRS, observers noted a very rapid acceleration of the STD and its reformation without a change of shape (ref. 7, 137-143): we noted above that this is how solitary waves interact.

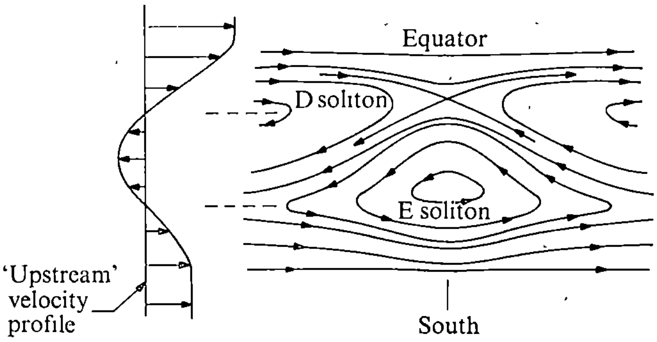


Fig. 3 A combined D–E soliton on an asymmetric jet-like profile

There are a variety of similar examples. The Dark South Tropical Streak (ref. 7, plate IX) has the structure of a D soliton. Again many of the 'spot-like' features in ref. 7, plates V and X, and also in the Pioneer 10 and 11 pictures (the Little Red Spot, for example) sit in regions between cloud bands, where one would expect horizontal shear to exist and have the morphology of E solitons. The 'plume' at the northern edge of the equatorial jet, seen in the Pioneer pictures and the historical record[8], seems to be one branch of a D soliton.

One can also extend, by inference, the present weakly nonlinear theory to a highly nonlinear regime. Then one would expect supercritical flows, with hydraulic jumps, or leewaves, to appear 'downstream' of the solitary waves (as in flow over bodies in rotating or stratified flows). Such flows have been observed around the GRS and can be seen in Fig. 4 downstream of the 'White Oval' below and to the left of the GRS.

The theory also places certain restrictions on the atmospheric parameters, and we now show that these are consistent with available models and observations. Taking a typical point on the eigenvalue curve, $k_n^2\simeq0.8$, $\beta=0.7$ with $U_o\simeq55$ m s^{-1} (ref 6), and a latitude of 24°, we obtain $l\simeq3{,}000$ km (corresponding to a shear zone width for the $\tanh(y)$ profile of 9,000 km) and $Nd/n\simeq1{,}500$ m s^{-1}. For example, an isothermal stratosphere at 110 K has $N=2.2\times10^{-2}$ s^{-1}, in which case $d/n\simeq6.7$ km, or four density scale heights. For more realistic atmospheric models in which N increases from zero, at a depth near the ammonia cloud base, to a maximum at an inversion, our restriction on Nd/n becomes, crudely, one on

$$\int_{0}^{d}(N/n)\mathrm{d}z$$

and more appropriately, we interpret the resulting 'averaged' value of d/n as the vertical wavelength of the wave. In this case the wave now propagates within the cloud layer to a depth at which N is effectively zero (decaying exponentially below this level) and to a height determined by the constraint on

$$\int_{0}^{d}(N/n)\mathrm{d}z$$

For the model of Wallace *et al.*[9], most of the first vertical amplitude oscillation will be in and below the inversion level. Thus, in this model the GRS is not a deep-seated feature, but one that propagates probably no deeper than one scale height below the base of the ammonia cloud layer. In this sense, it differs from the available explanations of Hide[10], Ingersoll[11], Smoluchowski[12] and Kuiper[13], which place most of the motion below the tops of these clouds. Finally, we note that since the flow is related to the corresponding instability of the barotropic shear flow that makes up the basic state, the wave is able to extract energy from this flow and maintain itself in the presence of dissipation, possibly accounting for the long lived nature of the GRS.

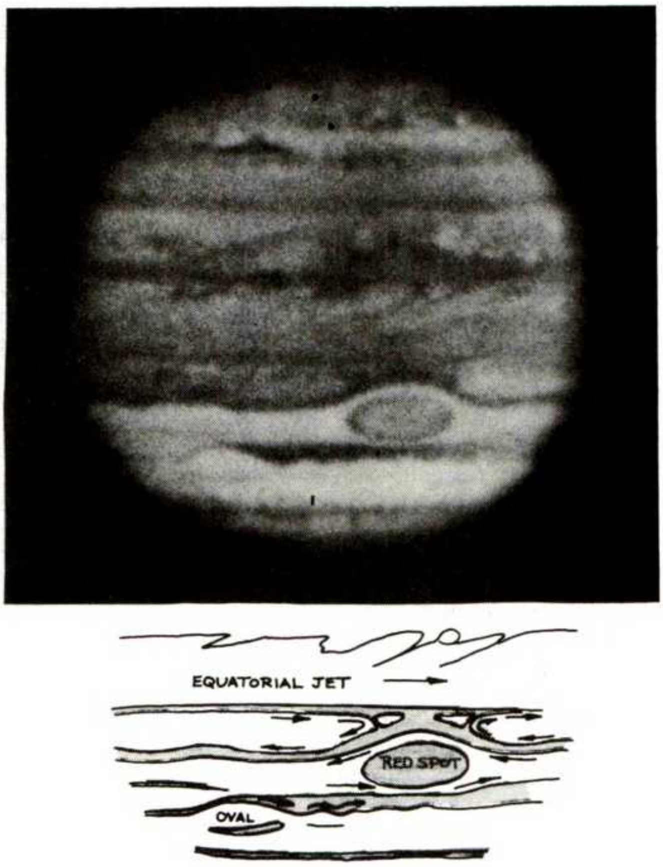

Fig. 4 Photograph taken at Pic-du-Midi Observatory on November 23, 1964 through a yellow filter (photo courtesy of Lowell Observatory) together with an interpretive sketch of the flow field that is consistent with the observations of Reese and Smith[5]. Compared to Fig. 3, this suggests that the GRS and Hollow can be interpreted as a combined D–E soliton. Also note the leewave type of flow downstream of the White Oval below and to the left of the GRS.

Preferential adsorption of ^{137}Cs to micaceous minerals in contaminated freshwater sediment

A MAJOR concern to environmentalists, health physicists and radioecologists is the fate of ^{137}Cs released to the environment from existing light-water power stations (estimated annual discharge of ^{137}Cs as liquid effluent exceeds 2.0 Ci per yr per power station) and future nuclear fuel reprocessing facilities[1]. Its long half life (30 yr) and its ability to be readily assimilated into body tissues make it potentially one of the most hazardous radionuclides for man. Numerous investigations into the fate of ^{137}Cs in terrestrial environments have revealed that soils exhibit a marked capacity to retain ^{137}Cs; thus soils act as a 'sink' for ^{137}Cs released to the environment[2,3], and sediments retain ^{137}Cs in a similar fashion in aquatic environments[4,5].

We report here the detection of preferential adsorption of ^{137}Cs to the micaceous component of a ^{137}Cs contaminated freshwater sediment, containing predominately kaolinite and quartz, using density-gradient mineral segregation in a large scale zonal rotor[10].

Experiments on reference clay minerals have shown that the single most important factor controlling caesium retention is the ability of certain layer silicates such as micas, vermiculites and interleaved micas (formerly called illites) to preferentially adsorb or 'fix' trace quantities of Cs (ref. 6). The 'fixation' mechanisms of these minerals are a result of the trapping of Cs ions in either the interlayer regions of vermiculite, a partially expanded mineral, or at the frayed edges of illites and micas[7]. ^{137}Cs is more strongly retained in soils containing predominately micaceous minerals, thus resulting in considerably less uptake of ^{137}Cs in plants grown on these soils as compared with tropical soils[8], peat soils[8] and acid sandy podzolic soils[9], which do not contain large quantities of micaceous minerals. In no instance before has preferential adsorption of ^{137}Cs to the micaceous component of a soil or sediment containing a variety of minerals been demonstrated in environmental conditions.

Sediment particles from Steel Creek (obtained in a previous experiment[11]) were largely distributed in three ranges: a large band covering the density range from 2.21 to 2.47 g cm^3, a smaller band between 2.47 and 2.57 g cm^{-3} and a band, mostly of quartz, from 2.57 to 2.65 g cm^{-3} (Fig. 1). These bands constituted approximately 48, 22 and 17% of the recovered sediment,

Table 1 Description of the major density ranges of sediment particles fractionated by density-gradient centrifugation in a large scale zonal rotor

Sediment particle density range (g cm^{-3})	Mineral composition* (%)	Fraction by Weight (%)	Fraction by ^{137}Cs activity (%)	^{137}Cs enrichment factor†
<2.21	95 Kl	7.1	5.1	0.72
2.21–2.47	95 Kl, 5 Qz	48.4	60.8	1.26
2.47–2.57	80 Kl, 15 Qz, 5 Mi	21.7	16.1	0.74
2.57–2.65	90 Qz, 5 Kl, 5 Mi	16.8	8.7	0.52
2.65–2.76	85 Mi, 15 Kl	1.9	6.0	3.16
>2.76	Hm	4.0	3.3	0.82

*Kl = Kaolinite, Qz = quartz, Mi = includes interleaved micas and muscovite, Hm = heavy minerals fraction containing anatase, iron-rich chlorite, traces of mica, and iron-rich sesquioxides. The quantities of each mineral were estimated based on their respective X-ray diffraction peak heights.

† Ratio of the fraction of ^{137}Cs activity to the weight fraction.

respectively (Table 1). Before density separation, X-ray diffraction showed only the minerals kaolinite and quartz in the <50-μm fraction (Fig. 2*a*). After fractionation, X-ray diffraction analyses revealed the mineral component in the density range 2.21–2.47 g cm^{-3} to be ~ 95% kaolinite (Fig. 2*b*), whereas the density range between 2.47 and 2.57 g cm^{-3} contained ~ 80% kaolinite and some quartz (~ 15%) and a little muscovite mica (~ 5%). The third major band (density range 2.57–2.65 g cm^{-3}) contained approximately 90% quartz, 5% kaolinite and 5% muscovite mica (Fig. 2*c*). The ^{137}Cs concentrations in these bands are ~ 1.0, 0.6 and 0.4 nCi g^{-1}, respectively. We attribute the decreasing ^{137}Cs concentration with increasing particle density to the increasing concentration of quartz (Table 1).

The highest ^{137}Cs concentration was observed in the particle density range from 2.65 to 2.76 g cm^{-3} (Fig. 1). The ^{137}Cs concentration in this density fraction (maximum >3.0 nCi g^{-1}) was three times that observed in the density fraction 2.21–2.47 g cm^{-3}, whose major mineral was ~ 95% kaolinite. The mineral component in the 2.65–2.76 g cm^{-3} density fraction was ~ 85% muscovite (Fig. 2*d*). The quantity of sediment particles isolated in this density range (2.65–2.76 g cm^{-3}) was only 0.28 g or <2% of the recovered sediment sample. Thus, through the use of density-gradient centrifugation in a large scale zonal rotor, sufficient quantities of the muscovite mica component of the sediment could be separated from the dominant minerals, kaolinite and quartz, so that the ^{137}Cs concentration associated with the micaceous component could be determined. This is the first explicit demonstration that ^{137}Cs is selectively adsorbed to 'Cs-fixing' minerals in environmental conditions.

Approximately 6% of the total ^{137}Cs burden is directly associated with muscovite and >80% is associated with density fractions whose major mineral component is kaolinite (Table 1). Less than 20% of the ^{137}Cs associated with the dominant kaolinite band (2.27–2.33 g cm^{-3}) could be displaced with 2 N CsCl and only 22% could be displaced with 5 N NaCl. On the other hand, 75–83% of the ^{137}Cs could be displaced from reference kaolinite clay using 1 N NaOAc[4], indicating minerals other than kaolinite are responsible for the observed 'fixation'. Delineating the ^{137}Cs 'fixation' mechanism for these kaolinite bands is beyond the scope of this paper. It is conceivable, however, that the quantities of interleaved micas present were sufficient to 'fix' ^{137}Cs, but could not be detected by X-ray diffraction procedures. Interleaved micas, because of their irregular interlayer spacing, are difficult to detect by X-ray diffraction. Soils that contain appreciable quantities of mica in the density range between 2.65 and 2.78 g cm^{-3} also contain interleaved micas that band between 2.21 and 2.47 g cm^{-3}. Mineral segregation in density-gradient centrifugation is good, but not perfect because of the incomplete dispersion of minerals in the non-aqueous density gradient[10]. Sufficient quantities of either interleaved micas or muscovite micas may have been present in the light density kaolinite band to provide

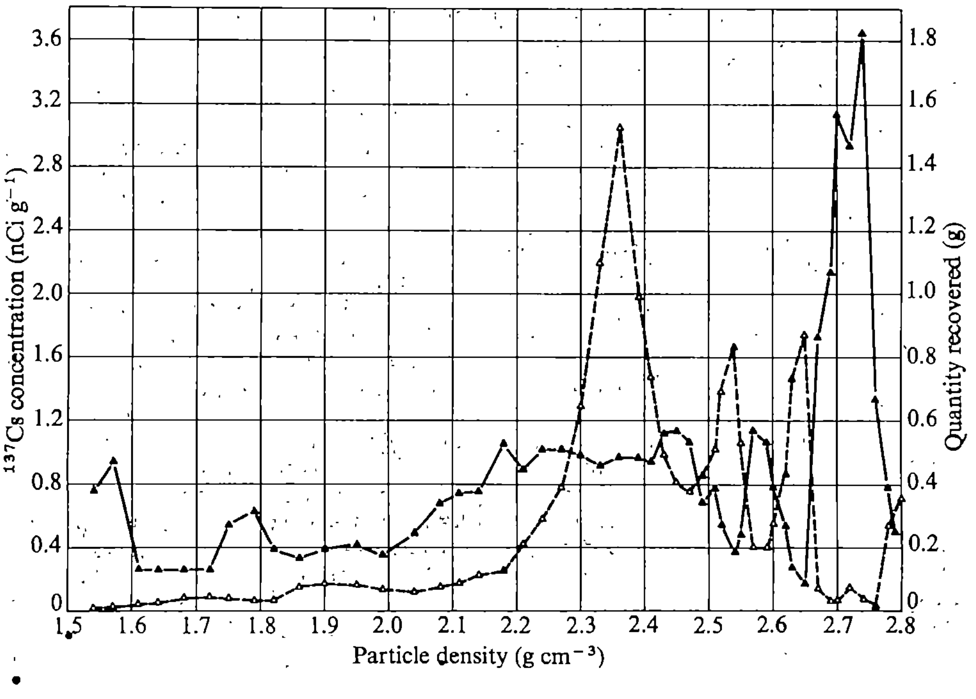

Fig. 1 Distribution of ^{137}Cs in sediment from Steel Creek, South Carolina. The concentration of ^{137}Cs in nCi g^{-1} (▲) and quantity of sediment recovered in g (△) at various densities (g cm^{-3}) after density-gradient centrifugation in a large scale zonal rotor.

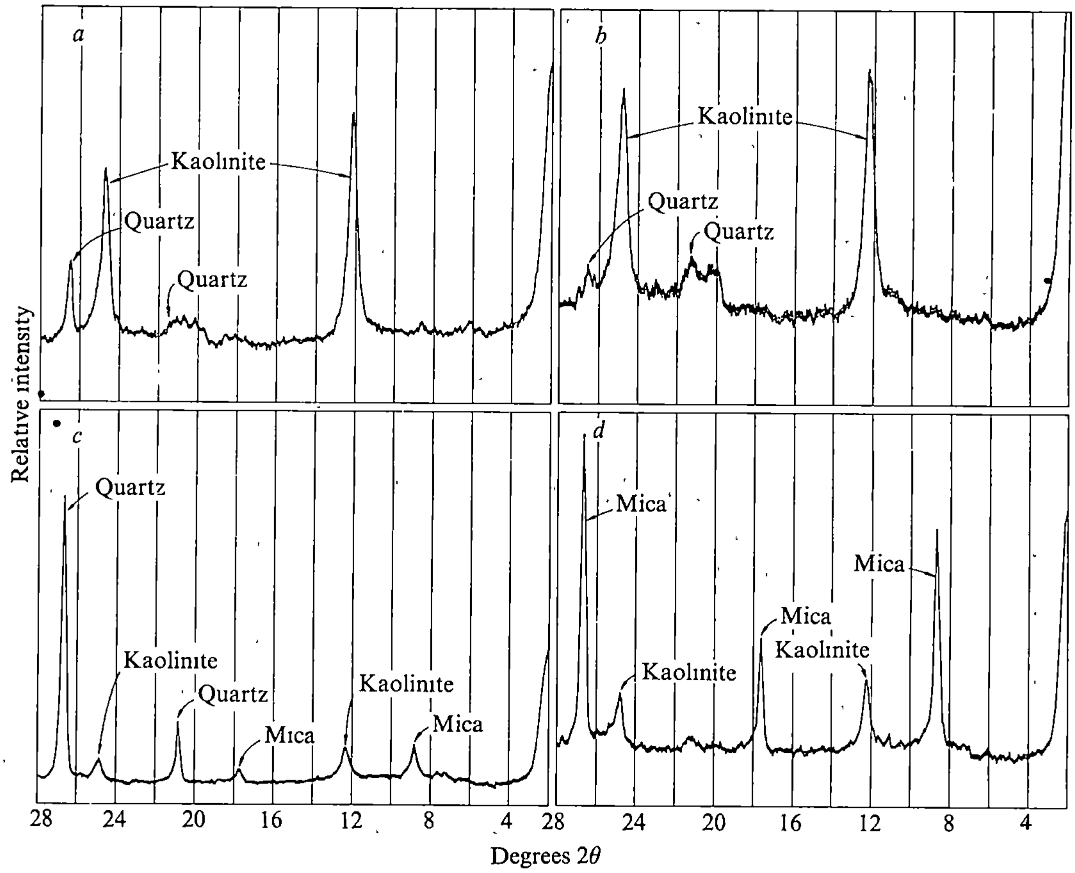

Fig. 2 X-ray diffraction patterns of the basal (001) diffraction maxima from oriented-aggregate mounts of *a*, Steel Creek sediment, <50 μm diameter; *b*, particle density fraction at 2.36 g cm^{-3}; *c*, particle density fraction at 2.65 g cm^{-3}; and *d*, particle density fraction at 2.74 g cm^{-3}. The abscissa units are degrees 2θ of Bragg's law and the ordinate reflects the relative intensities of the diffraction maxima using a Philips X-ray diffraction unit with a copper tube and nickel filter

'fixation' sites. For example, the ^{137}Cs associated with the density band identified as predominately a kaolinite mineral, is adsorbed to the weathered and unweathered mica minerals which cannot be detected by conventional X-ray diffraction procedures. Detailed examinations of a Georgia kaolinite using high resolution electron microscopy of ultramicrotomed sections of the kaolinite mineral revealed not only the expected 7 Å (001) spacing, but also occasional 10 and 14 Å spacings[12]. These higher interlayer spacings are thought to represent occluded and interleaved micas which will fix ^{137}Cs.

The consequence of selective adsorption of Cs to 'Cs-fixing' minerals in environmental conditions strongly influences the availability of ^{137}Cs cycling to the biotic component of a particular ecosystem. For example, as the ^{137}Cs diffuses from the less selective sites of soils or sediments to the more selective sites that 'fix' ^{137}Cs, the burden to biological organisms in that environment will be appreciably decreased. A case in point is the work of Eyman and Kitchings[13] who demonstrated that uptake of ^{137}Cs in bluegill (*Lepomis macrochirus*) and channel catfish (*Ictalurus punctatus*) from ingested clays containing adsorbed ^{137}Cs was ~ 8 times greater from montmorillonite and kaolinite than the interleaved mica, illite.

Oxygen isotopic evidence for the development of the psychrosphere 38 Myr ago

THREE major elements were involved in the evolution of oceanic circulation during the Cainozoic. The first of these was the diminishing role of oceanic meridional circulation in equatorial areas, the second was the development of circum-Antarctic circulation and the third involves the development of the present-day system of bottom waters of the world ocean, the 'psychrosphere'[1,2]. Because deep bottom waters are mostly derived from the polar regions, their characteristics, such as temperature, reflect surface conditions at high latitudes[3]. Past temperature changes of deep oceanic waters, and thus of polar surface waters, can be determined from the oxygen isotopic composition of deep-dwelling benthonic microfossils[3,4]. A deep-sea palaeotemperature record has been established[4] for the past 54 Myr based on DSDP sites in the sub-Antarctic; detailed arguments[4] give evidence that the Antarctic ice sheet developed during the Middle Miocene. Previous to this, however, a significant 5 °C decline in bottom-water temperature is recorded close to the Eocene–Oligocene boundary and is considered[4] to represent the onset of Antarctic bottom-water formation at temperatures close to freezing. This heralds the beginning of the modern thermo-haline circulation and is thus one of the most important palaeo-oceanographic events in the Cainozoic. We examine here

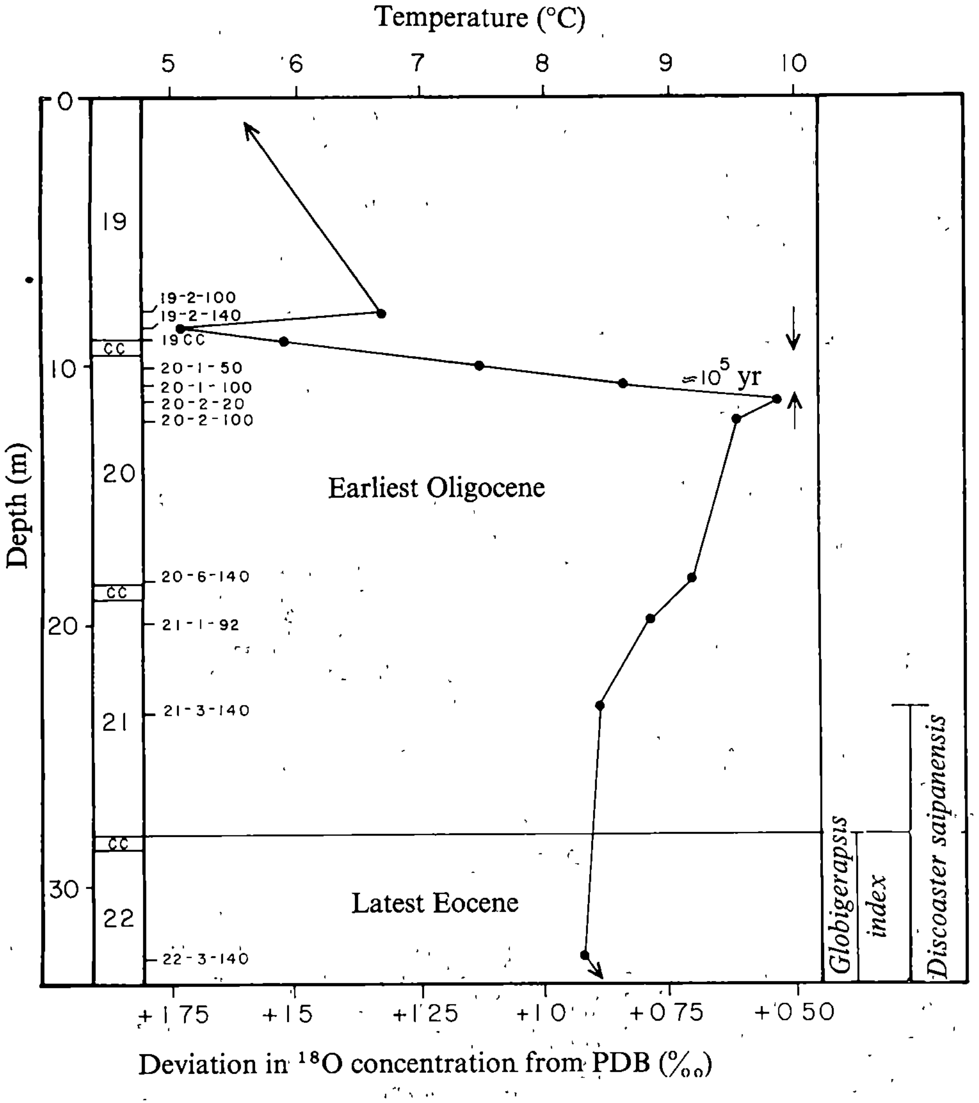

Fig. 1 Palaeotemperature curve and oxygen isotope data for benthonic foraminifera in latest Eocene–earliest Oligocene sediments of DSDP Site 277 (sub-Antarctic). Bottom temperature values were calculated using the procedure of Shackleton and Kennett[4]. The duration of the temperature drop of ~4 °C within core 20 is calculated from sedimentation rates at between only 75,000 and 100,000 yr. The Eocene–Oligocene boundary in this site is marked by the extinction of *Globigerapsis index*[6] as in New Zealand[32]. Thickness is plotted from top of core 19 which is 168.5 m below the ocean floor. Sample levels are shown.

in more detail the palaeotemperature event near the Eocene–Oligocene boundary, the latter having an age of 38 Myr (ref. 5).

Oxygen isotope measurements have been made on a series of latest Eocene to earliest Oligocene samples from cores 19 to 22 in DSDP Site 277, located on the Campbell Plateau in present day sub-Antarctic waters south of New Zealand (52° 13.43′ S; 166°11.48′ E; 1,222 m). This sequence consists of continuously cored late Palaeocene to late Oligocene foraminiferal-rich calcareous sediments[6]. About 38 Myr ago the southern part of the Campbell Plateau was at a palaeolatitude of ~ 65°S, 1,200 km nearer to Antarctica than now[7]. Samples of mixed benthonic foraminifera were analysed in 11 samples which consisted of ~ 0.1 and 0.4 mg carbonate after cleaning. Analytical methods, calibration and reproducibility of results have been discussed elsewhere[4–8]. The Antarctic continent was essentially ice-free before the Middle Miocene[4], and isotopic changes near the Eocene–Oligocene boundary are considered to have resulted from temperature changes.

A rapid reduction in bottom-water temperature from 10 °C to 5 °C during the earliest Oligocene is shown from the upper part of core 20 to the lower part of core 19 (Fig. 1), immediately followed by a brief warm oscillation (sample 19–2–100). Over half of the rapid temperature drop is represented in the uppermost part of core 20, the remainder between the upper sample of core 20 and the base of core 19 (sample 19–2–140). The sequence in core 20 represents a total recovery of 9 m (ref. 6) and thus the stratigraphic position of individual samples within this core is well established. The exact stratigraphic position of samples in core 19 relative to core 20 is unknown because of incomplete core recovery. Although there are now no geochronological methods to date the sediment of this apparently continuous sequence directly, the speed of the palaeotemperature change can be estimated using sedimentation rates. The rapid palaeotemperature change (Fig. 1) occurs over a thickness of only 170 cm. Sedimentation rates of ~1.6–2.2 cm per 1,000 yr for this interval[6] show that the duration of the palaeotemperature change was in the order of only 75,000–100,000 yr. About half (2.4 °C) of the temperature change recorded in the unbroken sequence at the top of core 20, took place in a period of 55,000–75,000 yr. The change occurs within the earliest Oligocene–latest Eocene *Globigerina brevis* foraminiferal zone[9] and the lower part of the *Reticulofenestra oamaruensis* to the top of the *R. placomorpha* calcareous nannofossil zones[10]. As in New Zealand, the Eocene–Oligocene boundary is placed at the extinction of *Globigerapsis index* (Fig. 1), and thus the temperature change occurs within the earliest Oligocene as recognised in temperate areas. At Site 277 the extinction of *Discoaster saipanensis* also precedes the isotopic event (Fig. 1). Further to the north in New Zealand, the extinction of *D. saipanensis* slightly precedes that of *G. index*[10]. A striking isotopic change in shallow-water benthonic fossils has also been shown close to the Eocene–Oligocene boundary in New Zealand sequences[11]. In the tropics, a decrease in bottom-water temperatures of ~5 °C is reported within the late Eocene between zones P15 and P17 (ref. 12), a change which must be isochronous with the sub-Antarctic event. This indicates that biostratigraphic correlations need modification between tropical, temperate and sub-Antarctic sequences. The extinctions of critical species probably occurred earlier in high latitude sequences creating diachronous usage of the Eocene–Oligocene boundary.

Our interpretation of the latest Eocene–earliest Oligocene oxygen isotopic change[4,11–13] is that it reflects a decrease in Antarctic surface-water temperatures to freezing and the production of extensive sea ice. This also marks the development of the psychrosphere. The oxygen isotopic evidence[4] indicates that no significant ice sheet formed at this time, and that the ice volumes on Antarctica remained relatively small until the Middle Miocene[4]. Ice-rafted debris in cores of Eocene and Oligocene age from the Southern Ocean off West Antarctica[14] record limited glaciation at this time, probably associated with alpine glacial development of West Antarctica[15], although others have suggested the presence of substantial thicknesses of ice since the beginning of the Oligocene[16]. In East Antarctica, ice conditions in the Palaeogene are unknown, but if glaciers were present, they did not reach sea level[17,18].

The drop in bottom-water temperatures in the earliest Oligocene caused a major crisis for the bathyal to abyssal benthonic fauna of the World's oceans including ostracods[2] and benthonic foraminifera[19]. The impact on planktonic fauna and flora was less dramatic but a simultaneous decrease (beginning in the late Eocene[20]) in surface water temperatures[4,11–13] caused a major reduction in diversity in planktonic organisms and a change in shallow-water echinoid fauna of South Australia[21] although these proceeded much less rapidly than in the deep-sea regions. A low diversity planktonic realm resulting from this crisis continued to the late Oligocene after which an increase in temperature resulted in increased diversity[22]. The planktonic microfossils at site 277 show no dramatic changes associated with the cooling[9,10].

It is now well established that the frequency of breaks or gaps in the stratigraphic record in all ocean basins reaches a maximum close to the Eocene–Oligocene transition[23–25]. There are also strong indications that the erosional event that created this disconformity commenced close to the Eocene–Oligocene boundary[7,24] and therefore is almost certainly linked with the development of Antarctic bottom water near the Eocene–Oligocene boundary. It is inferred that increased bottom-water activity caused erosion of deep-sea sediments in some areas and increased calcium carbonate dissolution in others, leading to mass wasting of calcareous sediments. The presence of widespread older disconformities[23,25] shows, however, that deep-sea erosion is not uniquely tied to the production of cold Antarctic bottom water.

Increased oceanic turnover, inferred to have commenced in the earliest Oligocene, is reflected by increased calcareous biogenic productivity in the central Pacific causing an increase in accumulation rates[26,27]. A major and apparently rapid deepening also occurred at this time in the calcium carbonate dissolution boundary creating a sharp contrast between carbonate-poor late Eocene and carbonate-rich early Oligocene deep-sea sediments[26,28,29]. Major palaeoenvironmental changes even occurred in shallow marine sequences related to extremely widespread shallowing of facies[30], although the causes of this sea-level lowering are unknown.

It is not clear what caused the rapid cooling of Antarctic waters 38 Myr ago. The Cainozoic palaeoclimatic development of Antarctica is marked by rather rapid temperature decreases superimposed on a steady climatic cooling after the early Eocene[4]. The Eocene–Oligocene boundary event therefore probably represents a critical threshold level in Antarctic climatic development, which in itself is related to more gradual isolation of the continent, resulting from the northward spreading of Australia and the opening of the Drake Passage. Intense circum-Antarctic flow did not develop until much later in the late Oligocene when the South Tasman rise split from Antarctica[7,31]. The timing of the opening of the Drake Passage is unknown, but is possibly linked to the palaeoglacial event 38 Myr ago[21,28]. Without additional Antarctic deep-sea drilling, the basic causal mechanisms of such Antarctic climatic changes will remain unanswered. In the meantime the events that occurred near the Eocene–Oligocene boundary will remain among the most profound for the entire Cainozoic.

Grenville age for rocks in the Moine of north-western Scotland

THERE is considerable debate concerning both the age of sedimentation of the Moine Series and its tectonometamorphic history. Though several workers have argued for the presence of Precambrian metamorphic and tectonic features within the Moine (see, for example, ref. 1), others have considered these features to be essentially of Caledonian age (see ref. 2). In consequence, syntheses of the evolution of north-western Scotland during Proterozoic and early Phanerozoic time include the Moine either as an older part of the Dalradian sedimentary prism which became involved in both early and late Caledonian orogenic activity[3], or as a pre-Dalradian sediment wedge affected by pre-Dalradian (Morarian) subduction[4]

In spite of the growing number of mineral ages from several parts of the Moine outcrop which lie between 600 and 820 Myr (see, for example, ref. 1) and a "preliminary isochron indicating" a Rb–Sr whole rock age of 810 Myr (ref 5) for the Ardgour Gneiss, there is no firm, published,

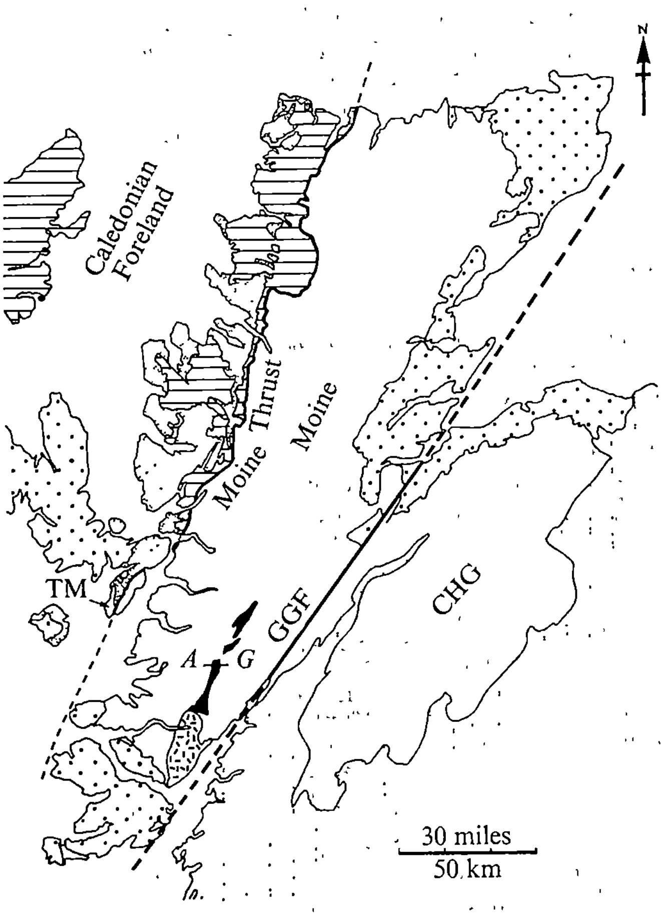

Fig. 1 Geological setting of the Ardgour Gneiss. isotopic evidence for either the age of sedimentation of the Moine or the antiquity of subsequent orogenic activity.

Data are presented here for a Rb–Sr whole rock isochron for the Ardgour Gneiss at Glenfinnan (Fig. 1), which suggest strongly that the sedimentation of the Moine and the early thermal events which affect them, are of Grenville age[6].

The Ardgour Gneiss is a large body of migmatitic gneiss which has been considered as a metasomatic derivative of Moine metasediments[7–9]. The suggestion that it is a deformed and metamorphosed pre-orogenic granite has not gained support[8–10]. The gneiss has a generally concordant and transitional contact with surrounding, high grade, migmatitic Moine metasediments[7,8] and it occupies the core of a major second phase fold[8]. Neither Harry[7] nor Dalziel and Johnson[8] consider the gneiss to be diapiric but rather the result of partial fusion and metasomatism *in situ*. Structural elements contained by the gneiss indicate that metasomatism (migmatisation) took place after the first regional deformation of the Moine but before the second[8,10]. The migmatisation is thus coeval with the acme of the early regional metamorphism which preceded and overlapped these second phase movements[8,10].

Eleven whole rock samples of the Ardgour Gneiss were collected along a 1.5-km road section east of Glenfinnan (Fig. 1). Seven of these weighed between 16 and 30 kg, the remaining four between 2 and 3 kg. The Rb and Sr concentrations were determined using X-ray fluorescence spectrometry; ^{87}Sr/^{86}Sr ratios by mass spectrometry.

The data obtained (Table 1) define an isochron (Fig. 2) giving an age of 1,050±46 Myr and an initial ^{87}Sr/^{86}Sr ratio of 0.708±0.002. This is the age of the last strontium isotope homogenisation, which we consider occurred during the migmatisation. Following the methods of Hurley *et al.*[11], and Faure and Hurley[12], it can be calculated that the parent material of the Ardgour Gneiss would have had a mantle ^{87}Sr/^{86}Sr ratio of 0.700, 1,250 Myr ago. On this basis Moine sedimentation must have occurred 1,250–1,050 Myr BP.

If the conclusions concerning the derivation of the Ardgour Gneiss relative to the tectonometamorphic history of the Moine are correct it follows that the main, early, metamorphism took place about 1,050 Myr BP. Because it is associated with the second phase of deformation of the Moine[13] both the first and second major tectonic events affecting these south-western, or Morar, Moine are not only of Precambrian age but are broadly equivalent to similar events in the Grenville Province of Ontario[14] and the Gothides of Southern Norway[15]. If the age of sedimentation of the Stoer Group[16] of the Torridonian can be considered as 995±24 Myr (ref. 17) it is likely that Moine sedimentation was earlier.

It is significant that there is, as yet, no evidence for pre-Dalradian tectonothermal events affecting the Central Highland Granulites[18], supposed equivalents of the Moine lying to the south-east of the Great Glen Fault (Fig. 1). It seems that the Central Highland Granulites are much younger than the Moine *sensu stricto*[13] and are possibly equivalent to the Torridon Group[16] of the north-western forelands of the Caledonian Belt; perhaps to the Tarskavaig Moine[19] of the Kishorn Nappe; and to the Moine-like rocks of northern Mayo[20]. On the other hand, the Moine *sensu stricto*, may be equivalent to rocks of similar aspect in Ireland, namely those of the Ox Mountains[21] and Lough Derg[22], for which a Grenville age has already been suggested[21].

The implications in terms of crustal movements in north-western Scotland during the Proterozoic are that the Moine

‡Analytical errors derived from replicate XRF analyses and the overall reproducibility of ^{87}Sr/^{86}Sr measurements. These were used in the calculation of the regression line[23], which has a value of 1.1 for $S/(N\text{-}2)$ (ref. 24), fulfilling the criteria for an isochron.

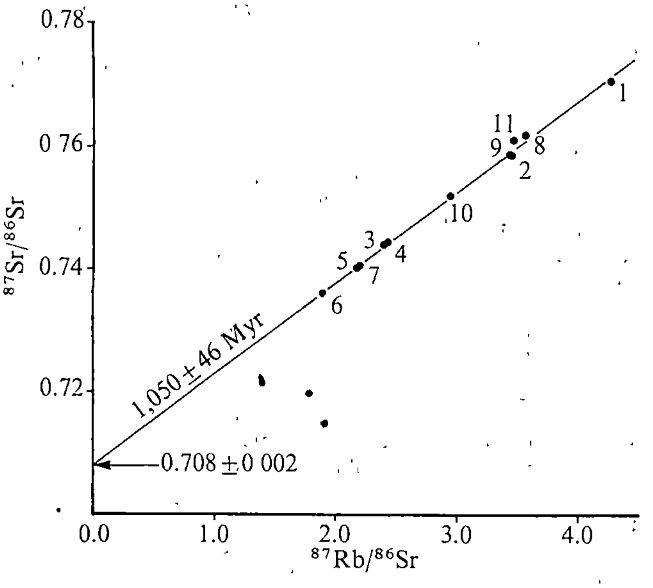

Fig. 2 Whole rock Rb–Sr isochron, errors quoted at the 2σ level. The ^{87}Rb decay constant is taken as 1.39×10^{-11} yr^{-1}.

achieved its orogenic condition some 600 Myr before the acme of subsequent Caledonian activity. Thus consideration of the Moine and Torridonian as broadly time equivalent sedimentary prisms on the western margin of the precursor to the Atlantic Ocean[3] is no longer tenable. The Stoer and Torridon Groups may have been deposited on a separate continental block from the Moine[4], but equally the Stoer Group could be considered as molasse derived during the Morarian orogen.

We thank N. J. Snelling for encouragement and advice, and J. Mitchell for help with sample preparation.

Pre-Palaeozoic basement of the Scottish Midland Valley

THE tuffs and agglomerates associated with Carboniferous volcanism within the Scottish Midland Valley comprise predominantly basic volcanic and unmetamorphosed sedimentary fragments. For the most part, the former can be confidently ascribed to the contemporary basaltic volcanism whereas the sedimentary materials seem to be derived from Carboniferous and possibly Devonian strata. In spite of the fact that the bulk of the clasts within the volcanic vents are undoubtedly of shallow crustal origin and are unlikely to have had a vertical travel of more than a few thousand metres, others—in particular the spinel lherzolite clasts known from several vents—have probably arisen from subcrustal levels. In the Elie Ness vent, high pressure pyroxenes and pyrope garnets indicate rapid elevation from depths in excess of 60 km (ref. 1). It would be surprising if such violent, gas-fluidised eruptions, capable of carrying mantle materials, entirely failed to sample lower levels of the crust.

We have to call attention to a previously undescribed assemblage of metamorphic rocks at the Partan Craig vent [NT 567852] on the southern side of the Firth of Forth, some 1.5 km east of North Berwick Harbour. The locality is situated roughly midway between the lines of the Southern Upland Fault and the extended line of the Pentland Fault.

The clasts within and around the vent comprise mainly altered alkali basalt and basaltic tuff, with a wide variety of quartzitic sandstones and scarcer cherts, limestones and indurated shales. Some relatively coarse-grained biotite-rich mafic and ultramafic clasts also occur and include (altered) mica-peridotite and glimmerite. One clast seems to be an intensely carbonated (mica-poor) peridotite.

In addition, coarse-grained gneissic fragments may be found sparingly among the pyroclasts, the largest samples up to 1,500 cm in size. From a thin-section examination of 30 samples, two main categories may be distinguished. First, garnetiferous quartzofeldspathic gneisses; second, less siliceous (but still quartz-bearing) plagioclase-clinopyroxene gneisses. The larger blocks show a foliation with flattened quartz grains parallel to a model mineralogical layering, and the whole metamorphic assemblage may well have been derived from a coarsely banded basic and acid gneiss formation.

The feldspars range from sodic labradorite to oligoclase and, like the quartzes, display strain textures. In several clasts, string perthite is present. A preliminary examination of garnet from one clast indicates a composition approximately midway along the pyrope–almandine join. Kelyphitic rims to the garnets are ubiquitous. The pyroxene is a dull greenish augite ($\sim Mg_{37}Fe_{18}Ca_{45}$) which has been extensively replaced by carbonate and chlorite. Biotite, apatite, rutile and zircon are common accessories.

These features strongly suggest granulite facies metamorphism and recall the gneisses recently described by Strogen[2] from Carboniferous agglomerates in central Ireland. Though the age of these gneisses is as yet unknown the metamorphic grade is clearly higher than that seen in any of the Lower Palaeozoic rocks of southern and central Scotland, and the mineral assemblages are unlike those of the Dalradian rocks of the Grampian Highlands. This strongly suggests that the gneisses were brought up from a pre-Palaeozoic 'basement'. It is worth noting that, in spite of extensive search, no clasts were found in the vent that could be unequivocally assigned to the Lower Palaeozoic greywacke-shale successions of the Southern Uplands or Pentland inliers, the Lower Devonian basalt–andesite–trachyte–rhyolite succession of the Pentlands, the Dalradian metasedimentary–metavolcanic successions, or to any equivalents of the Ballantrae spilite–serpentinite–blueschist complex. Though too much weight must clearly not be given to such negative evidence, the possibility should be considered that at North Berwick, Upper Palaeozoic sediments directly overlie a gneissic basement complex The biotite-rich mafic and ultramafic clasts are probably genetically related to the basanitic magmas the degassing of which was responsible for the drilling of the vent.

The discovery of gneissic blocks at North Berwick lends support to the views expressed by Kennedy[3] and George[4] that the Dalradian Basin was bounded to the south by a Precambrian landmass underlying the Midland Valley and the region further south. In north-western Ireland, upper Dalradian (mid-Cambrian) turbidites could have been derived[5] from an uplifted basement of amphibolite and granulite facies lying to the south-east, of which the Deer Park Complex formed a part. Church and Gayer[6] also considered that some of the Connemara metamorphic rocks could represent exposures of a sialic basement to the Midland Valley structural unit. The concept of continental crustal rocks underlying the Southern Uplands and their Irish (Longford Down) continuation has both geological and geophysical support[2,7,8] and the new observations from Partan Craig would seem to confirm that a high-grade metamorphic complex also underlies at least a portion of the Midland Valley. It is difficult to reconcile the presence of these gneissic clasts with the various models proposed by Jeans[9], Gunn[10] and Mitchell and McKerrow[11], in which post-Arenig formations of the Midland Valley are postulated to overlie an earlier Palaeozoic oceanic crust.

Cromagnon in the Iron Gate Gorge of the Danube

RADIOCARBON datings on human skeletons from the Padina site in the Iron Gate Gorge of the Danube in Yugoslavia have revealed that they belonged to a population at least 9,000 yr old This age is of especial importance because it is the earliest yet obtained by radiocarbon analysis for human bones from the region. It indicates for the first time the existence of a Cromagnon population in Yugoslavia.

During excavations at Padina[1], the remains of 37 individual skeletons, all in a very bad state of preservation, were uncovered. Anthropological study and laboratory examinations have shown that the skeletons possess all the morphological characters of the Cromagnon racial type. The skulls are long with huge supraorbital ridges and low vaults and the jaws are very large, with very rough areas for muscular attachments and with large prominent ridges and spines. The bones of the limbs are also large and robust with strongly marked muscular imprints. The average estimated height of the male individuals is approximately 180 cm (ref. 2).

Bone tissue for the analysis reported here came from the upper end of the best-preserved femora obtained. The specimens came from the lowest geological layer of the excavations. So far, two dates have been obtained· 6,487±83 yr b.c. (BM1144); and 7,248±103 yr b.c. (BM1147).

The Padina population lived in arc-like hollows beside the river bank which was intersected by rocky ridges and surrounded by wooded cliffs Alterations in the course of the river destroyed several such settlements, and gravely impaired the state of preservation of the human remains.

The excavations are into early Holocene deposits (~10000–6000 BC). At that time the climate, flora and fauna, and the general terrain and geography of Yugoslavia, became similar to those of the present day. The permanent snow cover of the Dinaric mountains melted, and grassland—bringing with it wild wheat, oats, barley and rye—spread along the Danubian plain. Wild goats, pigs, cattle and deer inhabited the forest[3]. It is very probable that in this region some Pleistocene hunters and gatherers adapted themselves to the new climatic conditions and migrated along the Danube, which offered them a new source of food Fishing became as useful as gathering and hunting.

Archaeological finds and cultural remains at Padina (and other sites such as Hajdučka, Vodenica, Lepenski Vir and so on[1] have not previously provided suitable material for accurate dating, although a radiocarbon date of 4,950 yr b.c. has been obtained from charcoal from the floor of one of the houses at Lepenski Vir (British Museum Radiocarbon Laboratory). Recently, similar material from Vlasac (not very far from Padina), examined at the Radiocarbon Laboratory in Zagreb has given a date of 5,609±93 yr b.c. (ZG 267); until this report, that was the earliest estimated age for these populations.

It is expected that further excavations further down the River Danube in the near future will reveal more human material in a better state of preservation, thus enabling a more detailed study of this newly discovered Cromagnon population.

I am grateful to the British Museum Research Laboratory for performing the ^{14}C analysis, and to the Radiocarbon Committee for financial support. I also thank the Institute of Archaeology in Belgrade, Yugoslavia, for providing the financial support for the field work and anthropological study

Effect of sewage sludge on mineralisation of organic carbon in soil

SOME 40% of the sludge produced at inland sewage works in England and Wales is applied to agricultural land[1]. In addition to the plant nutrients and organic matter they provide, such sludges also contain various quantities of heavy metals[2]. In some cases, repeated and very heavy dressings of sludge have led to accumulations of harmful elements that are toxic to plants[3]. There has been concern about their possible accumulation in agricultural soils receiving sludge[4]

since, as Tyler[5] suggested, microbial activity in soils is susceptible to enhanced levels of heavy metals. The state of soils receiving sludge is monitored by regular analyses[6], and the Advisory Services of the Ministry of Agriculture (ADAS) have recommended a combined upper limit[7] to the total load (pre-existing and applied) of Zn, Cu and Ni, above which crop plants may be affected. We have investigated whether the approved quantities of sludge have adverse effects on the microorganisms responsible, in aerobic conditions, for mineralising the organic carbon in the soil, and have shown that three contrasting sludges from the same works, when mixed with soil in amounts up to five times the recommended limit, had no adverse effect on carbon mineralisation.

The three sludges tested (Table 1) came from a treatment plant receiving mixed domestic and industrial effluent, and they have all been used agriculturally. A single potting soil was chosen for this investigation because its properties (loam, pH 6.7, organic matter 4.1%) placed it near the centre of the range of agricultural soils. It was air dried and sieved through a 2-mm mesh. Samples of soil were treated with quantities of sludge—roughly equivalent to multiples of the maximum amount likely to be applied to agricultural land in one year (Table 2, level I)—thoroughly mixed, and placed in 15-cm pots. Maximum applications of two of the sludges (activated and secondary digested sludge) were limited by their high liquid content. Table 2 describes the sludge applications in three ways: as the actual amount of sludge added per treatment (*A*); as the ratio of the combined load of Zn, Cu and Ni (calculated according to ADAS procedure) to the recommended maximum load (*B*); and as the amount of organic matter added, expressed as a percentage of total soil (*C*). It should be noted that the three highest rates initially increased the soil organic matter by 25–250%.

The pots were planted with barley and set up in an illuminated greenhouse (minimum temperature 10 °C) for nearly a year, during which three crops were grown to the five-leaf stage and harvested. The barley was watered regularly, and the drainings recycled. The soils were allowed to drain and to dry out between crops and after the last crop. At this time samples of soil were taken from each pot, air dried, and again sieved through a 2-mm mesh. Their pH in water then ranged from 6.0 to 6.4.

Duplicate aliquots (10 g) of each sample were mixed with 0.5 g of ground oat straw (< 1 mm, 0.68% total nitrogen and 40.1% organic carbon), brought to 50% saturation with water containing ammonium nitrate to provide 100 p.p.m. N in the dry soil, and incubated at 30 °C Carbon mineralised as CO_2 was determined by the barium peroxide method[8] and expressed as p.p.m. of air-dry soil.

After 76 d incubation the pH in water ranged from 5.7 to 6.3, and soluble nitrogen (NO_3^- and NH_4^+ extracted with 1 M KCl) from 93 to 151 p p.m. dry soil, neither being related to sludge treatments. Clearly, carbon mineralisation had not been retarded by low pH or lack of available nitrogen. Figure 1 presents the cumulative CO_2–C release after 14, 35, 50 and 76 d. The lack of a consistent pattern in the results from the 0–III treatments indicates the degree of intra-treatment error.

There are only small differences between sludges and heavier applications of sludge increase the quantities of CO_2 produced, presumably in part from the organic carbon they contain. Since a parallel comparison showed no significant difference between the CO_2 produced by equal applications (350 g per pot) of filter cake, one of which had been first ignited to destroy its organic matter, it seems unlikely that the effects of the higher applications can be explained as reduced microbial activity on increased organic matter. So it seems that the overall activity (as measured by CO_2 production) of the organisms responsible for the decomposition of natural and added organic matter is unaffected by any of the types and levels of sludge applied.

Our highest sludge additions raised the copper concen-

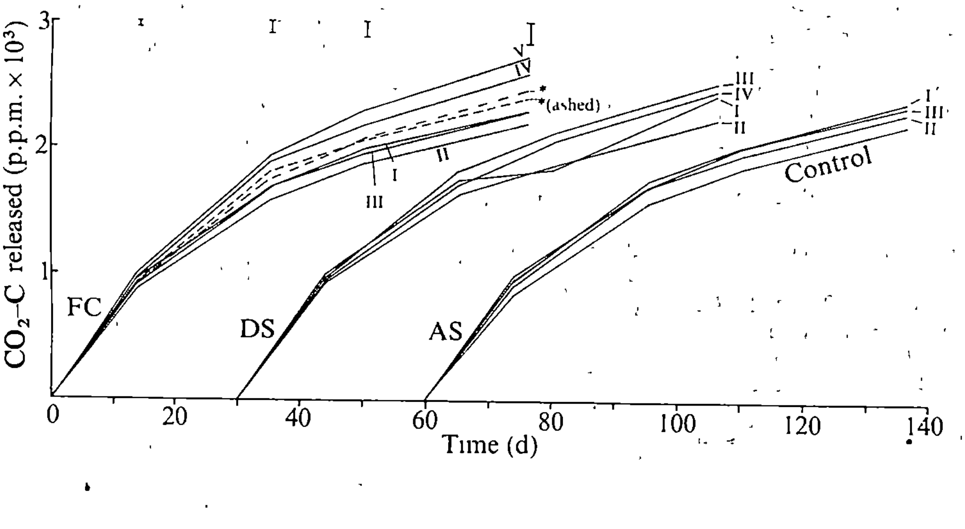

Fig. 1 Carbon mineralisation, measured as p.p.m. of C released as CO_2, in soil treated with increasing amounts (I–V, see Table 2) of consolidated activated sludge (AS), secondary digested sludge (DS) and filter cake (FC). Three control soils have been averaged. The pot treatments were not replicated and the least significant differences ($P < 0.05$) shown relate only to the two samples from each pot that were incubated separately. *Indicates a subsidiary comparison of ashed and unashed 350-g samples of FC.

tration in the soil by 123 p.p.m., whereas Tyler[5] reported that the mineralisation of soil N may be adversely affected by copper concentrations greater than ~50 p.p.m. of dry soil. Nitrogen mineralisers are, however, thought to be more susceptible than carbon mineralisers, and Tyler's soils were very acidic (much more so than most agricultural soils in Britain). Heavy metals are widely reported to be more harmful in acidic conditions, so we do not find his or our results inconsistent.

Human olfactory communication

IT has long been known that animals use their olfactory senses to communicate information, including sexual status, individual identification and maternal attraction[1-3]. Olfactory communication has been demonstrated throughout the Mammalia, including the primates[4,5], and there has been speculation as to whether or not it exists in some form in man[6,7]. Substances are know to exist on man that serve an olfactory function in other animals[8] and there are many apocrine and sebaceous glands on the human body that produce such secretions. We have done two experiments, the first to determine whether adults can identify an individual and determine his or her sex by the odour of an article of clothing, and the second to examine whether an infant can identify its mother's odour by a behavioural response

In the first experiment the subjects were 29 freshmen college students, 16 male and 13 female, all recruited by announcing the nature of the experiment in class and asking for volunteers The subjects were asked not to use any soap, perfume or deodorant for 24 h before the experiment and to wash only with clear water during this period. Then they were each given a plain white, appropriately sized, T shirt of 50% polyester and 50% cotton, and asked to wear the shirt as an undergarment for 24 h. The subjects were asked to don the shirts after class and remove them before class the next day. They were provided with new identical sealable plastic bags in which to place their shirts. The shirts were then collected, removed from the bags, and put in wax-coated cardboard ice buckets in which a one-inch triangular hole had been cut (to allow the subjects to sniff the contents). The ice buckets were then placed on waxed paper with the shirts arranged so that the under-arm portion was closest to the hole. Each subject was tested individually in a testing room. The placement of containers was randomised for each subject.

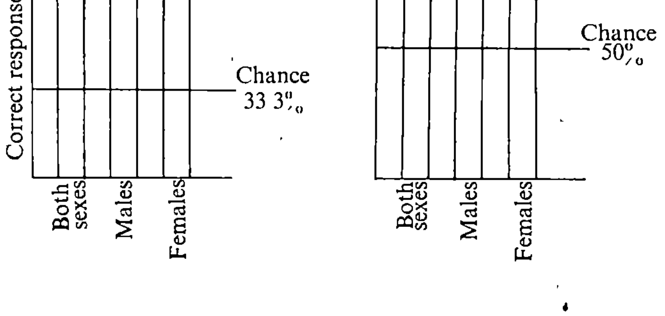
The first test was a three-choice discrimination consisting of: (1) the subject's own T shirt; (2) a strange male's T shirt, and (3) a strange female's T shirt. After each subject entered the testing room and was seated, he was asked to "sniff each bucket three times and indicate which one is yours—take as much time as you wish, and sniff as many additional times as you wish". Generally, each subject sniffed each bucket once in succession and then repeated this process.

The second test always followed the first and was the same except that it was a two-choice discrimination between the same strange male and the same strange female T shirt as used in the first test, and the subject was asked to discriminate the sex of the wearer by indicating which was male. Test 2 followed test 1, within a few minutes.

In each test, thirteen of the sixteen males and nine of the thirteen females answered correctly. This provided a highly significant result of $P=<0.001$ for test 1 and $P=<0.005$ for test 2 when a binomial expansion was used as a statistical measure.

While the number of correct responses was the same in each test, the individuals who answered correctly were not always the same. Several of the students remarked that they felt they would have been able to make the discrimination

Fig. 1 Experiment 1. *a*, Test 1 shows the percentage of correct responses in identifying subjects' own odour in a three-choice discrimination. *b*, Test 2 shows the percentage of correct responses in identifying male odour in a two-choice condition.



at a lower concentration of odour, but none of them mentioned finding either the strength or types of odour objectionable.

There was considerable variation in the concentration of the odour samples and no attempt was made to control diet, sexual cycles, or drug variations within the subjects or donors, yet most subjects could select the correct odour easily. During informal questioning after the test the male odours were usually characterised as musky and the female odours as sweet.

These tests show that at least the rudimentary communications of sexual discrimination and individual identification can be made on the basis of olfactory cues.

In the second experiment we investigated whether a similar type of ability could be demonstrated in an infant and, further, if olfactory discrimination would elicit a behavioural response. Several authors, including Darwin[9], have provided anecdotal reports that children may use odour to identify their mothers at an early age. Pratt *et al.*[10] reported that Pryer, Canestrini and Peterson Rainey in separate experiments obtained preliminary but conflicting evidence that infants may be attracted to the odour of their mothers' milk when nursing.

The subjects were recruited by asking mothers in the delivery ward of the University of California Moffitt Hospital to volunteer for the experiment. The subjects were 14 healthy full-term breast-feeding mothers (both multiparas and primiparas) and their infants. Tests were conducted on the second day, during the second week, and during the sixth week after birth. The olfactory stimulus used for these tests was obtained by asking each mother to place a breast pad (white cotton sponges) inside her bra for 3 h before testing. The mothers were also asked not to feed their babies during this period so that the infants would be somewhat hungry, but not distressed, during testing.

The test consisted of the experimenter holding a folded breast pad with thumb and index finger under the infant's nose at a distance of 1–2 cm for approximately 30 s while being careful not to touch the infant. During each test the infants were exposed to: (1) a clean moist pad; (2) a familiar (own) mother's pad, and (3) a strange mother's pad. For each infant the sequence of presentation was random. During the 6-week test the infants were also tested with a pad that had been moistened with raw cow's milk. Each test was conducted in either a standard hospital bassinet, or the infant's crib at home.

The test on day two was conducted in the hospital at the mother's bedside, and the 2- and 6-week tests were conducted in the home of the subject with the mother present. All breast pads were collected just before testing, except when it was necessary to travel between homes and then the pad from the strange mother was stored in a plastic bag The order of presentation of pads was random.

Infants were tested while sleeping whenever possible and not tested when distressed or crying. Pilot work had indicated that this was the only time that the infants could be tested independently of visual and auditory cues When an infant was aroused by the stimulus, time was allowed between presentations for the infant to return to its original behavioural state.

As Fig. 2 shows, during the rest on day two, only one of the 10 responded to any of the stimuli presented. That infant made a sucking response to both the strange and familiar odour.

At 2 weeks, eight of the 10 infants responded to the odour of the strange mother, seven responded to their own mother, and three infants showed a differential response between the two. A differential response occurred when the infant responded only to his/her own mother's pad and not to the strange mother's pad. In the case of the 2-week test nine infants responded, six similarly to both odours, two just to the strange odour, one just to the strange odour and one just to the familiar odour. At no time did any infant respond to the clean moist pad.

At 6 weeks only one of the infants responded to the strange mother, seven responded to the mother's pad and six showed a differential response. The most common response observed (in five of the infants) was a sucking orienting response to the mother's pad and no response at all to the strange mother's pad. A sixth infant who was hungry and sleeping when the test began did not respond at all to the presentation of the strange mother's pad, but awoke and began to cry when its own mother's pad was presented.

In each of the 6-week tests the responses to the raw cow's milk were the same as to the strange mother's pads.

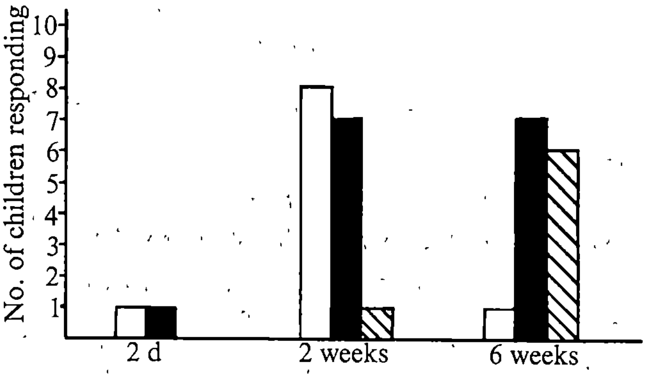


Fig. 2 Experiment 2. The responses of the 10 infants at 2 d, 2 weeks and 6 weeks to the strange mother's odour (open bars) and their own mother's odour (black bars). The hatched bar represents the number of children responding to their own mother and not to the strange mother.

Experiment two tested the infants' abilities to identify their mothers by odours left on breast pads at 2 d, 2 weeks, and 6 weeks after birth. At 2 d there was no response. At 2 weeks the infants showed general arousal and minimal, if any, discrimination. Then at 6 weeks six of the 10 infants tested could identify their own mother's odour from that of a strange mother's odour. At 6 weeks of age infants responded to their own mother's odours with a pattern of orienting and sucking that was markedly different from their response to both the strange mother's odour and the odour of raw cow's milk, which was added as an additional control. Furthermore, at least six of the infants showed a positive attraction to the mother and only one infant responded at all to the strange odour. This was a negative response, with a head jerk and a cry. The existence of olfactory maternal attraction suggests that humans have a pheromonal system and that it operates at a very early age. Since doing this work I have become aware of a strikingly similar experiment by Macfarlane[11] in which he was able to show a differential response at 6 d of age.

The initial identification of the mother may not be due to a response to her odours but rather to odours placed on her by the infant during earlier contacts, as demonstrated in other primates[12]. Furthermore, the possibility of this maternal scent marking in humans is supported by the common observation by parents of children who reject a favourite teddy bear or blanket after it has been washed because of the loss of odour acquired from earlier contacts.

Although the source of these odours has not been clearly demonstrated, olfactory cues seem to generate behavioural responses in infants, and sexual and individual identification seems to occur in adults.

This work was supported in part by a grant from Ms Imelda Finnigan and the National Institutes of Health. I thank Ms Margaret Rooney, Larry Elam, Dr Joseph Kitterman and Marc Russell for help

Importance of antennae for orientation of insects in a non-uniform microwave electromagnetic field

MICROWAVES can affect living organisms in different ways[1]. Radiation of high intensity is lethal, due to the thermal effect on the living tissues. Different organs are selectively sensitive both in vertebrates[2] and in insects[3]. Behavioural studies with rats have demonstrated that, in a choice situation, the animals will respond to an electromagnetic field of a rather low intensity, by leaving it[4]. Our investigations revealed that insects respond to the intensity gradient of a non-uniform microwave electromagnetic field in a similar way. In an arena illuminated by a non-uniform field insects carry out oriented movements avoiding the regions which are more intensely illuminated. In this paper we analyse the involvement of antennae in the orientation mechanisms underlying the avoidance response.

Adults of *Caryedon gonagra* (Fab.) and last instar nymphs of *Pyrrhocoris apterus* L. were used. The former species represents a beetle with low tendency to crawl, the latter one an active and fast moving bug. Antennectomised and intact specimens were tested in a round arena constructed from a polystyrene Petri dish. The arena was placed on the broad wall (bottom) of the waveguide of rectangular cross section (Fig. 1*a*). In this position a symmetrically non-uniform electromagnetic field was obtained inside the arena, with maximum flux density (power density) occurring in the axial E plane of the waveguide. The insects were released in the centre of the arena and all individuals avoiding the most intensively illuminated central band of the arena were counted every 60 s for 10 consecutive min. The width of the band was arbitrarily chosen so as to enclose the region of power densities greater than 50% maximum power density (Fig. 1*b*). The observations were made at five different power densities and the controls observed at zero electromagnetic field intensity. Behaviour of the beetles and bugs was observed three and five times with 11 and 5 fresh specimens, respectively. The maximum numbers of individuals observed at each repetition outside the central band after cessation of response, were summed up; the figure obtained served to express the avoidance response at a given power density. The significance of differences was estimated on the basis of a χ^2 test. Mortality was expressed as percentage of dead animals at the end of the 10-min observation period. A TESLA 50SA51 magnetron was used to generate the microwave power. Incident power levels used ranged from 100 to 1,200 W in a continuous wave (CW) regime and at a frequency of 2,375 MHz. The maximum power density inside the dish for the transverse electric (TE_{01}) mode used was 3 3–40 W cm^{-2}.

At zero incident power the beetles *C. gonagra* (Fig. 1*c*) tend to remain near the site of release. At 3.3 W cm^{-2} both antennectomised and intact specimens retained a tendency to remain in the central band. When electromagnetic power of increasing intensity was applied the intact animals began to respond by moving out of the central band at power densities of 6.6 W cm^{-2}, the avoidance response being highly significant at power densities greater than 6.6 W cm^{-2}. The corresponding threshold value for significance of the response of antennectomised beetles was at power densities greater than 13.2 W cm^{-2}. Lethal effects of microwaves were observed only at highest intensities used and predominantly in the antennectomised individuals.

Both antennectomised and intact nymphs of *P. apterus* (Fig. 1*d*) spread more or less equally to the periphery of the arena at zero incident power and quickly changed their positions

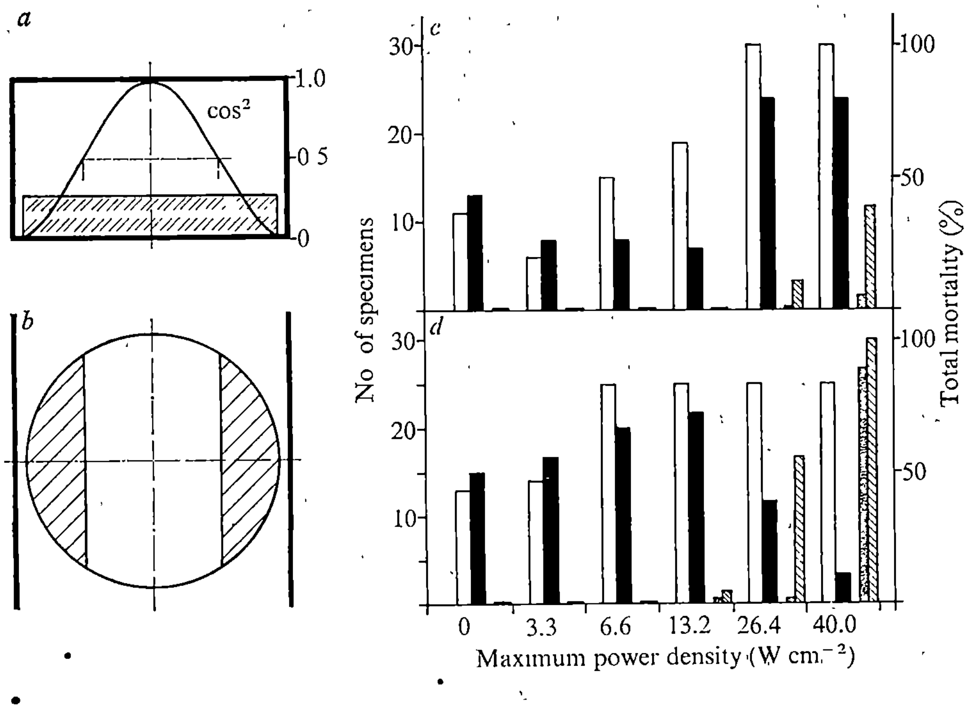

Fig. 1 *a*, Cross section of waveguide showing microwave energy distribution (cos^2) across arena. *b*, Surface view of arena; central (clear) band receives power densities greater than 50% maximum. Avoidance of central band by *C. gonagra* (*c*) and *P. apterus* (*d*) in intact (open columns) and antennectomised specimens (solid columns), and mortality in intact (stippled columns) and antennectomised specimens (hatched columns).

thereafter. Significant avoidance response was recorded only in intact specimens at power densities 6.6 W cm^{-2} or more. The response in antennectomised bugs was not statistically significant, although they showed a slight tendency to avoid the central band at higher power densities. Mortality was higher in the antennectomised specimens than in the intact ones.

These experiments thus provide two lines of evidence for importance of antennae in the orientation of insects along the intensity gradient of a microwave electromagnetic field. First, the threshold incident power levels for initiating the avoidance response are higher when the antennae are lacking. Second, the lack of antennae increases vulnerability of insects to microwave energy non-uniformly distributed over the arena, apparently because of impairment of their orientation mechanisms. A certain ability, although significantly reduced, of antennectomised individuals to avoid the field of intensive microwave radiation, however, suggests that still other mechanisms of orientation, which do not depend on sensory input from the antennae, may exist. We hesitate to speculate about their nature as well as about a possible biological significance of antennal sensitivity to microwaves. The threshold densities causing aversion in intact insects are 1,000 times higher than those in rats[4]; however, they are still well below the lethal dose (J.O., J.Ž. and J.D., unpublished). We suspect that in our experiments the aversion induced by microwaves is mainly due to thermal effects. Nevertheless, the sensitivity of intact specimens to rather low densities (6.6 W cm^{-2}) of the microwave field may indicate that the sensory apparatus of insects can detect, and that the animals can respond to, quantities of radiation producing no harmful effects. Nonthermal effects of microwave radiation on developing insect tissues have already been demonstrated[5].

We thank Dr B. Holubičková, Mathematical Centre of Biology, Czechoslovak Academy of Sciences, Prague, for assistance with the statistical evaluation of the results.

Non-ageing developmental variant of *Caenorhabditis elegans*

THE study of mechanisms affecting the rate of ageing can be facilitated by naturally occurring phenomena, innate to some organisms, that enable the species to retard its ageing rate and extend its life span[1]. Such a phenomenon exists in certain species of nematode. Larval forms of the free-living soil nematode, *Caenorhabditis elegans*, possess the ability to enter a semi-dormant, quiescent state referred to as the dauer larval stage (German, "enduring" larva). Newly hatched larvae of *C. elegans* undergo four larval stages (L1–L4) punctuated by moulting. If larvae are starved, they will enter the dauer state during the second larval moult. At this time, the old cuticle is replaced by a special, relatively impermeable cuticle unique to dauer larvae[2].

During this state the larvae cease to feed, the pharyngeal muscles become inactive and all development ceases. Dauer larvae are thermotactically opposite to non-dauer larvae[3] and are resistant to harsh chemicals such as 1% sodium dodecyl sulphate (SDS)[2]. Although no food is ingested, the dauer larvae are capable of moving during the dauer state. Dauer larvae maintain a high degree of motility close to or greater than that of non-dauer larvae for the first 2–3 weeks after dauer formation. This motility never completely ceases but declines gradually to a minimum by the end of the dauer life span (approximately 70 d). All dauer larvae used in these experiments were moving. Placing dauer larvae in a bacterial suspension of $\geq 5\times10^8$ bacteria per ml will stimulate the larvae to come out of the dauer state, undergo the third and fourth larval moults, and become mature, productive adults.

Fig. 1 *Caenorhabditis elegans* var. Bristol was cultured in liquid S-medium supplemented with *E. coli* strain OP50 at 10^9 bacteria per ml as described previously[4]. All cultures were grown at 20±1 °C. Initial inoculum was 6 worms per ml. 0, Time of hatching. △, Number of bacteria per ml as determined using Petroff Hauser counter; ○, worms per ml; ●, dauer per ml as determined by resistance to 1% SDS[2].

Table 1 Effect of duration of dauer state on life span

Duration of dauer state (d)	Post-dauer life span (Mean ± 95% c.i.m.*)	Mean no. of eggs	Egg viability (% hatch)	Total life span
5	11.16±1.20	283	100.0	16.16
10	10.08±0.96	330	98.1	20.08
15	9.68±1.16	236	97.7	24.68
20	10.89±1.13	304	100.0	30.89
25	10.19±1.08	323	91.3	35.19
30	10.53±0.93	242	93.4	40.53
35	9.38±1.12	282	97.4	44.38
40	10.23±1.42	270	95.0	50.23
45	9.90±1.47	290	84.8	54.90
50	10.16±1.71	339	100.0	60.16
55	11.05±1.85	274	94.2	66.05
60	10.24±1.81	394	97.7	70.24

*c.i.m., Confidence interval of the mean.

Dauer larvae were isolated by the SDS resistance method of Cassada and Russell[2] and were maintained in M-9 salt solution[4] At 5-d intervals samples of 100 dauer larvae were removed and placed on NGM agar plates seeded with a drop of *E. coli* (10^9 ml^{-1})[4]. Percentage survival, number of eggs laid and egg viability were determined at daily intervals at 20 °C. The mean life span of nematodes that never entered the dauer state at 20±1 °C is 12.76±1.08 d (n=50) and the average number of fertilised eggs produced per parent is 280±40 (±95% c.i m.*; n=25). Normal egg viability is ≥97%.

Dauer larvae can be maintained for more than 70 d (Fig. 1). The 50% survival time is approximately 45 d at 20 °C. There is a small increase in the frequency of post-dauer mortality (Fig. 2). As the duration of the dauer state increases, the percentage of larvae which fail to recover from the dauer state increases from 0% at 10 d to 32% at 60 d. This effect is probably due to the reduced vitality brought on by starvation.

The duration of the dauer state has no effect on the post-dauer life span (Table 1). There is no observable effect of the dauer state on (1) post-dauer life span; (2) post-dauer egg production; or (3) egg viability. Worms that have been in the dauer state for 60 d have the same post-dauer life span, lay the same number of eggs, and have the same egg viability as worms that have been in the dauer state only 5 d.

Dauer larvae have a primordial gonad composed of approximately 35 nuclei. The duration of the dauer state has no effect on the life span of the F_1 progeny which are descendants from these germ cells (Table 2).

If ageing in *C. elegans* is a result of random accumulation of damage (nuclear or cytoplasmic) due primarily to external insult for example, ultraviolet, X rays, cosmic rays, and so on, then it is reasonable to presume that prolonging the dauer state would be correlated to an increase in accumulated damage and subsequently a decrease in the post-dauer life span. This result was not found. There was no detrimental effect on life span observed by extending the dauer state up to 60 d. Mean post-dauer life span remained constant and the total life span simply increased by the amount of time spent in the dauer state.

Table 2 Life span of progeny of experimental worms

Duration of dauer state (d)	F_1 Life span (Mean ± 95% c i.m.*)	Mean no of eggs
5	11.10±1.29	275
10	12.47±1.02	279
15	11.70±1.19	198
20	11.59±1.01	224
25	10.13±0.94	269
30	11.44±0.75	294
35	11.02±1.15	198
40	11.70±1.33	169
45	11.52±1.18	264
50	11.78±1.37	273
55	11.53±1.21	199
60	10.77±1.32	248

*c.i.m., Confidence interval of the mean.

Samples of 100 F_1 larvae were taken on the second day of egg laying from parents who had been in the dauer state for increasing durations. The life span of the F_1 larvae and the average number of fertilised eggs produced by the F_1 worms were measured.

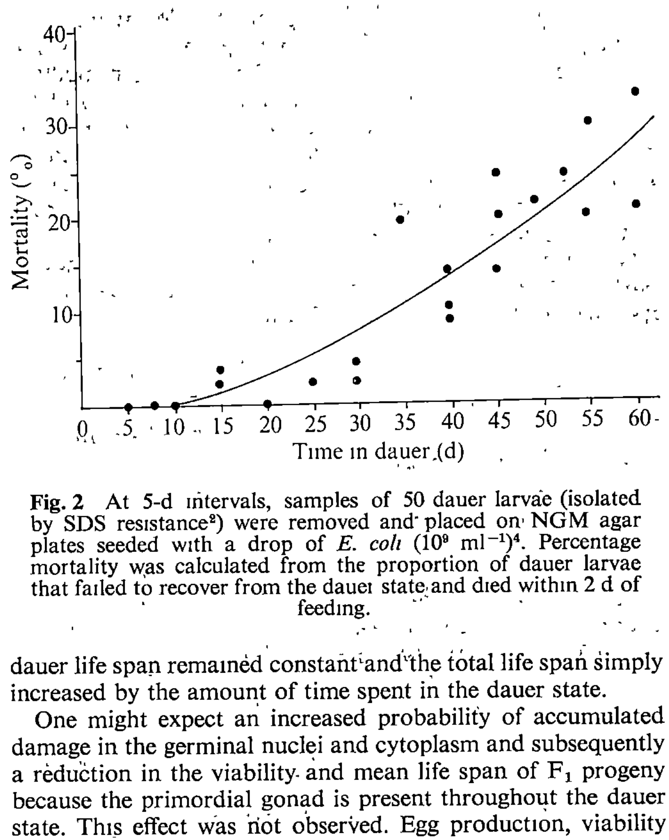

Fig. 2 At 5-d intervals, samples of 50 dauer larvae (isolated by SDS resistance[2]) were removed and placed on NGM agar plates seeded with a drop of *E. coli* (10^9 ml^{-1})[4]. Percentage mortality was calculated from the proportion of dauer larvae that failed to recover from the dauer state and died within 2 d of feeding.

One might expect an increased probability of accumulated damage in the germinal nuclei and cytoplasm and subsequently a reduction in the viability and mean life span of F_1 progeny because the primordial gonad is present throughout the dauer state. This effect was not observed. Egg production, viability and F_1 life span remained constant. It must be concluded that because there is no life-shortening effect of prolonging the dauer state up to 60 d (four times the normal life span) externally induced damage is not a primary cause of ageing in *C. elegans*. Normal ageing therefore must be an innate process whose rate is directly related to the metabolic rate.

The phenomenon of dauer larvae has been observed and described for many years. Many parasitic forms have infective larvae which can survive for extended periods in a dauer-like state. If they contact a host and subsequently develop, there is no correlation, above a survival threshold, between "age" of the larva and its ability to become an adult[5]. Our observations with *C. elegans* parallel the results obtained with parasitic forms.

Dauer larvae seem to be able to reduce or suspend the rate of ageing. This "non-ageing" quiescent state offers an interesting model for the study of mechanisms that control the ageing process. Analysis of the developmental processes that enable a metabolically active, rapidly growing larva of *C. elegans* to enter a developmentally dormant, "non-ageing" state may offer valuable insight into the controlling mechanisms of ageing.

Graphs of contracting glycerinated *Amoeba proteus*

GLYCERINATED *Chaos-Proteus* amoebae preserve their normal shape, but will contract after washing and introduction of physiological concentrations of ATP, Ca^{2+}, and Mg^{2+} (ref. 1). We have recorded the motion of activated glycerinated amoebae (amoeboid models) in a manner such that endoplasmic motions, shape changes, and contractile sites are pictorially graphed by the model during its contraction. Our findings contradict the frontal-zone contraction hypothesis, but do not unequivocally support the ectoplasmic tube contraction theory.

Glycerination of *Amoeba proteus* was carried out in 50% glycerol (v/v), EDTA 5 mM, Tris-HCl buffer 0.01 M, KCl 0.05 M, *p*H 7.0, at ~10 °C. It is critical to reduce the medium to a small volume containing a few starved amoebae and then rapidly to apply a large volume of this solution. Glycerination was continued for at least 24 h and its quality was judged by retention of amoeboid shape and by subsequent contractility of the model. Actual contractions of amoeboid models were in 25% glycerol (v/v) with ionic contents and buffers as above plus ATP, Ca^{2+}, and Mg^{2+}, each at 0.5 mM. The time for contraction varied from 1 to 10 min following ATP–Ca–Mg application.

Contractile dynamics were recorded under darkfield microscopy at low power (×60), and photographs were taken sequentially at 1-min exposures with ~5-s intervals. Figure 1 is a sequence of four photographs recording movements of amoeboid model contraction. The first photograph shows the amoeboid model washed immediately after adding ATP–Ca–Mg. Cytoplasmic granules appear white in the photographs and their horizontal displacement is recorded as streaks whose lengths vary with their velocities[2]. Granules that are moving vertically will show only a sharp single image. The beginning of contraction (second photograph) is indicated by the streaks of granules in motion. Their velocity can reach 50 μm min^{-1}. The third photograph in this sequence illustrates the continuing contractility of this model. The last photograph is the contracted amoeboid model, indicated by a lack of recorded motion.

Study of these photographs facilitates precise determination of the contractility sites and the resultant motion of this model. The outlines below the fourth photograph summarise the visible changes in shape displayed by this glycerinated model. Measurement of the large leading pseudopodium reveals a slight change in length, emphasising that contraction occurs predominantly in the width of the model. Ectoplasmic contraction towards the central portion would account for this observed motion.

Figure 2 is a three-photograph sequence of a glycerinated model illustrating that pressure can be generated by contraction, as indicated by endoplasmic displacement. In the first and second photographs, at pseudopodial junctions near the tail end (bottom of photograph), prominent streaks can be seen in the central portion of the model, indicating endoplasmic motion. The volume change during contraction of this model is relatively small. The last photograph of this sequence records the endoplasm being forced out of an ectoplasmic rupture into the environment.

These photographs of ATP–Ca–Mg-activated *A. proteus* models demonstrate that contraction first, is localised in the ectoplasmic tube; second, can displace glycerinated fluid-like endoplasm at a velocity reaching 50 μm min^{-1}; and third, can generate a pressure within these models displacing the fluid-like endoplasm.

The ectoplasmic tube contraction theory (ETC)[3] requires that ectoplasmic tube contraction produces a pressure which displaces relatively non-contractile endoplasm; these specific requirements are supported by this investigation. Further, during normal amoeboid motion, the ETC theory predicts some interconversion of ectoplasm to endoplasm at its interface as a part of the contraction process. Ectoplasm to endoplasm interconversion may occur once, but it is not a continuous feature during contraction of glycerinated models. Reversible relaxations and contractions of these models were not achieved. Amoeboid models can contract, but they do not exhibit organised amoeboid motion, which might be explained by the lack of ectoplasm to endoplasm interconversion.

Frontal endoplasmic contractions were never observed in our studies, which conflicts with the fundamental contractile requirements of the frontal-zone contraction hypothesis[4,5] for amoeboid motion.

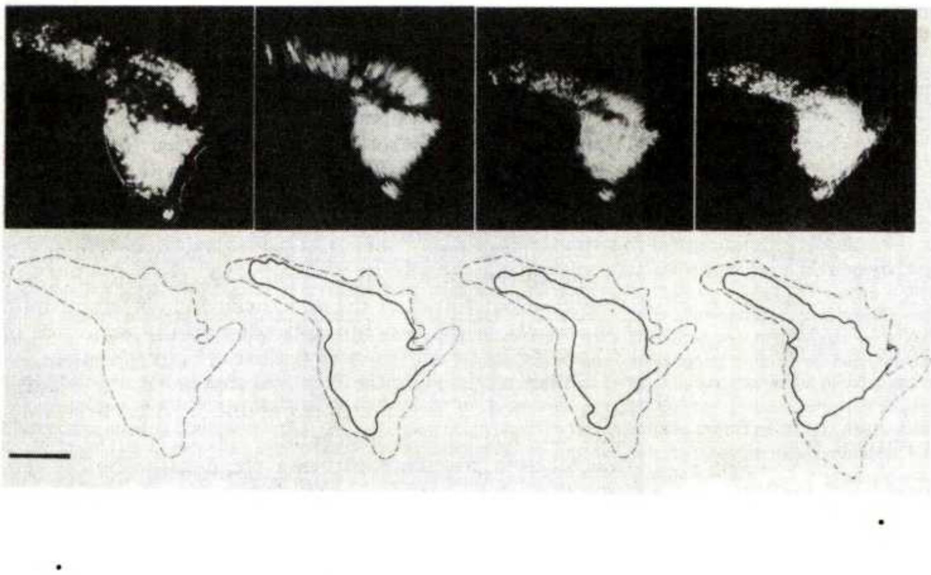

Fig. 1 Graphic sequence of a single glycerinated model contracting: - - - -, Before contraction; —, outline of contraction state of photograph directly above it. The bar represents 100 µm.

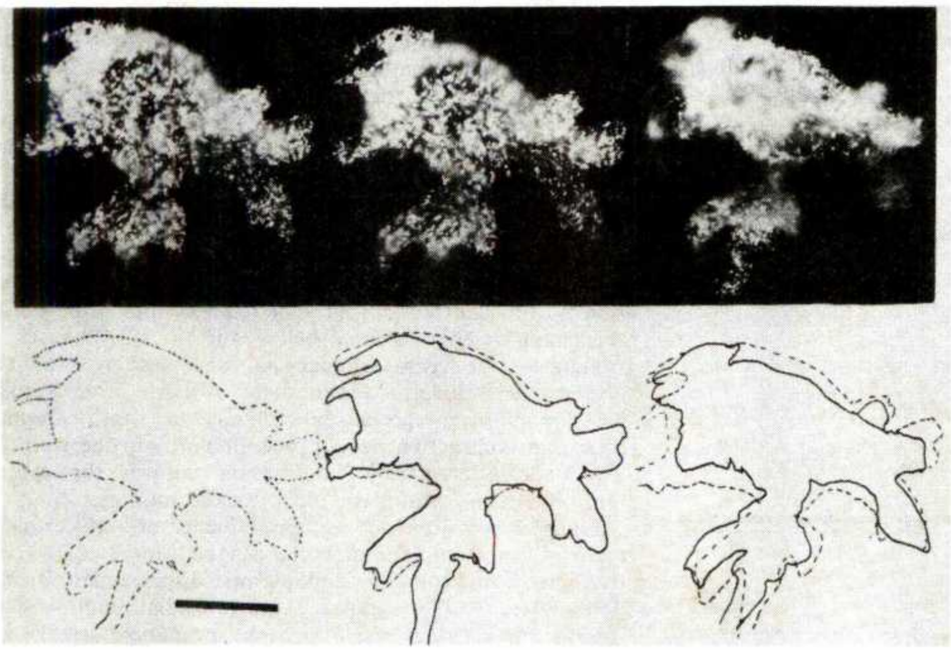

Fig. 2 Sequence illustrating amoeboid model contraction, displacement of endoplasm, rupture of plasmalemma (ectoplasm) and expulsion of some endoplasm. – – – –, Gives the beginning of contraction; —, is photograph above. The bar is 100 μm.

In preliminary experiments, the endoplasm of glycerinated models was moved reversibly in either direction by applied external pressures at values which have been found to move amoeboid endoplasm *in vivo*[6,8]. Pseudopodia could be collapsed or expanded by pressure depending on flow of the glycerinated endoplasm.

Numerous investigators have reported muscle-like proteins in amoeba (see refs 9–11). Some actin-like filaments may be attached to the plasmalemma[9]; whereas, myosin-like proteins do not always display a 'thick' filament component as reported in *Acanthamoeba castellanii*[10]. But thick filaments can have ATPase activity[10]. Also, thick and thin filaments have a remarkable orientation and interdigitation in the ectoplasmic tube region of *A. proteus* similar to striated muscle cells[11]. Although thick and thin filaments are present in glycinerated *Chaos-Proteus* amoebae, these filaments, their interactions and sites during contraction–relaxation have not been determined by electron microscopic investigation. It seems, however, that sliding filaments as proposed for muscle contraction[12] constitute the basic contractile mechanism for amoeboid motion[13,14].

Bilateral cortico-tectal projection from the visual cortex in the cat

THERE is anatomical and electrophysiological evidence for a heavy and well organised fibre projection from the visual cortex on the superior colliculus of the midbrain in several species[1–4]. In the cat, areas 17, 18 and 19 of the visual cortex each project to the colliculus and the arrangement is such that a point in the cortex related to a particular part of the retina sends fibres to that part of the colliculus receiving fibres directly from the same part of the retina. The available evidence is for a cortico-tectal projection to the ipsilateral superior colliculus only. In several brains of cats with lesions involving the visual cortex of one hemisphere, fibre degeneration has now also been found in the superior colliculus of the opposite side. This observation provides an explanation for several findings made in electrophysiological studies of the representation of the visual field in the superior colliculus which have been difficult to interpret, and it should help in the interpretation of functional studies on the visual connections of the cerebral hemisphere.

Studies of the visual system of the cat have made available a number of brains with lesions of varied size in the visual cortex and in the superior colliculus. The cats were anaesthetised with intraperitoneal Nembutal and, with aseptic precautions, lesions were made under direct vision in the visual cortex of one hemisphere or electrolytically in the superior colliculus of one side by a horizontal stereotaxic approach through the cerebellum. After survival periods of 4–6 d the animals were perfused with saline and 10% formalin and the brains were immersed for a further period in the same fixative. Frozen sections were cut in the coronal plane and a 1 : 10 series of sections stained with the Fink–Heimer or Wiitanen methods[5,6].

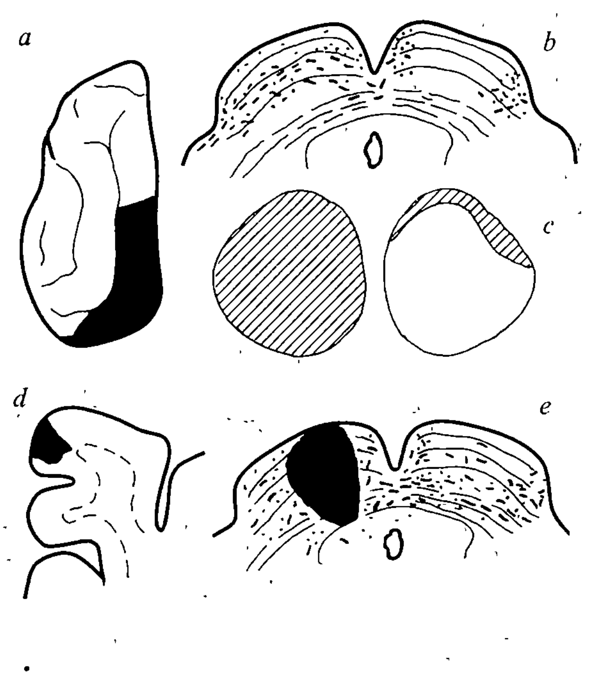
After a large lesion of the visual cortex with damage to or undercutting of areas 17, 18 and 19, there is fibre and terminal degeneration in the superficial four layers of most of the extent of the superior colliculus on the same side of the brain (Fig. 1*a* and *b*). The features of this degeneration are similar to previous descriptions based on the Nauta–Gygax method. There are horizontally disposed fibre fragments and fine granular degeneration in the stratum zonale; in the stratum griseum superficiale the degeneration is very dense in its deep half and much less in its superficial part;

in the stratum opticum the fibre fragments are coarser with less terminal degeneration, whereas in the stratum griseum intermediale the intensity of the degeneration is less and diminishes progressively towards its deep margin. On the contralateral side there is degeneration in the same superficial layers over a restricted area close to the medial and lateral margins. It is present over approximately the rostral half of the lateral margin, affects rather less of the medial margin and some continues round the rostral end of the colliculus (Fig. 1*b* and *c*); this part of the superior colliculus contains the representation of the midline of the retina[2-4]. The intensity of the degeneration is less than that of the operated side and is most evident in the stratum opticum and stratum griseum superficiale. Degeneration on the contralateral side is also found after smaller lesions of the visual cortex, and when the lateral half only of the ipsilateral colliculus contains degeneration, as after damage of the anterior half of the visual cortex, the degeneration on the contralateral side is found only at the lateral margin. Even with relatively small lesions at the boundary of areas 17 and 18 a few fibre fragments are found in the contralateral colliculus and always at a site corresponding to that on the operated side.

In three Siamese cats with lesions in the visual cortex degeneration is also present close to the margins of the anterior half of the contralateral superior colliculus as well as on the ipsilateral side. In one of these cats, the lesion was virtually restricted to the cortex related to the aberrant projection of the 20° of the ipsilateral visual field[7] (Fig. 1*d*).

The fibres which terminate in the contralateral colliculus probably reach that side after passing through the ipsilateral colliculus. The evidence in support of this is that no fibre degeneration has been seen in the brachium of the superior colliculus on the contralateral side, but a few degenerating fibres can be seen passing through the deeper layers of the superior colliculus on the operated side into the commissure of the superior colliculus. In addition, in several cats with lesions restricted to the superior colliculus of one side there is severe degeneration throughout the deeper layers of the contralateral superior colliculus with less in the stratum opticum, in most of the extent of the stratum griseum superficiale there is only an occasional fragment and there is none in the stratum zonale. In those parts containing the representation of the midline of the retina, and in which the fibres from the contralateral visual cortex terminate, the distribution and intensity of the degeneration is the same as after lesions of the cortex (Fig. 1*e*).

Fig. 1 The distribution of the fibre (dashes) and terminal (dots) degeneration in the superior colliculus of the two sides of the midbrain, in a coronal section (*d*) and (as hatching) on an orthographic reconstruction (*c*), after a large lesion (solid black) of the visual cortex (*a*). The solid black in (*d*) shows the site of the lesion in the representation of the aberrant 20° of the visual field of a Siamese cat, which also resulted in fibre and terminal degeneration in the contralateral superior colliculus. The solid black in (*e*) shows the site of a lesion restricted to the superior colliculus of one side and the resulting degeneration in a coronal section of the midbrain.



The finding of the projection from the visual cortex to the superior colliculus of both sides and the fact that the fibres to the contralateral nucleus end in the site of the representation of the midline of the retina may help to explain certain electrophysiological observations. It has been found in the cat that about 40° of the ipsilateral hemifield are represented in the rostral part of the colliculus and that this representation is binocular[8-10]. The pathway serving the representation of the ipsilateral hemifield has not been determined but it has been suggested that it is an indirect one and not direct from the retina[8,10]. The cells in the superficial layers of the representation of the ipsilateral hemifield had small receptive fields which were close to the midline and those in the deeper layers were large and extended further from the midline[10]. On the basis of these findings we suggest that the pathway for the ipsilateral hemifield representation to the superficial layers is through the projection from the contralateral visual cortex and that to the deeper layers is from the superior colliculus of the opposite side. The finding of a similar crossed cortical fibre pathway in the Siamese cat is interesting because the representation of the ipsilateral hemifield seems to be related to the opposite eye only[10], and because some fibres at least of the pathway to the opposite colliculus seem to arise either in the part of the cortex related to the aberrant projection of the 20° of the visual field or in the immediately adjoining part of the visual cortex. Finally, as the superior colliculus is now known to send fibres to the lateral geniculate nucleus and other thalamic nuclei[11,12], the contralateral projection to the opposite superior colliculus from the visual cortex could serve as an indirect pathway from the visual cortex of one hemisphere to that of the other hemisphere even after section of the corpus callosum and other forebrain commissures.

Size accentuation in the dominant eye

CONTRARY to popular opinion, people do not use their two eyes equally. It has been found that in tasks where only one eye can be used (such as sighting down a telescope) ~65% of all observers consistently select the right eye, 32% the left and only 3% are ambiocular[1-4]. This preference[5] occurs even when both eyes are open, as when one points to a distant object with the finger-tip. If one alternately closes each eye, it will be apparent that the distant target is aligned with the dominant eye but not with the other. Here we report investigations into whether there is a difference in the apparent size of stimuli presented to the dominant and non-dominant eye. We found that ~2/3 of our subjects see the object as being bigger with their dominant eye.

A sample of 45 observers was pretested to verify equal acuity in the two eyes. Each was screened to determine sighting dominance using two tests. The first dominance test was the Point Test, which involves having the observer point to the experimenter's nose with both eyes open. The experimenter notes which eye is aligned with the finger. Four repetitions were administered with the observer alternating hands to control for manual dominance. The second procedure for assessing eye dominance was the ABC Test, in which the observer holds the wide end of a truncated cone up to his face and views a target through the smaller aperture while keeping both eyes open. The cone must be squeezed in order to be held open, and the eye aligned with the aperture is scored as the dominant eye. There were four repetitions of this test. These procedures have been shown to be reliable indicators of the sighting dominant eye[1,3,5,6]. The sample was selected to contain 25 right-eyed and 20 left-eyed subjects.

Observers next viewed two white circular targets with a diameter of 10.5 cm at a distance of 40 cm through a haploscope which separated the inputs to the two eyes. They were asked to judge which of the two disks appeared 'larger' to them. This was a simple phenomenal judgment which all observers made without difficulty. Of the right-eyed subjects, 17 thought the object shown to their right eye to be larger, while of the left eyed, 13 thought objects presented to that eye the larger. In both cases, therefore, ~2/3 of the subjects thought that objects seen with their dominant eye were larger. These results are statistically reliable with a $\chi^2 = 4.90, P < 0.05$.

This difference is clearly psychological, rather than reflecting different magnification in the two eyes, since observers had been prescreened for equal refraction in both eyes. The reasons for these size distortions are not immediately clear. It seems likely that it may arise from image enhancement in the dominant eye or, perhaps, to differential selective attention to that image which gives rise to accentuation.

This research was supported in part by a grant from the Medical Research Council of Canada and from the National Research Council of Canada. The authors would like to acknowledge the assistance of Carole Behman, Michael Hewison, and Fred W. Whitford in the collection of the data.

Possible role of surface Ig in non-random recirculation of small lymphocytes

THE selective extravasation of some lymph-borne immunoblasts in the gut-associated lymphoid tissue (GALT) is well established[1-5]. It seems that immunoblasts generated in the GALT return to it, whereas those formed in peripheral somatic lymph nodes (PSLNs) go to the spleen or other lymph nodes[6]. On the other hand, for want of contrary evidence, it is assumed generally that the small lymphocytes comprising the recirculating pool recirculate more or less randomly through the various nodes in the body. T and B lymphocytes may have different rates and microanatomical routes of recirculation through a given lymphoid organ[7-9] but until now it has not been possible to show that recirculating lymphocytes discriminate between different lymphoid organs. By comparing the recirculation of small lymphocytes from the intestinal lymph with that of lymphocytes from the efferent lymph of PSLNs in unanaesthetised sheep, we found that each population tends to recirculate preferentially through the type of lymphoid tissue from which the collections were made.

Crossbred adult wethers or ewes were anaesthetised and polyvinyl cannulae were inserted into the intestinal lymph duct and into an efferent duct of one or two of the PSLNs (popliteal, prefemoral or prescapular). After operation the conscious sheep were placed in metabolism cages and the lymph collected quantitatively[10-12]. Serial collections were made over periods of 8–16 h and in each experiment either a collection of intestinal lymph or a collection of efferent lymph was incubated *in vitro* with ^{51}Cr. The washed, labelled cells were returned to the sheep through an intravenous cannula after which regular samples of each type of lymph were taken for 24–48 h. The lymphocytes were washed, counted and radioassayed and their specific radioactivities determined. Eight such experiments were performed; four in which labelled intestinal cells were reinfused and four in which efferent cells from PSLNs were used (Fig. 1). Cells from intestinal lymph tend to reappear in that lymph, whereas cells from peripheral

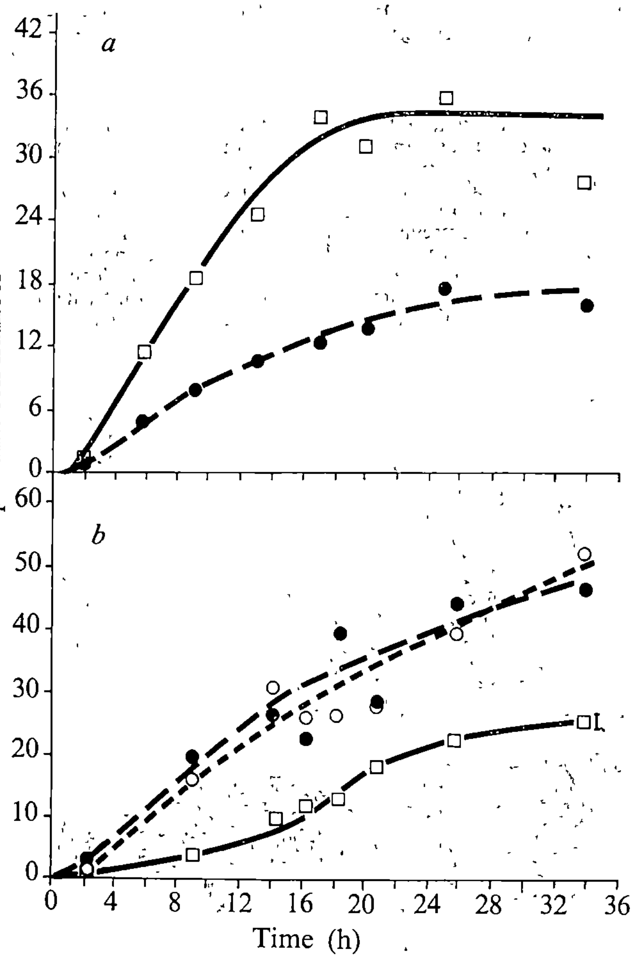

Fig. 1 The specific radioactivities (counts per unit cell number) of ^{51}Cr-labelled small lymphocytes in various lymphatic ducts after the injection, at time 0, of 3×10^9 cells from intestinal lymph (*a*) or 2×10^9 cells from prescapular efferent lymph (*b*). The cells had been labelled *in vitro* with Na$_2^{51}$CrO$_4$ at 15 μCi ml^{-1} for 1 h at 38 °C. □, Intestinal lymph; ●, prefemoral efferent lymph; ○, prescapular efferent lymph. Counting rates in individual samples were usually well above 10^3 c.p.m. except for the first few hours after injection of the labelled cells.

efferent lymphatics tend to recirculate through PSLNs; this happened quite unequivocally in every experiment.

In all experiments 2% of the injected labelled cells were immunoblasts; by labelling the immunoblasts with ^{125}I-iododeoxyuridine (^{125}IUdR) it was possible to compute the amount of ^{51}Cr associated with this type of cell and rule out the possibility that their presence could bias the results. The lower graph (*b*) confirms our previous report[13] that efferent cells from any one PSLN will recirculate equally well through any other PSLN. It should also be noted that there was no fall in the specific radioactivities of the lymph cells within the experimental period. This suggests a longer recirculation time for lymphocytes in sheep than in rodents[14], but is in agreement with other results from sheep[13,15].

It is obvious that the distinction between peripheral and intestinal recirculation is by no means absolute. This may indicate that there is only a tendency for a given cell to return to its place of origin, but the results could just as well be explained by the presence of two populations; one made up of cells with a strong preference for a given pathway, and the other made up of randomly recirculating cells. The return of immunoblasts to the GALT is possibly mediated by their immunoglobulin A (IgA) or a closely associated molecule[6,14]. It seems plausible, therefore, that those small lymphocytes which recirculate preferentially through the GALT do so because of their α-associated determinants, as up to 40% of all Ig-bearing lymphocytes are believed to have α chains on their surfaces[17]. Thus, we suggest that the route of recirculation of B cells may be influenced by the class of their surface Ig, while the non-Ig bearing T cells recirculate randomly. Sordat *et al.*[18] found significant amounts of Ig in the walls of post-capillary venules in the tonsil and although functional evidence was lacking they suggested that the presence of Ig was in some way related to lymphocyte recirculation. If these ideas are true it is possible that the number of B cells available to a given tissue may be limited to those with the corresponding Ig subclass; this could be important in determining the nature of immune responses and possibly also the metastatic pattern of some malignant lymphomata.

Serum-dependent adhesion and cytotoxicity of cells to *Litomosoides carinii* microfilariae

SERA from infected or immunised hosts have been reported to promote adhesion of leukocytes from those hosts to a variety of parasitic helminths[1–5]. Higashi and Chowdhury[6] found selective adhesion of eosinophils to the infective larvae of *Wuchereria bancrofti* in the presence of serum from filariasis patients showing microfilaraemia, lymphoedema or elephantiasis. In albino rats infected with the filarial parasite *Litomosoides carinii* a termination of microfilaraemia (onset of latent infection) is associated with the adhesion of cells to microfilariae in the pleural cavity where the adult worms reside. Cells which seem morphologically to include macrophages, lymphocytes and polymorphs can be seen attached to living as well as to disintegrating microfilariae[7]. Virtually no attachment is seen during the patent stage of the infection. Furthermore, immunosuppression of rats with latent infection by means of cortisone, cyclophosphamide anti-lymphocyte serum or whole-body irradiation can lead to the appearance of microfilaraemia in the animals[7–9]. Because the observations suggest the occurrence of an immune reaction, perhaps cell mediated, against microfilariae we investigated the mechanism of cellular adhesion. The results reported here show that adhesion *in vitro* is mediated by a serum factor and is accompanied by a cytotoxic effect on microfilariae.

Microfilariae were isolated from heparinised blood of *L. carinii*-infected rats by sedimentation of blood cells with dextran (molecular weight 200,000–275,000). They were washed and resuspended in tissue culture medium (HEPES-buffered RPMI1640 (Gibco)), containing penicillin (100 U ml^{-1}) and streptomycin (100 μg ml^{-1}). They were then counted in a haemocytometer. Spleen cells were prepared by teasing the tissue in medium and were washed twice before use. The peritoneal cavities of normal rats were washed out with 10 ml of the medium containing heparin (10 U ml^{-1}) and the cells were cultured in ring-and-slide chambers[10]. The non-adherent cells were washed off after incubation for 2 h at 37 °C, leaving cultures of peritoneal macrophages. The sera used were obtained from normal rats, from rats with patent infection and from rats with latent infection (samples from eight rats in each group) and from rats and rabbits hyperimmunised with homogenates of adult parasites in Freund's complete adjuvant (samples from two rats and two rabbits).

For adhesion experiments the reaction mixtures contained microfilariae and spleen cells at a ratio of 1 : 500–1 :2000 in a volume of 0.5 ml of medium with 20% rat serum. They were incubated at 37 °C for 16 h with occasional shaking A drop of the mixture was examined microscopically and the percentage of microfilariae having cells attached calculated. Adhesion occurred only when the mixture contained serum from rats with latent infection. Some typical results are presented in Table 1, which shows that spleen cells from rats with latent infection can become attached only in the presence of latent rat serum and that cells from mice and guinea pigs, but not man, can become attached, although to a lesser degree. Other experiments showed that adhesion was appreciable at 6 h and had reached a maximum by 16 h incubation. In general, adhesion was not seen in mixtures containing less than 10% latent rat serum. In

Table 1 Adhesion of spleen cells to microfilariae

Source of cells	Source of serum	% Microfilariae with spleen cells attached
Normal rat	Latent rat	80
	Normal rat	2
	Infected rat	4
	Immunised rat	0
	Immunised rabbit	0
Latent rat	Latent rat	75
	Normal rat	4
Mouse	Latent rat	54
Guinea pig	Latent rat	17
Human*	Latent rat	0

*Peripheral leukocytes were used in the experiments.

Table 2 Role of complement in adhesion

Experiment	Treatment of latent rat serum	% Microfilariae with spleen cells attached
1	None	92
	Heated (56 °C 30 min)*	0
	Heated+NRS†	39
2	None	78
	HSA–anti-HSA*	10
	HSA–anti-HSA+NRS†	20

*No haemolytic complement activity detectable.

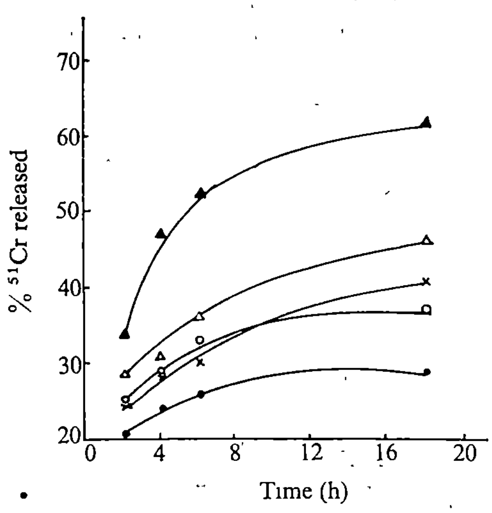
†Amount of normal rat serum (NRS) used completely lysed 10^9 antibody-sensitised sheep red blood cells. Mixture contained 20% latent serum and 20% NRS. HSA, Human serum albumin.

other experiments spleen cells which had been passed through a glass wool column[11] became attached to only 15% of microfilariae in the presence of latent rat serum, whereas virtually all microfilariae become attached to peritoneal macrophages after incubation in the presence of latent rat serum.

On the assumption that immunoglobulin antibodies were required for adhesion, the role of complement was investigated. Table 2 shows that latent rat serum decomplemented by heat (56 °C, 30 min) or by an antigen–antibody precipitate failed to induce adhesion and that its capacity to induce adhesion was only partly restored by normal rat serum. The poor restoration in the second experiment may have been due to persistence of small amounts of immune complexes, which are potent inhibitors of reactions between cells and antibody-treated targets[12]. These observations may indicate the operation of two mechanisms for inducing adhesion, one involving antibody only and one involving antibody plus complement.

Further experiments were carried out to determine whether lymphoid cells damaged microfilariae in the presence of latent rat serum. Microfilariae liberated from washed adult worms during incubation (37 °C, 1 h) in medium were labelled with ^{51}Cr essentially as described by Butterworth *et al.*[13] for schistosomulae, except that tissue culture medium containing 20% normal rat serum was used. They were then washed five times in medium and resuspended in medium containing normal rat serum. The suspension contained 3,000 microfilariae per ml, giving about 300 c.p.m. per microfilariae. They were incubated with normal spleen cells and with additional serum (to a concentration of 20%) at 37 °C. The release of ^{51}Cr was measured at intervals. Figure 1 shows that there was a marked increase in ^{51}Cr release over control levels in the presence of latent rat serum and normal spleen cells.

Fig. 1 Release of ^{51}Cr from labelled microfilariae on incubation with normal spleen cells and latent rat serum. ▲, Normal spleen cells (NC) + latent rat serum (LRS); △, NC + normal rat serum (NRS); ×, NRS; □, LRS; ●, medium.



Our earlier observations[7–9] suggested that cell-mediated immunity may be important in the destruction of microfilariae. The experiments described here implicate both humoral and cellular factors in a collaborative reaction, which may be similar to that directed against schistosomules.

HeLa cells secrete α subunit of glycoprotein tropic hormones

THE HeLa line, derived from a carcinoma of the cervix, was the first continuous human tissue culture line to be established *in vitro*[1], and has been one of the primary sources for the study of human cell biology. Although such studies have documented the biosynthesis of certain intracellular and membrane proteins[2–4], there has been little specific characterisation of proteins secreted by these lines The human glycoprotein tropic hormones, thyroid-stimulating hormone (HTSH), follicle-stimulating hormone (HFSH), luteinising hormone (HLH), and chorionic gonadotropin (HCG), are each composed of two subunits—an immunologically indistinguishable and probably common α subunit ('α') and distinct β subunits which confer biological specificity on the complete molecule[5–8]. Complete hormones and free, isolated subunits are secreted by their normal cells of origin in pituitary or placenta under a variety of physiological and neoplastic circumstances[9–11]. Furthermore, complete hormones and isolated subunits can even be secreted ectopically—that is, by tissue which does not in normal conditions produce these proteins. Since ectopic α secretion has been documented for a variety of neoplasms, both *in vivo*[12] and *in vitro*[13], we examined the possibility that HeLa lines might also ectopically secrete the α subunit. We have found that three different HeLa strains secrete a substance immunologically indistinguishable from the α subunit, with secretion rates differing by as much as 50-fold

In identical laboratory conditions we have grown

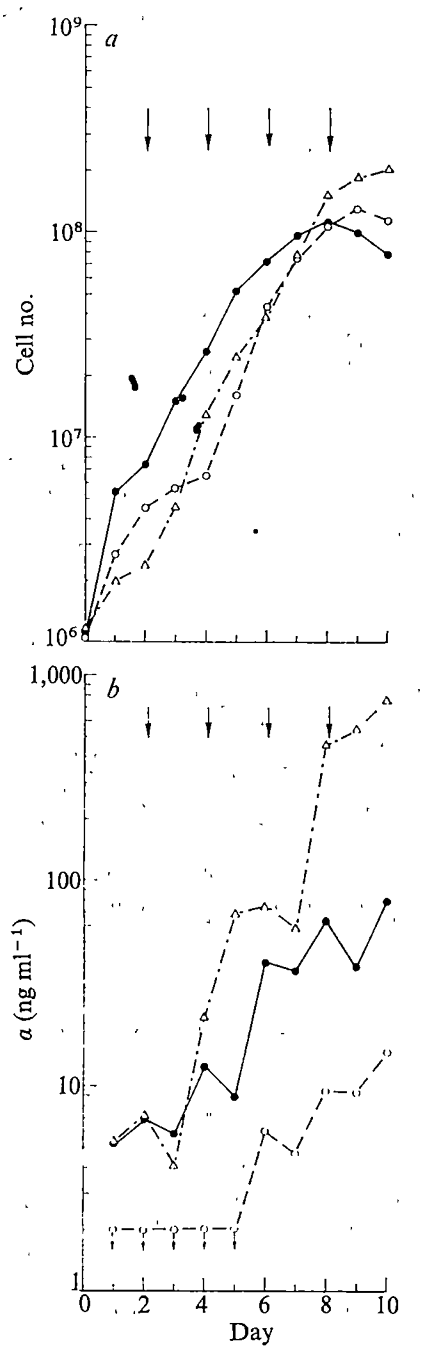

Fig. 1 Growth curves and α concentrations for the three strains: ●, HeLa CCL 2; ○, HeLa CCL 2.1; △, HeLa CCL 2.2. All cultures were established at day 0, and for each strain two cultures were used on each day of measurement. *a*, Total cell number per 75-cm^2 flask; *b*, media concentrations of α measured in the same double-antibody radioimmunoassay using HCG-α as reference standard. Arrows indicate days when the medium in each remaining flask was exchanged with fresh medium; α concentrations on those days were measured immediately before medium change. HeLa CCL 2 has also been called HeLa or HeLa(Gey), HeLa CCL 2.1 has been called HeLa 229, and HeLa CCL 2.2 has been called HeLa S$_3$

sequential separate cultures of three HeLa strains—HeLa CCL 2, 2.1 and 2.2 (American Tissue Culture Collection)[14]. Each culture was grown at 37 °C in 75 cm^2 flasks in 30 ml α minimal essential medium with 10% foetal calf serum. On each day of measurement, two cultures of each strain were used. On each day, we counted cell number after trypsinisation and measured α concentration in the culture media by a specific double-antibody radioimmunoassay using HCG-α as a reference standard[12]. As the cell numbers increased, all three lines progressively accumulated α immunoreactivity in the media, although in markedly different concentrations (Fig. 1). At no time was HCG-β detected by radioimmunoassay (<0.2 ng ml^{-1}) in the media[15]. Complete glycoprotein hormones containing α subunit have small (1–3%) cross reactions in the α assay[12], and a very large amount of any of these hormones could have accounted for the α immunoreactivity. This possibility was excluded by examining the media in specific radioimmunoassays for HTSH, HLH, HFSH and HCG[12,16,17]; all were undetectable (HTSH <1.0 μU ml^{-1}, HCG <0.2 ng ml^{-1}, HLH <1 mIU ml^{-1}, HFSH <1.5 mIU ml^{-1}). Control medium not exposed to HeLa cells had undetectable amounts of α (<2 ng ml^{-1}). Media exposed to HeLa cells had no effect on ^{125}I-HCG-α tracer integrity, since such tracer was still fully immunoprecipitable by excess antibody to HCG-α. The peak secretory rates of α by HeLa 2.1 was 0.1, by HeLa 2 was 1.0 and by HeLa 2.2 was 5.0 pmol per 10^6 cells per day.

The ectopic secretion of α by cell lines derived from a carcinoma of the cervix is of interest. Whether the original tumour secreted α *in vivo* is not known. Certain tumours and cultures are known, however, to secrete progressively more α subunit *in vitro* with time[9]. Indeed, the K_1 clonal strain of the ChaGo bronchogenic carcinoma cell line secretes 290 pmol α per 10^6 cells per day, substantially more than the wild type[18].

Serial dilutions of alpha in the HeLa tissue culture medium exactly paralleled standard curve dilutions of HCG-α in the radioimmunoassay, indicating virtual immunological identity. The gel chromatographic behaviour of HeLa-α was also studied (Fig. 2). Medium from a confluent culture of HeLa 2.2 was cochromatographed on Sephadex G-100 with ^{131}I-HCG-α as an internal marker. This procedure discriminates between the glycoprotein hormones and their subunits, and on this column the α subunits of HTSH, HFSH, HLH and HCG all elute identically[19]. The HeLa-α eluted in the α subunit region, again clearly differentiating it from the complete glycoprotein hormones. Although the elution pattern of HeLa-α is similar to that of HCG-α, HeLa-α does have a slightly higher apparent molecular weight. In this respect, HeLa-α is similar to the α produced by a gastric carcinoid *in vivo* and a bronchogenic carcinoma *in vitro*[19]. The very similarity in α produced by these diverse neoplasms raises the possibility, among several other explanations, that tumour α may be a precursor of normal α (ref. 19).

All three strains of HeLa studied secreted α, in fact two different cultures of HeLa 2.2 obtained from different sources (American Type Culture Collection and Flow Laboratories) had almost identical α-secretion rates. It has been suggested that many human tissue culture lines have been overgrown and replaced by HeLa cells[20–22]. Although α secretion is not exclusive for HeLa—certain cell lines such as ChaGo, which are not HeLa by karyologic criteria[18], secrete α—the presence of α secretion by a human cell line should prompt careful examination for known karyologic and enzymatic HeLa markers. For example, we have found significant quantities of α (14 ng ml^{-1}) in the medium of HBT$_3$, a line originally derived from a breast cancer which has been found to have karyologic HeLa markers[22]. On the other hand, it is not known whether the absence of α secretion rules out HeLa. Three different HeLa strains, including two different sources of HeLa 2.2, secreted α, but in the case of HeLa 2.1 we could only detect α at high cell density after a number of days. We do not know, however, whether all HeLa strains secrete α even at high density after many days.

It has been reported that another HeLa strain, HeLa$_{65}$—a variant of HeLa CCL 2.2—secretes very small amounts (0.0024 ng per 10^6 cells per day) of material which has activity in an HCG-β immunoassay[23]. This basal secretion

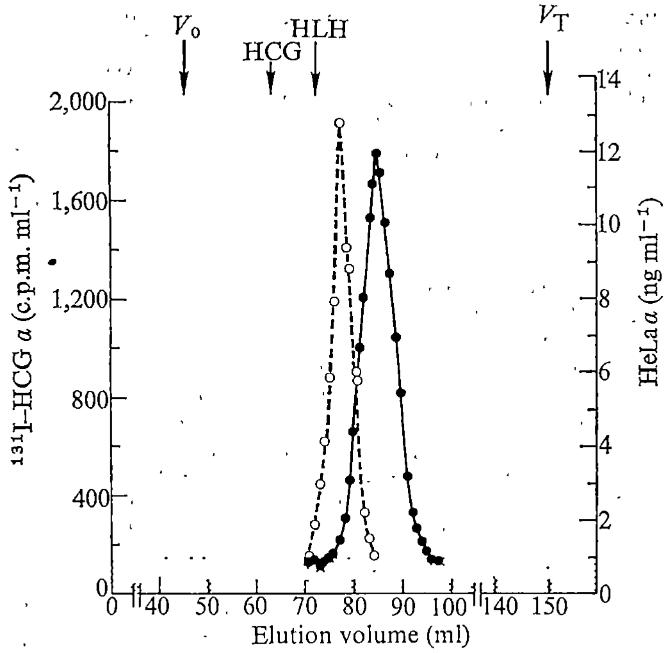

Fig. 2 Gel chromatography of ^{131}I-labelled α subunit of chorionic gonadotropin (^{131}I-HCG-α) added to medium from a confluent culture of HeLa CCL 2.2. The Sephadex G-100 column (1.5×90 cm) was equilibrated at 4 °C and eluted with 0 15 M NaCl, 0.01 M Na phosphate, *p*H 7 4, at a flow rate of 5 ml h^{-1}; 1-ml fractions were counted for ^{131}I radioactivity (●) and measured for α immunoactivity (○) by a ^{125}I radioimmunoassay. The shaded area is below the detection limits of the radioimmunoassay The void volume (V_0) and the total volume (V_T) were determined in the same chromatogram. In separate experiments HCG and HLH migrated with elution volumes as indicated by the arrows. The column was calibrated with five standard proteins (apoferritin, gammaglobulin, ovalbumin, chymotrypsinogen A, and ribonuclease). HeLa-α had an apparent molecular weight of ~33,000, whereas HCG-α had an apparent molecular weight of ~24,000 The molecular weight calculated from the chemical composition of purified HCG-α (15,000) was used to calculate the secretion rates in the text. Differences between the apparent molecular weight of α and that calculated from chemical composition have been discussed elsewhere[19].

rate is four orders of magnitude less than the α secretion (75 ng per 10^6 cells per day) by HeLa CCL 2.2 reported here. Although this reported HCG-β immunoactivity (HCG and/or HCG-β) may to some extent be accounted for by cross reaction with large access of free α, it has been observed that certain ChaGo clones which secrete large amounts of free α also secrete small amounts of biologically active HCG[13].

We do not yet know what relation α secretion by these HeLa strains has to their different karyotypes or even to intracellular production of other HeLa proteins such as placental alkaline phosphatase. The fact that three HeLa strains derived from a carcinoma of the cervix have widely different secretion rates of α suggests that they may be useful in identifying the factors controlling the production of this protein, which is normally repressed in cervical cells.

A number of diverse neoplasms have been shown to secrete the α subunit ectopically *in vivo* and/or *in vitro*; these include cancers of lung[13], stomach[12], pancreas[12], and now uterine cervix Studies of α secretion should be extended to other human cell lines and, when assays become available, to cell lines from other species. Perhaps the α subunit will turn out to be a relatively easily derepressed and 'primitive' protein.

We thank Dr Arlene Levine for supplying HBT₃ medium, Ms Ida Stotler for assistance, Dr Richard Dimond for measuring HTSH, and Drs Nimai Ghosh and Rody Cox for sending us their preprint.

Interference between anti-HLA antibodies and chlorpromazine

IT has been suggested that the effects of chlorpromazine in man and animals are genetically influenced[1,2]. In mice, genetic control of sensitivity to this drug seems to reside in two loci, the more important of which lies on chromosome 9 at about the region which controls the histocompatibility system H2 (ref. 3). We have investigated whether the presence or absence of some alleles of the HLA system—analogous to the H2 system of mouse—correlate with individual sensitivity to the drug. We evaluated the clinical responses to chlorpromazine of 33 chronic schizophrenic subjects who had been HLA typed during previous investigations[4,5]. There was a highly significant positive response to chlorpromazine in patients with the antigen HLA-A1 of the HLA-A locus (unpublished results of E.S., L. Bellodi and E. Sacchetti). A possible explanation of the correlation is that the presence of HLA-A1 on the cell membrane makes chlorpromazine bind more readily to the cell. As chlorpromazine binds to lymphocyte membranes[6], we investigated whether or not the binding of the drug could interfere with the specific binding of anti-HLA antibodies, particularly anti-HLA-A1 antisera. Furthermore, as chlorpromazine binds to the β-adrenergic cell receptors, which are also present on peripheral blood lymphocytes[7], we also used the β-adrenergic mediators dopamine (DA) and noradrenaline (NA).

Five healthy volunteers were selected on the basis of their HLA types from our HLA reference panel. Three were HLA-A1 positive and two were negative for the

Table 1 Effect of chlorpromazine, DA and NA on absorption of two anti-HLA-A1 sera and serum MI P1 (anti-HLA-B_{12},B_{13}) by human peripheral blood lymphocytes

Results are expressed as the serum dilution giving a cytotoxicity >80%.

same antigen. Each subject was typed many times in different typing sessions and tested with the antisera used in this work. The types were: G.C.: HLA-A1, A9, B7, B12; L.B.: HLA-A1, B8, B12; L.M.: HLA-A1, B5, B8; B.P.: HLA-A9, B12; R.S.: HLA-A2, B5, B12. Thirteen anti-HLA antisera were selected from sera supplied from the NIH bank (Bethesda) and from cytotoxic sera from multiparous women screened in our laboratory for their specificity and compared with highly selected antisera from the Institute of Medical Genetics of the University of Torino. The sera, with their corresponding specificities were: Morrison: anti-HLA-A1, A9, B8; MI P42: anti-HLA-A1, AW25; MI P80: anti-HLA-B8, AW32+; MI P106: anti-HLA-A2; MI P138: anti-HLA-A2; MI Pt1 18/3: anti-HLA-A9; MI P145: anti-HLA-A9; D666222IX: anti-HLA-B5; MI P71: anti-HLA-B5+; MI P55: anti-HLA-B7; MI P128: anti-HLA-B7; MI P1: anti-HLA-B12, B13; MI P109: anti-HLA-B12+.

Each antiserum was tested for its cytotoxic titre against lymphocytes bearing the corresponding HLA specificity. Lymphocytes (6×10^{-6})—obtained from heparinised peripheral blood by flotation on Lymphoprep[8]—were incubated in Hanks' solution (buffered at *p*H 7.2 by adding isotonic bicarbonate solution) containing chlorpromazine or DA or NA at a concentration of 1.5×10^{-4} M and rocked at 2 °C for 1 h. Afterwards, tubes were centrifuged at 0 °C for 15 min at 600*g*, the supernatant layers were discarded and the cells washed once with cold Hanks' solution. Then, the washed lymphocytes (6×10^{6}) were resuspended in 0.3 ml of HLA cytotoxic antisera and incubated again at 2 °C for 1 h. Controls were carried out by incubating the same amount of cytotoxic antisera with 6×10^{-6} lymphocytes which had not been preincubated with the drugs. Afterwards tubes were centrifuged at 600*g* for 15 min at 0 °C and the supernatant layers, after a further centrifugation at 2,000*g*, were tested for their cytotoxic titre on fresh lymphocytes from the donors used for the absorption study.

We found no difference between the cytotoxic titres of antisera absorbed by control lymphocytes and by lymphocytes preincubated with drugs, except for the anti-HLA-A1 sera MI P42 and Morrison when tested with HLA-A1 positive cells (Table 1). Morrison serum showed no variation when it identified the antigen HLA-A9 on HLA-A1 negative cells (donor B.P.).

We also made a dose-inhibition study to determine the lowest concentrations of the drugs we were investigating, which were able to cause the greatest inhibitions of anti-HLA-A1 antisera.

We found that chlorpromazine was active at 0.4×10^{-4}, whereas DA and NA had their greatest effects at 0.8×10^{-4} M. At a higher concentration of chlorpromazine (0.6×10^{-3} M) we observed slight inhibition of two other antisera not detecting HLA-A1—sera MI P109 and MI P71. At the same concentration, DA and NA were ineffective.

Our data suggest specific binding of chlorpromazine to the antigen HLA-A1 of the first HLA locus which interferes with the specific binding of the anti-HLA-A1 immune sera. DA and NA also seem to bind to the HLA-A1 antigen, but perhaps with a lower affinity than chlorpromazine, as greater concentrations were needed to exert less inhibition than that due to chlorpromazine.

We think two interpretations of our results are possible. First, the HLA antigens could be structurally linked to the β-adrenergic lymphocyte receptors in the cell membrane grid. HLA-A1 might modify the quaternary structure of these receptors, making it easier for chlorpromazine to bind it and making possible a reciprocal steric inhibition of anti-HLA-A1 antiserum and chlorpromazine or DA and NA. The other HLA antigens, less intimately connected with the β-adrenergic receptors, show no such reciprocal interference. There is another possibility as many cell membrane structures are originally derived from a common ancestor. For example, all the structures governed by the HLA region are phylogenetically related[9,10]. Moreover, the structural analogies between the immunoglobulins, the HLA antigens and β_2-microglobulin have also suggested a common evolutionary origin for these molecules[12].

Thus we think it possible also that β-adrenergic receptors and HLA antigens descend from a single precursor and that HLA-A1 is the antigen which is less divergent from this common original structure and from the cell β-adrenergic receptor than the other HLA specificities. For this reason it would be interesting to investigate the relationships between such receptors and those HLA antigens which cross react with HLA-A1.

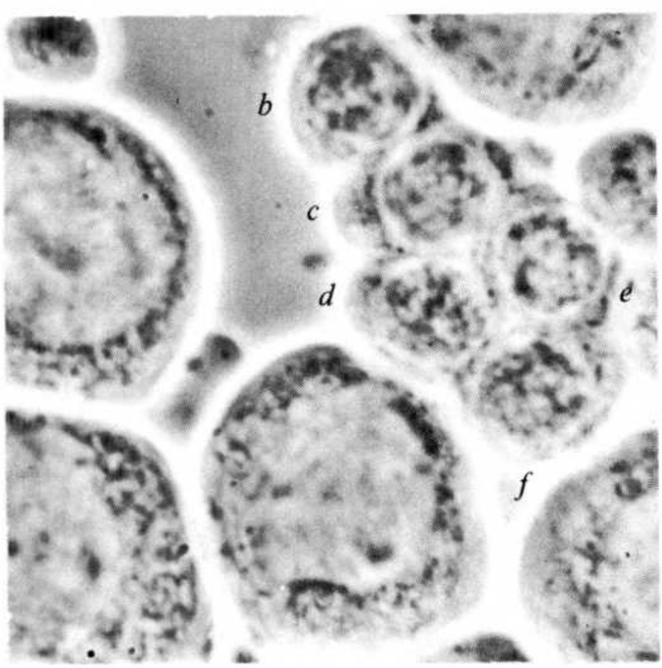
Chromosome rotation and formation of synapsis

ALTHOUGH the rotation and oscillation of the nuclei of cultured spermatocytes have been known for some years[1,2], no correlations of this phenomenon with the stages of mitosis or meiosis, or with the biochemical or cytogenetic events during germ-cell development have been made. Using a new technique for the rapid separation of segments of rat seminiferous tubules containing accurately known cellular associations and stages of meiotic prophase[3] we have been able to correlate the rotation of living spermatocyte nuclei with synapsis during rat spermatogenesis.

Immediately after removing the testes from the animal, the seminiferous tubules were removed and transilluminated under a stereomicroscope. Cells representing different stages of meiotic prophase were selected for analyses with time lapse phase-contrast cinemicrography[4]. Figure 1 shows a phase-contrast photomicrograph of early zygotene spermatocytes developing synchronously at stage XII of rat spermatogenesis. The chromosomes of cell *c* are not sharp in the figure, indicating chromosome movement during the 4-s exposure time. That these structures really are chromosomes, was shown by Pleshkewych and Levine[5] using electron microscopic preparations of mouse primary spermatocytes, previously analysed by phase-contrast microscopy.

At the beginning of meiotic prophase at stages IX–X (ref. 6) no movements were observed in the chromosomes of the leptotene spermatocytes. In late leptotene spermatocytes, at stage XI, some nuclei were seen rotating, and an oscillatory movement of the chromosomes was common. At the next stage (XII) the early zygotene spermatocytes showed the most active rotations and oscillations of their chromosomes. The movements then gradually slowed down towards the end of zygotene stage (XIII–XIV) and ended during the early pachytene stage (before stage III). Some oscillatory movements of the chromosomes were seen up to stage VI, but mid- and late-pachytene spermatocytes (stages VII–XII) showed no chromosomal movements.

Fig. 1 Phase-contrast photomicrograph of early zygotene spermatocytes developing synchronously at stage XII of rat spermatogenesis. Seminiferous tubular fragments containing accurately identified cellular associations and stages of meiotic prophase were separated using a variation in the transillumination pattern of freshly isolated unstained seminiferous tubules as a marker for different stages of spermatogenesis[3]. The cells were squeezed to form a monolayer between object and cover glass slides, and observations were made under phase-contrast optics. The rotational pattern of the cells *b*–*f* are analysed in corresponding tracings in Fig. 2. Owing to the 4-s exposure time, the chromosomes of cell *c* have moved and are unsharp in the figure. Note the size difference of the late pachytene spermatocytes.



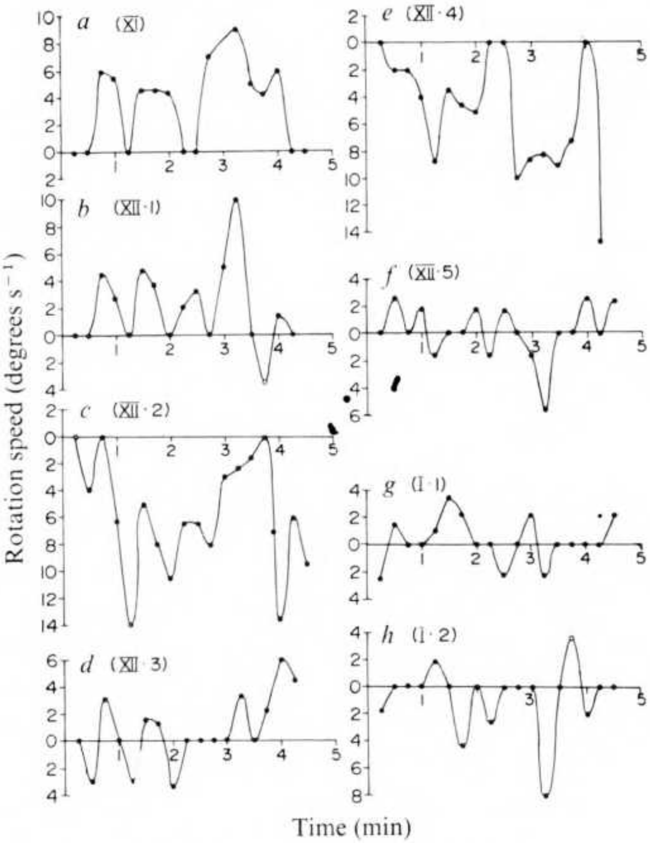


Fig. 2 Analysis of the rotating movements of the chromosomes of rat primary spermatocytes at different stages of development. Time-lapse cinemicrographs were taken at a speed of 2 frames s^{-1} with a Beaulieu 4008 ZM camera using super-8 film. The film was analysed using a viewer, which makes it possible to trace the interesting frames and to measure the time intervals. All observations were made within 4 h of killing the animal and 3.5 h of sealing the specimen chamber. The rotation speed is indicated as degrees s^{-1} at the ordinate, clockwise direction above the abscissa and counterclockwise direction below it. The observation time (min) is indicated on the abscissa. The movement is not even, and most cells change the rotation direction several times during the observation. The maximum speed (cell *e*) is 14.6 degrees s^{-1}. Tracings *b*–*f* are for cells belonging to the same synchronously developing group of cells depicted in Fig. 1.

In individual cells, the speed and direction of the rotational movement varied considerably. Figure 2 shows an analysis of cells from early zygotene (stages XI and XII) and early pachytene (stage I) primary spermatocytes. The chromosomes were followed on time-lapse film and traced every 15 s, and the rotation angle was measured. The clockwise rotation speed (degrees s^{-1}) is seen above the abscissa and the counterclockwise rotation speed below it. The cells were followed during 4.5 min (abscissa). The speed of the nuclear rotation was not even in any cell, and in most cases the direction of the movement changed during the observation time. In addition, the chromosomes seemed to move around several axes in numerous different planes. This is not shown in the tracings. Even in synchronously developing clones of early zygotene spermatocytes (Fig. 1) the rotation speed and direction vary considerably between individual cells (Fig. 2, *b*–*f*).

It is generally known that during zygonema (stages XII–XIV in rat spermatogenesis) the homologous sets of sister chromatid pairs begin to come together and associate with one another. The result is a precise point-for-point alignment, synapsis. The fully developed apparatus, the synaptinemal complex, is completed during pachynema. The rotational movements of the chromosomes seem to correlate to the formation of synapsis, so that in zygonema, where the synapsis is formed, the chromosomal movements are the most rapid. In early pachynema when the synapsis is completed there is still some movement of the chromosomes, but when the synaptinemal complex is fully developed the movements of the chromosomes cease completely. The movements of the chromosomes may be helpful in the physical mutual recognition of the specific parts of chromosomes, leading to the formation of synapsis between homologous chromosomes.

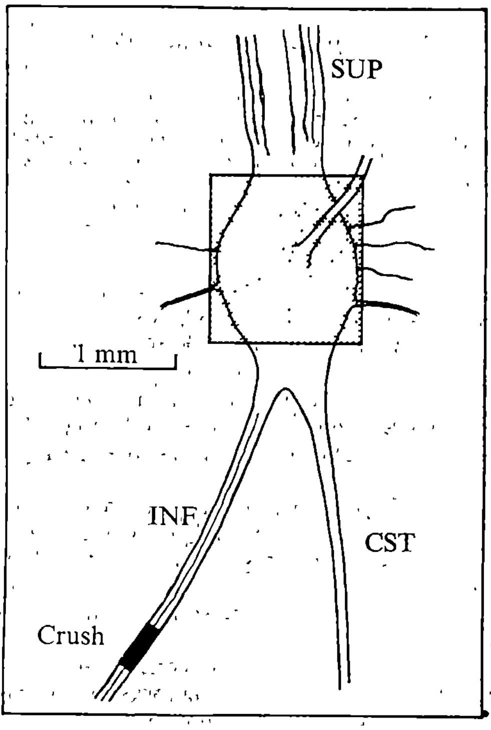
Effect of nerve growth factor on synaptic depression after axotomy

INTERRUPTION of the axon of a mammalian nerve cell leads to severe depression of synaptic transmission to the affected neurone within a few days, due primarily to loss of synaptic contacts[1–4]. In the superior cervical ganglion of the guinea pig, recovery of synaptic contacts on many neurones occurs if axon regeneration is allowed, but generally does not take place after axon ligation[4]. Furthermore, application of colchicine to postganglionic nerves causes synaptic loss in the absence of mechanical axon interruption[5] (see also ref. 6). These findings indicate that axonal extension to the periphery in some way provides the parent neurone with a 'trophic' signal which is instrumental in maintaining preganglionic synaptic contacts. In the sympathetic nervous system the protein nerve growth factor (NGF) has a number of effects on the metabolism and morphology of developing neurones whose survival is ultimately dependent on the presence of this agent[7]. One mechanism by which NGF affects neurones is an interaction with specific surface receptors on cell bodies[8]. More recent experiments have supported the suggestion[9] that NGF may also act as a messenger from the effector organ to innervating sympathetic neurones: NGF is selectively taken up by sympathetic endings[10], can be retrogradely transported to the neuronal somata[10,11], and has been shown to prevent some of the biochemical changes that follow axotomy in young animals[12,13]. Thus a natural question to ask is whether NGF might be involved in the regulation of synapses on mature ganglion cells. We report here that exogenous NGF can, to a large extent, prevent the synaptic depression seen in adult sympathetic ganglion cells after interruption of their axons.

Ten adult guinea pigs (200–400 g) were anaesthetised with pentobarbitone and both superior cervical ganglia exposed in aseptic conditions. On the right side, the inferior postganglionic nerve was crushed 2–3 mm from the ganglion; at the same time a silicone rubber (Silastic, Dow Corning) pellet measuring approximately 1.2 × 1 × 0.5 mm and containing 100–500 μg of purified 2.5S mouse salivary gland NGF[14] (from Dr R. A. Bradshaw) was implanted in contact with the ventral surface of the ganglion (Fig. 1). Pellets were prepared by mixing NGF with the silicone rubber before curing. On the left side, the inferior branch was crushed, but no pellet was implanted. In a further series of seven control animals, a silicone rubber pellet without NGF was implanted at the time of crushing the inferior postganglionic branch. After 4–7 d, the interval after which postaxotomy synaptic depression is maximal[4], ganglia were removed and studied by means of intracellular recording. Neurones on the dorsal surface of the ganglion were impaled with glass microelectrodes, and excitatory postsynaptic potentials (e.p.s.p.s) were measured in response to supramaximal stimulation of the preganglionic sympathetic trunk. Axons of individual neurones were determined to emerge in the crushed inferior branch, or the intact superior branch, by antidromic stimulation. The methods of impalement, stimulation, and e.p.s.p. measurement were as described previously[4].

In the animals in which a control pellet without NGF had been implanted, the amplitude distribution of e.p.s.p.s in neurones whose axons had been crushed (Fig. 2*b*) was shifted towards lower values, compared with the synaptic responses of normal neurones (Fig. 2*a*). This degree of synaptic depression is similar to that after crushing alone[4,5]. Thus, the presence of the control pellet had no effect on the course of postaxotomy synaptic depression. In each of 10 animals in which the implanted pellet contained NGF, however, the reduction in e.p.s.p. amplitude was curtailed; the synaptic responses elicited in most neurones whose axons had been crushed in treated ganglia fell within the normal range, whereas relatively few showed severe depression of synaptic transmission (Fig. 2*c*). In the course of studying NGF-treated ganglia, many nerve cells were impaled whose axons emerged in the intact superior branch (Fig. 1). Synaptic responses in these neurones were of normal amplitude (20–44 mV) suggesting that exogenous NGF has little effect on normal synaptic transmission. The input resistances, resting potentials, and action potential amplitudes were similar in treated and untreated control neurones whose

Fig. 1 Diagram of operative procedure. Ventral view of right superior cervical ganglion. CST, Cervical sympathetic trunk; INF, inferior postganglionic branch; SUP, superior postganglionic branch. Stippled area shows approximate size and location of silicone rubber pellet impregnated with NGF.



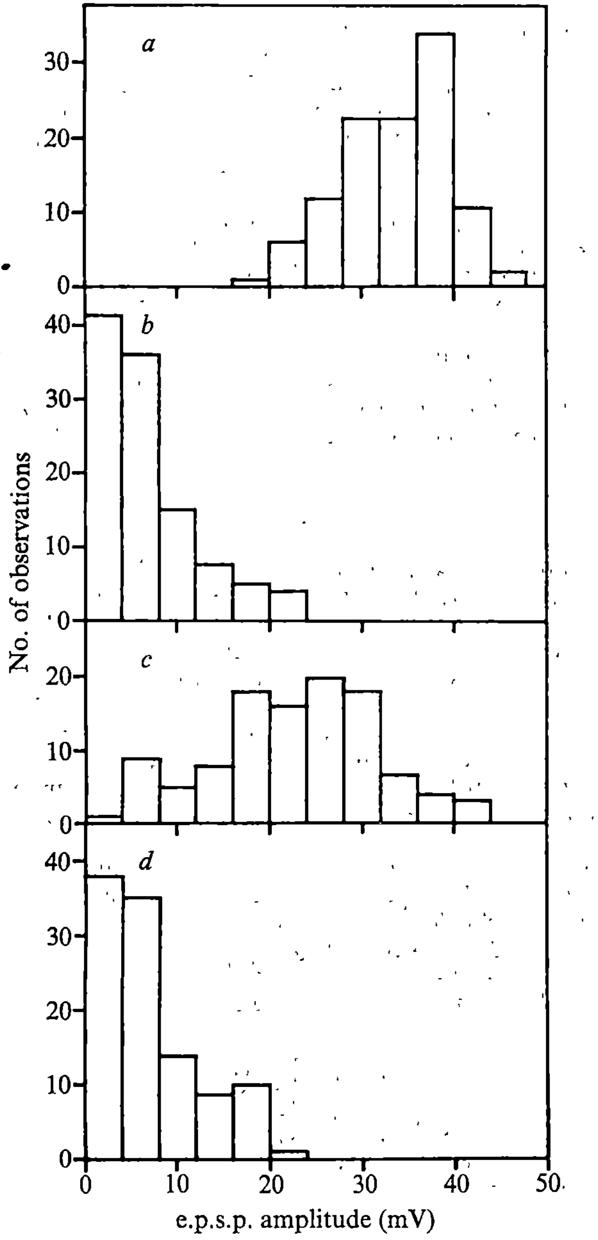


Fig. 2 Ability of exogenous NGF to curtail synaptic depression after axotomy. See text for detailed explanation *a*, Responses of normal neurones replotted from previous work[4] (number of neurones impaled $n=112$); *b*, Axotomy+control pellet ($n=109$); *c*, axotomy+NGF pellet ($n=109$); *d*, axotomy+NGF pellet, contralateral ganglion ($n=107$).

axons had been crushed; values for these parameters were in the same range as those reported previously[4,5].

In ganglia contralateral to the site of the NGF-containing pellet, neurones whose axons emerged in the crushed inferior branch gave synaptic responses that were as depressed as those in animals without exogenous NGF (Fig. 2*d*; compare with Fig. 2*b*). This result indicates that the sparing effect of NGF is a local one.

Exogenous NGF also prevents at least one other electrophysiological sign of axotomy in sympathetic neurones, the development of regenerative responses in dendrites[4,5] (see also refs 15 and 16). Rapidly rising local responses identical to those described previously[4,5] were seen superimposed on subthreshold e.p.s.p.s in 27% of axotomised neurones impaled in ganglia treated with a silicone pellet containing no NGF, and in 28% of axotomised neurones in ganglia contralateral to those treated with exogenous NGF. Such potentials were observed in only 1 of 109 axotomised neurones impaled in the NGF-treated ganglia.

The rate of NGF release from the impregnated pellets was determined by incubation for 24 h in 1 ml of sterile saline either before implantation, or after removal from the animal. The incubation medium was then assayed by the chick dorsal root ganglion method[17-19]. Pellets tested before implantation released about 1,000 biological units (BU) per ml incubation fluid per 24 h, whereas pellets which had been implanted 4–7 d before testing released 10–100 BU per ml per 24 h (1 BU corresponds to about 10^{-2} μg). Although showing that NGF is released in relatively large amounts from the pellets, these results do not provide any information about the effective concentration of NGF in the vicinity of the neurones studied.

The ability of exogenous NGF to reduce markedly synaptic depression after axotomy provides the first example of an electrophysiological effect of NGF on mammalian sympathetic neurones. We do not yet know whether the exogenous NGF acts at receptors on the surface of the cell body or intracellularly after retrograde axonal transport from the site of injury. Our results suggest, however, that NGF may normally regulate synaptic function in mature sympathetic ganglia.

We thank R. A. Bradshaw, I.-M. Jeng and R. Silverman for advice. Supported by the National Institute for Neurological Diseases and Stroke, the Muscular Dystrophy Association of America, and a US Public Health Service International Research Fellowship to A.N.

Brain immunoreactive gonadotropin-releasing hormone in Huntington's chorea and in non-choreic subjects

THERE is evidence which suggests that the release of gonadotropin-releasing hormone (GRH) is modulated by dopaminergic neurones[1-3]. Dopamine receptors seem to be hyper-responsive in Huntington's chorea[4,5], and consequently the synthesis and secretion of GRH may be altered in this condition. For this reason we have compared the concentration of immunoreactive GRH in hypothalamic tissues taken *post mortem* from choreic and non-choreic ('control') subjects. The distribution of GRH in the human brain, and changes in concentration which occur with age have also been examined.

The collection of brain tissue was carried out at Cambridge as described previously[6]. At autopsy the median eminence was removed by making a horizontal incision at the edge of the

Table 1 Mean (± s.e.m.) concentrations of GRH (pg mg^{-1}) in median eminence and hypothalamus

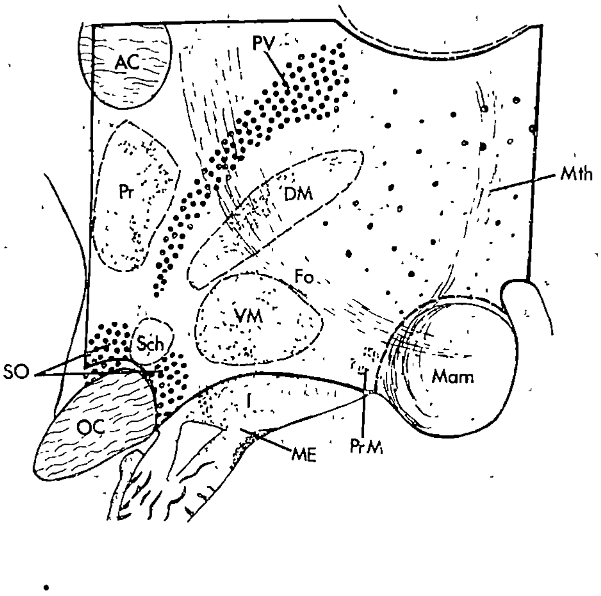
	Male		Female	
	Median eminence	Hypothalamus	Median eminence	Hypothalamus
Huntington's chorea	558±173 (6)	18 (7)	1,231±410 (9)	26 (6)
Age range	47–71	46–72	46–74	52–72
Controls	675±131 (28)	27 (23)	314±84 (11)	27 (15)
Age range	17–78	29–84	39–88	25–88

Numbers in parentheses indicate numbers of specimens. s.e.m are not given for concentrations in the hypothalamus since some values in all groups were undetectable.

vascular plexus which covers this area. The remainder of the hypothalamus (here termed 'hypothalamus') was removed as indicated in Fig. 1, the dissection being completed by vertical sagittal cuts 0.2 cm on either side of the midline. The hypothalamus of three control males (aged 39, 45 and 65 yr) was subdivided into blocks containing the preoptic, suprachiasmatic, ventromedial, dorsomedial and mammillary nuclei, respectively (Fig. 1). Frontal cerebral cortex from Brodmann's areas 9–12 of seven controls and three choreics was also taken. The tissues were stored on liquid nitrogen, and transported on dry ice to Oxford where they were weighed and homogenised (15 strokes using a Potter–Elvehjem-type homogeniser) in 0.1 N HCl at 4 °C. The homogenates were stored at –25 °C. The concentration of GRH in the homogenates was determined by a double-antibody radioimmunoassay[7,8] which is sensitive to 2–3 pg synthetic GRH per tube. The homogenates were thawed and neutralised immediately before assay, and an aliquot containing the equivalent of 0.4–0.5 mg tissue (or less at higher concentrations) was added to each of two (duplicate) assay tubes.

The slopes of the inhibition of binding curves produced by serial dilutions of the homogenates were similar to that of synthetic GRH which was used as a standard (Fig. 2), suggesting that GRH in human median eminence is immunologically similar to that found in the median eminence of the rhesus monkey, pig, sheep and rat[7,8]. Although the median eminence–pituitary stalk region had the greatest concentration of GRH, relatively large amounts of the hormone were also present in the preoptic nuclei (Fig. 1). In one specimen from a 45-yr-old male a small block of tissue was also taken from just in front of the anterior commissure. The concentration of GRH in this tissue was 55 pg mg^{-1}. The concentration of GRH in the frontal cortical tissue could not be detected (< 4.3 pg mg^{-1}) in all but one specimen from a choreic patient in which it was 16 pg mg^{-1}. In this patient, the concentration of GRH in the hypothalamus–median eminence was relatively high, 3,025 pg mg^{-1}.

Fig. 1 Diagram of sagittal section of the human hypothalamus (after Diepen[19]). The continuous lines indicate the cuts made to prepare blocks of median eminence and hypothalamus for data in Table 1. The interrupted lines indicate blocks of tissue used to determine the distribution of GRH. The mean concentrations of GRH (pg mg^{-1}) in brains from three control males were: median eminence (ME), 760±175, preoptic nuclei (Pr), 119±44; suprachiasmatic nuclei (Sch), 34±16; ventromedial nucleus (VM), 14±1; dorsomedial nucleus (DM), 12±5; mammillary bodies (Mam), 68±59. I, Infundibular nuclei; PrM, pre-mammillary nucleus; SO, supraoptic nucleus; PV, paraventricular nucleus; OC, optic chiasma; AC, anterior commissure; Fo, fornix; Mth, mamillothalamic tract.



The mean concentration of GRH in the median eminence of the female choreics was significantly greater ($P < 0.05$) than that in the female controls (Table 1). There was, however, no significant difference between the mean concentrations of GRH in the median eminence tissues from the choreic and control males. The concentration of GRH in the blocks of hypothalamic tissue was relatively small. In the control males the mean concentration (±s.e.m.) of GRH in the median eminence varied with age and was 1,315±467 ($n=6$), 535±225 ($n=5$) and 490±91 ($n=17$) pg mg^{-1} in the age ranges 17–40, 41–60 and 61–78 yr, respectively. The difference between the mean concentrations in the age groups 17–40 and 61–78 yr was significant at $P < 0.02$.

The median eminence concentrations of GRH are similar to those in rat hypothalamus (including median eminence) taken immediately before (under anaesthesia) or after death (S.A.C. and G.F., unpublished). As in the human, the greatest concentration of GRH in the rat (and guinea pig) is found in the region of the median eminence, and most but not all workers have found GRH also in the rostral hypothalamus[8–10]. The relatively high levels of GRH in the preoptic region of the human (Fig. 1) cannot be attributed to post-mortem diffusion, for, in the same specimens, the ventromedial and dorsomedial nuclei contained much smaller amounts of GRH. In the rat, the preoptic nuclei have a critical role in the causation of the preovulatory surge of luteinising hormone (LH), and may also be important for mating behaviour[11]. Preoptic GRH is conceivably present in neurones which send axons to the primary capillaries of the hypophysial portal vessels, but the presence of GRH in this region should also be considered in the context of the recent hypothesis that GRH may act as a neurotransmitter within the central nervous system[12,13].

It is not clear why the concentrations of GRH in the median eminence of choreics compared with controls differed significantly in the case of females but not males. The delay between death and the freezing of tissues was similar for the male and female specimens, and preliminary studies showed that there is no appreciable change in the concentration of GRH of hypothalamic tissue maintained at 4 °C for 6 d after death. Choreics of both sexes had been subjected to similar therapeutic regimes; all had spent the terminal stage in a psychiatric institution where they received phenothiazines regularly, and three of the males and four of the females had also been given tetrabenazine. Present radioimmunoassay methods do not enable reliable estimates of the concentration of GRH in

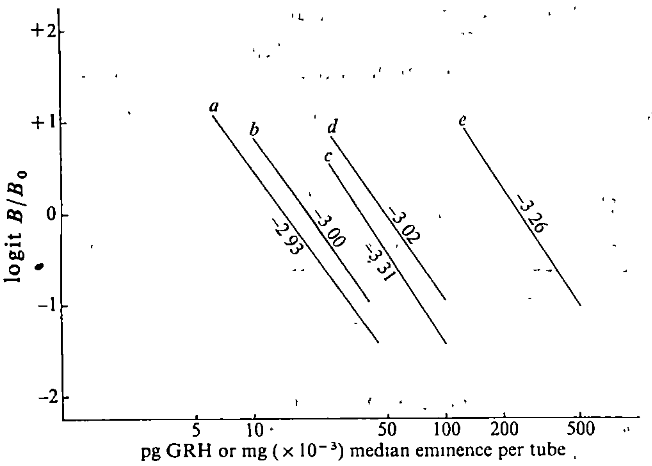


Fig. 2 Radioimmunoassay for GRH: logit* B/B_0 (percentage bound) against log dose curves of synthetic GRH (*a*) and serial dilutions of extracts of median eminence from choreic (*b*, *d*) and control (*c*, *e*) males (*c*, *d*) and females (*b*, *e*). Lines were calculated by the method of least squares from three points (four replicates per point) in the working range 20–80% bound. Numbers adjacent to the lines are the slopes. *Logit defined by ln $[y/(1-y)]$.

peripheral blood[12], and it was difficult to obtain reliable information regarding the pre-mortem menstrual or sexual history of these cases. The hypothalamic content of dopamine, noradrenaline and activity of glutamic acid decarboxylase in choreic patients is similar to that in control subjects[14].

The low concentration of GRH in the median eminence of the control females (Table 1) as well as in the older men may be due to increased release of the hormone. In the female this could not account for the marked rise in plasma gonadotropins which occurs between the ages of 45–50 yr and which is sustained at least until 75 yr (ref. 15). Although the changes are not so dramatic, the concentrations of plasma gonadotropins also increase with age in the male[15–18]. The possibility that decreased synthesis of GRH also contributes to the lower concentrations of GRH in the median eminence of the older controls cannot be excluded.

We thank the many physicians who helped us in the collection of post-mortem tissues, Miss W. McCauley-Gordon for assistance, and Dr G. D. Niswender (Colorado) and Drs H. Gregory, J. Gormley and A. L. Walpole (ICI) for gifts of R-42-anti-GRH and synthetic GRH, respectively. Supported by the National Fund for Research into Crippling Diseases (E.D.B.) and the MRC (G.F.).

Aspartate and glutamate as possible transmitters of excitatory hippocampal afferents

IN the rat hippocampal formation, the major excitatory inputs possess a remarkable degree of physiological and morphological plasticity. Long lasting potentiation has been reported[1–3] and, at least in the dentate gyrus, the synaptic loss consequent on removal of one afferent is compensated by formation of additional synapses by intact afferents[4,5]. These phenomena must involve profound alterations of synaptic biochemistry, but the requisite biochemical studies cannot be performed until the transmitters used by these inputs are known.

One of the most critical tests of a transmitter substance is the demonstration of its release from specific fibres. Accordingly, as a first approach to the identification of the transmitters used by hippocampal afferents, we analysed the efflux from hippocampal slices of the excitatory amino acids, aspartate and glutamate. Aspartate and glutamate depolarise neurones in the central nervous system[6], and they are present in large amounts[7]. They are thus putative excitatory transmitters, although they have not been clearly related to specific fibre projections. We now report that aspartate and glutamate are released from superfused slices of hippocampal regions in a Ca^{2+}-dependent manner and that their efflux is associated in part with two excitatory afferents, the hippocampal commissural fibres and the perforant path.

In preliminary experiments, slices of rat dentate gyrus and regio superior were depolarised with 56 mM K^+ in Ca^{2+}-free medium into which Ca^{2+} was then introduced (Fig. 1). The rate of efflux of glutamate and aspartate was elevated somewhat by depolarisation of the tissue in the absence of Ca^{2+}, but the subsequent introduction of Ca^{2+} into the medium increased the efflux rate more dramatically (by 500–1,100 pmol per 30 s for a standard number of slices). This effect of Ca^{2+} was nearly always evident within 30 s. In other studies, the Ca^{2+}-evoked efflux was shown to be dependent on depolarisation of the tissue (with K^+ or veratridine); addition of Ca^{2+} to medium containing only 6 mM K^+ did not increase the rate of efflux.

Since physiological transmitter release invariably requires Ca^{2+} (ref. 8), it seemed quite possible that the Ca^{2+}-dependent portion of the depolarisation-evoked efflux was derived from synaptic boutons. In view of this relationship between Ca^{2+} and transmitter release, we tested whether boutons of the commissural or entorhinal projections to the hippocampal formation could have been responsible for the Ca^{2+}-dependent efflux of aspartate or glutamate. The commissural fibres arise from hippocampus regio inferior and terminate in all three regions of the contralateral hippocampal formation–dentate gyrus, regio inferior and regio superior[9,10]. The perforant path fibres originate in the entorhinal cortex and make synaptic contact with the granule cells of the dentate gyrus[11,12]. Some fibres of entorhinal origin also terminate in regio inferior and regio superior. In these experiments, either the contralateral hippocampal formation or both entorhinal cortices were removed, and slices of dentate gyrus and regio superior were cut, incubated and superfused as before 8–9 d after operation. We reasoned that, if aspartate or glutamate were the transmitter of the commissural or entorhinal projections, its Ca^{2+}-dependent efflux should have been reduced by eliminating the appropriate fibre tract.

By comparison with paired, sham-operated control groups, the Ca^{2+}-dependent efflux of glutamate from the dentate gyrus, but not from regio superior, was reduced almost 50% by a bilateral entorhinal lesion (Table 1). Efflux in the absence of Ca^{2+} was unaffected. Our data indicate that about half the Ca^{2+}-dependent efflux of glutamate from slices of the rat dentate gyrus is associated with the perforant path fibres, and glutamate may therefore be their transmitter.

Boutons which utilise aspartate and glutamate as transmitters are thought to possess a high affinity uptake mechanism for these amino acids[13,14]. In accordance with the postulated role for glutamate as a transmitter of the perforant path, a bilateral entorhinal lesion reduced the uptake of labelled glutamate (at a concentration below the K_m of the high affinity uptake system[13]) into slices of the dentate gyrus, but not into slices of regio superior (Table 2). In the same experiments, the high affinity uptake of GABA was unaffected by the lesion.

Commissurotomy significantly reduced the Ca^{2+}-dependent efflux of aspartate from both the dentate gyrus and regio superior (Table 1), two regions to which commissural fibres project, but did not affect efflux in the absence of Ca^{2+}. Therefore aspartate is probably released by these fibres and may be the commissural transmitter.

Commissural fibres have been shown to form additional synapses in the dentate gyrus after unilateral[15] or bilateral (unpublished) entorhinal lesions, and these connections begin to assume electrophysiological function 9 d after operation[16]. One would expect some increase in the Ca^{2+}-dependent efflux of the commissural transmitter at this time. In agreement with the hypothesis that aspartate is released from boutons of the commissural fibres, the Ca^{2+}-dependent efflux of aspartate from slices of the dentate gyrus was increased 8–9 d after a bilateral entorhinal lesion.

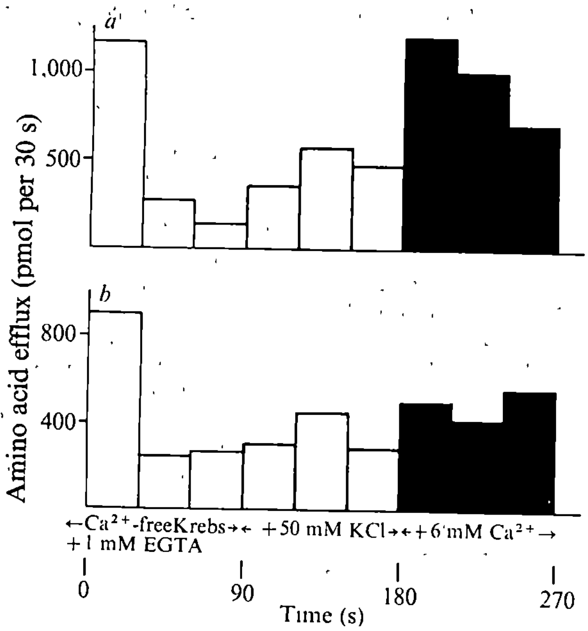

Fig. 1 Time course of glutamate (*a*) and aspartate (*b*) efflux from slices of the rat dentate gyrus Slices of about 300 μm thickness cut from 12 1-mm thick coronal slabs[18] of dentate gyrus (about 11 mg wet weight) were used in each experiment. After a 10-min incubation in Ca^{2+}-free Krebs bicarbonate medium containing 1 mM EGTA and 10 mM glucose, the slices were loaded by gentle suction on to a glass fibre filter, which was then inserted into a continuous superfusion device[19]. The slices were initially superfused at 10.8 ml min^{-1} for 90 s with Ca^{2+}-free, glucose-free, Krebs bicarbonate medium containing 1 mM EGTA. Then the K^+ concentration was increased and finally Ca^{2+} was introduced into the medium. The superfusate fractions were desalted with cation-exchange columns, and the glutamate and aspartate contents were determined by micro-enzymatic fluorometric methods[20]. The bars represent mean values for 13 (glutamate) or 7 (aspartate) experiments. Similar results were obtained with slices of regio superior.

Table 1 Ca^{2+}-stimulated efflux after lesions of hippocampal afferents

Regio superior	1130±360	85±19(4)

Slices were cut from 12 1-mm thick coronal slabs of hippocampal formation and superfused (see Fig. 1). Slices from operated and control animals were used in consecutive experiments conducted in random order on the same day Controls received sham lesions. Values are expressed as means±s.e.m for the number of experiments in parentheses.

*The amount of Ca^{2+}-dependent efflux was calculated by subtracting the efflux rate immediately preceding the Ca^{2+} stimulus (previously shown to remain approximately constant, if Ca^{2+} was not introduced) from the peak efflux rate during stimulation with Ca^{2+}.

Results differed from control at† $P < 0.05$, ‡$P < 0.02$, §$P < 0.01$ (two-tailed, paired *t* test). For all other differences $P > 0.05$.

In 4 of 5 experiments, the Ca^{2+}-dependent efflux of aspartate from slices of regio superior was also increased by a bilateral entorhinal lesion. We do not know, however, whether the commissural fibres form additional synapses in regio superior after this lesion.

The Ca^{2+}-dependent efflux of glutamate from slices of regio superior, but not from dentate gyrus slices, was also reduced by a commissurotomy. This effect was not attributable to inadvertant section of the crossed temporo-ammonic tract, fibres of entorhinal origin which innervate the contralateral hippocampus[9,17], since a bilateral entorhinal lesion would then have produced a similar result. Possibly some of the commissural fibres which innervate regio superior release glutamate or else glutamate is released by some other crossed pathway that was damaged.

In summary, the results presented here demonstrate lesion-induced changes in Ca^{2+}-dependent excitatory amino acid efflux from slices of hippocampal regions which are selective

Table 2 Uptake of glutamate and GABA into slices after bilateral entorhinal lesion

Immediately before the preliminary 10-min incubation of slices from rats with bilateral entorhinal lesions (see Fig 1), 2,3-^{3}H-GABA (10 μCi, 36.7 Ci mmol^{-1}) and U-^{14}C-glutamate (1 μCi, 237 mCi mmol^{-1}) were added at a final concentration of 0.03 μM and 0.4 μM respectively The amount of radioactivity taken up and retained by the tissue was calculated by adding the radioactivity released during superfusion to that still present in the tissue after superfusion was terminated Values are expressed as means ± s.e.m. for the number of experiments in parentheses.

*Slices from animals with bilateral entorhinal lesions differed from control at $P < 0.05$ (two-tailed, paired *t* test).

for the type of lesion, the hippocampal region and the particular amino acid. On this basis, we suggest aspartate as a strong candidate for transmitter of the hippocampal commissural fibres and glutamate for transmitter of the perforant path fibres. The possibility has not, however, been excluded that the lesions induce specific reductions in amino acid efflux from undamaged cellular elements or that substances other than those tested are also released by the fibre tracts in question. In any case, these studies should aid our understanding of adaptive mechanisms within hippocampal afferents.

We thank Miss H. Hyatt for performing the lesions and the National Institutes of Health for support.

γ-Aminobutyric acid in rat superior cervical ganglion

RADIOLABELLED γ-aminobutyric acid (GABA) is taken up by both neurones and glial cells in the central nervous system[1,2], where it mixes with endogenous GABA stores[3]. Superior cervical and dorsal root ganglia also accumulate radioactive GABA and this amino acid is taken up exclusively in satellite glial cells[4,5]. The presence of GABA in peripheral neural tissues has not, however, been demonstrated unequivocally[6–8]. We have measured GABA and glutamic acid in rat superior cervical and nodose ganglia by mass fragmentography. The concentration of GABA in nodose ganglia was lower than in the superior cervical sympathetic ganglion (SCG). Moreover, our results suggest that the content of GABA in the SCG may be controlled by neuronal activity.

Sprague–Dawley rats (Zivic Miller) were killed by exposure of their heads and necks to a focused microwave beam for 2.2 s (ref. 9) before the dissection of SCG and nodose ganglia. In other experiments, where the effect of preganglionic stimulation on the GABA content of SCG was studied, the rats were not killed by microwave (see below). Glutamic acid and GABA were determined according to the method of Bertilsson and Costa[10]. Briefly, tissues were homogenised in 150 µl of 80% aqueous ethanol containing 330 pmol of δ-aminovaleric acid and 7.5 nmol of pentadeuterium-labelled glutamic acid used as internal standards to quantitate GABA and glutamic acid, respectively. After centrifugation, the supernatant was evaporated to dryness and the residue was reacted with 50 µl of 1,1,1,3,3,3-hexafluoroisopropanol and 100 µl of pentafluoropropionic anhydride at 60 °C for 1 h, in a small sealed vial. The pentafluoropropionyl amide hexafluoroisopropyl ester of GABA, glutamic acid and their internal standards are formed during this reaction. The reagent was evaporated and the residue was dissolved in 10 µl of ethyl acetate. About 3 µl of the solution was injected into a gas chromatograph–mass spectrometer (LKB model 9000 with a multiple ion detector). The temperature of the column (1.5 m × 3 mm internal diameter packed with 3% OV-17 on Gas Chrom Q) was 112 °C. The ionising potential was 80 eV and the trap current was 60 µA. To ascertain absolute specificity of the analysis, the intensity of three characteristic fragments of GABA (*m*/*e* 176, 190, and 204) and two of glumatic acid (*m*/*e* 202 and 230) were monitored in each determination. The mean of the relative intensity of these fragments from the SCG deviated less than 2% from those of standards. The fragments *m*/*e* 204 and 206 were used to monitor the internal standards of GABA and glutamic acid, respectively.

The GABA content of SCG was 297±18 pmol per mg protein (Table 1). Although this concentration is only a few per cent of that in brain, it is of the same order of magnitude as dopamine and noradrenaline content of SCG[11]. The GABA concentration of nodose ganglion, which has only a few synapses, was about 106 pmol per mg protein. At this low concentration, no absolute identification (by the three fragments *m*/*e* 176, 190, and 204) could be obtained; however, it can be stated that the GABA concentration in SCG is at least 3 times greater than in the nodose ganglion. The concentration of glutamic acid in the SCG (Table 1) agrees with that reported by Nagata *et al.*[6].

To determine if GABA stored in SCG is in a dynamic equilibrium the GABA content in SCG was measured 4 h after amino-oxyacetic acid injections (50 mg kg^{-1} of the hemihydrochloride intraperitoneally). Amino-oxyacetic acid, an inhibitor of GABA transaminase, the enzyme responsible for the catabolism of GABA[12], increased the GABA content of SCG more than fourfold (Table 1). Chlorisondamine HCl (10 mg kg^{-1} intraperitoneally) given 8 h before killing, SCG decentralisation (7 d before) and urethane (1,500 mg kg^{-1} intraperitoneally, 20 min before) decreased the GABA content of SCG by about 50% (Table 1). Amino-oxyacetic acid, decentralisation or urethane did not change the glutamic acid level in SCG. Thus, the GABA level was decreased by (1) blocking the ganglionic nicotine receptors, (2) destroying the preganglionic nerve terminals and (3) giving an anaesthetic agent that may act by decreasing the stimuli originating from the central nervous system and reaching the SCG[13]. These results indicate that GABA in SCG may be under neuronal control. The observation that only 50% of the GABA content disappeared after decentralisation indicates that the remaining GABA may either

Table 1 Concentration of GABA and glutamic acid in rat superior cervical ganglion

Treatment	GABA pmol per mg protein	Glutamic acid nmol per mg protein
Saline	297±18 (16)	27.5±2.6 (4)
Amino-oxyacetic acid (50 mg kg^{-1}; intraperitoneally; 4 h)	1,348±147 (4)†	36.0±3.6 (4)
Chlorisondamine (10 mg kg^{-1}; intraperitoneally; 8 h)	143±11 (4)†	NA
Decentralised	137±11 (8)†	31.1±0.9 (4)
Urethane (1,500 mg kg^{-1}; intraperitoneally; 20 min)	154±16 (4)*	30.0±3.7 (4)

Animals were killed by focused microwave beam. Values are mean±s.e.m. Number of determinations in parentheses.
* $P<0.01$; † $P<0.001$; NA, not assayed.

reflect the low steady state in absence of stimulation or originate from other sources than local synthesis; perhaps, it may be blood borne to the ganglion, where it is taken up by the glial cells.

In other experiments, rats were anaesthetised with urethane (1,500 mg kg^{-1} intraperitoneally) and 10–20 min thereafter; both SCG were exposed. One side was stimulated preganglionically at 20 Hz for 60 s (3.5 V, 0.3 ms duration pulse) and the other ganglion was used as a control. Immediately after stimulation, both ganglia (stimulated and unstimulated) were dissected out and immediately frozen on dry ice. The stimulated SCG contained more GABA (1,486±73 pmol per mg protein; $P<0.01$ by paired t test) than the unstimulated ganglia (1,256±95 pmol per mg protein). The interpretation of this result is difficult, since in the absence of microwave inactivation of enzymes the process of dissection and isolation by itself increases the concentration of GABA by about 8 times (from 154±16 in urethane-treated and microwaved animals to 1,256±95 pmol GABA per mg protein obtained in this experiment). Nevertheless, these data lend support to the hypothesis that GABA stores in SCG are under the control of neuronal activity.

We have demonstrated that the GABA content in the rat SCG is higher than in the nodose ganglion. Since the nodose ganglion has only a few interneurones and synapses, it may be surmised that the GABA storage in nodose and SCG resides in glial cells and can be regulated by the synaptic activity of the tissue. The endogenous GABA present in the glial cells of the SCG is stored against a concentration gradient by the high affinity uptake system which has been demonstrated in SCG[4]. As this GABA seems to be under control of neuronal activity, there may be a functional role of GABA in glial cells. Perhaps, it is released by the high potassium concentration which may be formed in the interstitial fluid during intense neuronal activity. The presence of neurones in the SCG that lack a GABA uptake mechanism but can synthesise GABA cannot, however, be excluded.

Stimulation-dependent release of ^{3}H-adenosine derivatives from central axon terminals to target neurones

ADENOSINE is postulated to function in the brain as an intercellularly active neurohumoral substance. This has been suggested by *in vitro* studies showing that adenosine can be released from brain tissue by electrical stimulation at quantities which are sufficient to increase the formation of cyclic AMP[1]. The finding that adenosine derivatives are released from dendrites and particularly axon terminals points to the neurones as a major source for the released nucleotides[2]. Thus, nucleotides may function as 'secondary' or 'additional' neuronal transmitters mediating long lasting effects of a neurone on the metabolism and function of its target cells. Further evaluation of these hypotheses will require demonstrations that endogenous adenosine or its derivatives are actually released by synaptic connections in the intact brain and that this process is influenced by activation of these connections. We have carried out experiments in which tritiated adenosine was transported from cell bodies into a population of terminals, and in which the amount of radioactive materials taken up by the target cells of these terminals was measured in the presence and absence of synaptic stimulation. Stimulation was found to increase the release of ^{3}H-adenosine derivatives from central axon terminals to their postsynaptic neurones.

These studies were carried out in rat entorhinal cortex–dentate gyrus projection ('perforant path'). This system was selected because its terminals form a compact, discrete layer in the distal dendrites of the dentate gyrus granule cells. As a result of this arrangement it is possible to microdissect samples of the dentate gyrus which are purely postsynaptic to the entorhinal terminals (that is, the cell bodies of the granule cells) and to compare it with a sample which contains both terminals and postsynaptic (that is, dendritic) elements (see Fig. 1). Finally, because of its laminated organisation, the entorhinal dentate gyrus connection produces easily recordable extracellular physiological responses when activated[3]; this makes it a simple matter to establish optimal location for the electrical stimulation required in the following experiments.

Adult Sprague–Dawley rats (350–400 g body weight) while under Nembutal anaesthesia were stereotaxically injected with ^{3}H-adenosine (25 μCi = 2.3 nmol in 0.5 μl, specific activity: 11 Ci mmol^{-1}) into the dorsal aspect of the entorhinal cortex. The amounts injected were in the physiological range of the normal tissue content of adenine derivatives (2–3 nmol per mg tissue). Using recordings of the extracellular field potentials from the granule cell layer as a guide, a bipolar stimulation electrode was localised to a position in the injection site where it optimally activated the rostral dentate gyrus by way of the

Fig. 1 *a*, Region of perforant path (PP) termination (shaded area) in the hippocampus ipsilateral to the injected entorhinal cortex (EC). Positions of recording (R) and stimulating (S) electrodes as indicated. *b*, Areas sampled in the microdissection procedure (dotted area). M, Molecular layer receiving afferents from the perforant path; G, granule cell layer containing only postsynaptic elements.

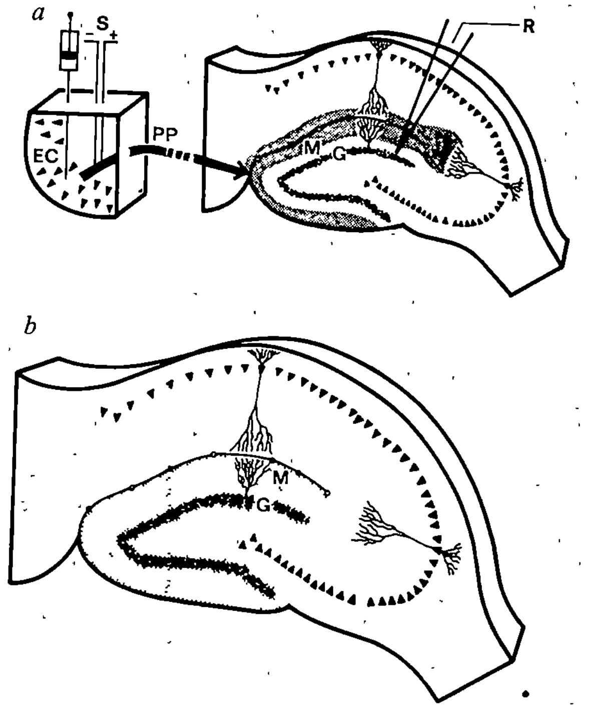

Table 1 Effect of electrical stimulation on release of ^{3}H-adenosine derivatives from axon terminals to granule cells

Duration of experiments	Ratio $G/(M+G)$ Control	Ratio $G/(M+G)$ Stimulated	% Increase in stimulated compared with control rats
5–8 h	0.20±0.03* (n = 5)	0.28±0.03 (n = 2)	40
18 h	0.19±0 03 (n = 4)	0.26±0.01 (n = 5)	37
1 d	0.26±0.04 (n = 3)	0.36 (n = 1)	39
3 d	0.33±0.01 (n = 3)	0.36 (n = 1)	9

G and *M* represent measured content of radioactivity (d.p.m.) in granule cell layer (*G*) and molecular layer (*M*) samples. ($M+G$) was usually equivalent to 8,000–14,000 d.p.m at transport times of 18 h and longer. Values are means ±s.d. *n*, Number of experiments (rats).

perforant path (see Fig. 1). Both the recording and stimulating electrodes were then cemented in place. The animal was then attached to a cable and placed in a chamber which allowed continuous recording and stimulation while the animal was awake and freely moving. Stimulation of the entorhinal cortex was carried out throughout the experiment. Pulses of 0.10 ms and 4–8 Hz were presented in a cyclic manner (10 min on and 2 min off). Such stimulation was capable of, but did not normally produce, post-tetanic potentiation of the granule cell response at the stimulus intensities used in the experiment. A second group of rats serving as controls were treated and analysed in the same way but received no electrical stimulation. The rats were killed by decapitation at various times after injection and the different samples indicated in Fig. 1 were dissected from 400-μm thick sections of the ipsilateral hippocampal target area. Homologous samples from ten slices were pooled, homogenised, sonified, and their radioactivity measured by scintillation counting. The consistency of the microdissection procedure was checked by measuring the protein content of the samples with the Lowry technique.

In normally behaving, unstimulated rats, the quantities of ^{3}H-adenosine derivatives released from the entorhinal axon terminals and taken up by the different target neurones in the hippocampus, were found to depend on the density of the entorhinal input to these neurones and the time allowed for transport (our unpublished results). The effect of electrical stimulation is shown in Table 1. For these experiments a period of 18 h was used since, at this time, a high proportion of TCA-soluble ^{3}H-adenosine derivatives had reached the ipsilateral hippocampus by way of axonal transport. Their concentration at this time was 30 times greater than that of the non-target cortical control tissue. The amount of the transported ^{3}H-nucleotides channelled to the granule cell target area (including the terminals of the entorhinal axons) is represented by the total radioactivity recovered from the molecular layer (*M*) and granule cell layer (*G*) samples. The ratio $G/(M+G)$ gives the relative content of radioactivity in the somata of the granule cells. This value will be an underestimation of the radioactivity in the granule cells since it does not include material in the distal dendrites of these cells. But this ratio represents a useful relative measure for the release to and uptake by the granule cells.

Comparison of stimulated with non-stimulated animals revealed that release and uptake were increased markedly (by about 40%) as a function of electrical stimulation (see Table 1). These results complement the *in vitro* findings of McIlwain[1]. They indicate that a functionally dependent release of adenine derivatives (which is well documented for peripheral monaminergic[4], cholinergic[5,6] and purinergic nerves[7]) also occurs from central neuronal pathways. Since the nucleotide levels in the central nervous system are rather shielded from foreign influences by the blood–brain barrier[8] they seem to be largely determined by intracerebral recycling processes. A release from axon terminals may therefore significantly alter the local concentration of adenosine at the target neurones and induce metabolic changes which reflect the amount of input received. It is tempting to speculate whether the unusual physiological plasticity of the entorhinal–dentate gyrus synapses, which seem to be potentiated for hours and perhaps days[9] after repeated stimulation, is related to adenosine-induced metabolic changes in the granule cells.

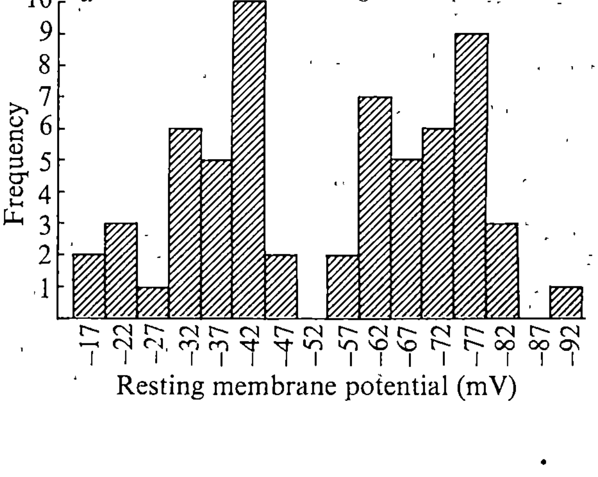
Membrane potential of juxtaglomerular cells

THE juxtaglomerular granular cell of the kidney is the site of renin storage and release, and is located most commonly within the media of the afferent arteriole, often in close apposition to the distal tubule and to sympathetic nerve endings. Morphologically, it seems to be a smooth muscle cell that has been modified for secretory activity, and contains both myofibrils and membrane-limited renin granules[1–3]. Evidence has accumulated to suggest that the juxtaglomerular cell, either directly or by way of its neighbouring cells, is stimulated to release renin by catecholamines, by changes in intravascular or interstitial pressures, and by variation in local ionic concentrations[4]. But, even though the juxtaglomerular cell is central to all theories of renin secretion, little effort has been made to investigate its physiology at the cellular level. In this paper, a new method is described for visualising living juxtaglomerular cells, and for recording their electrical activity

Fig. 1 Distribution of resting potentials of juxtaglomerular cells, showing the two groups. *a*, Group I; *b*, group II.



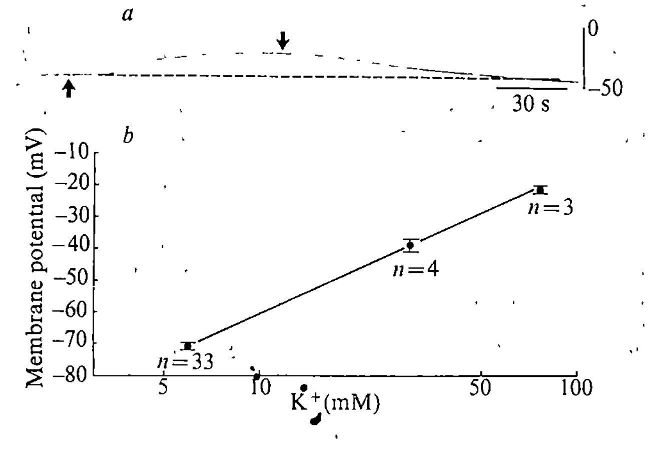


Fig. 2 *a*, Depolarisation by 70 mM K+ (first arrow) and repolarisation after return to Ringer's solution (second arrow). Ringer's solution contained (mM): Na^+ 138.0, K^+ 5.8, Ca^{2+} 2.5, Mg^{2+} 1.2, Cl^- 123.6, $SO_4{}^{2-}$ 1.2, $HCO_3{}^-$ 25, $H_2PO_4{}^-$ 1.2, glucose 10; and was bubbled with 95% O_2/5% CO_2. Solutions of increasing K^+ concentration were made by equimolar substitution of KCl for NaCl. *b*, Relationship of membrane potential to log $(K^+)_o$.

using intracellular microelectrodes. The results suggest that changes in the membrane potential of the juxtaglomerular cell occur with changes in renin secretion.

At least one stable resting potential was recorded in each of 25 successful experiments. For each experiment both kidneys were removed from a sodium-depleted mouse under ether anaesthesia, sectioned as thinly as possible using a razor blade, and then pressed through a 240-μm sieve. The fragments were stained with neutral red (which stains juxtaglomerular cell granules[2]), and transferred to a chamber maintained at 37 °C with Ringer's solution flowing through at a rate of 3 ml min^{-1}. Adherence of the fragments to the chamber was achieved by precoating the glass with polylysine (10 mg ml^{-1}, Sigma), a polycationic molecule that fixes tissue to glass electrostatically[5]. Glass microelectrodes, pulled with a fibre inside to tips < 1 μm, were filled by injection with 2 M KCl; tip potentials were < 5 mV, resistances 80–160 MΩ. Using Normarski optics and a ×40 water immersion lens, the juxtaglomerular cells, with their granules stained red, were readily identifiable as chains or clusters clearly distinct from the larger, diffusely stained tubular cells. Impalement by the microelectrodes proved difficult because of the small size and adventitial coats of the juxtaglomerular cells, so that it was only possible to penetrate and record stable potentials from 62 of the more than 1,000 cells in which it was attempted. In general, the potentials were stable for 10–20 s; but in several instances stable potentials were observed for up to 7 min. In those trials in which the membrane potential of a cell remained stable to within 1 mV for at least 7 s, the composition of the surrounding medium was altered by changing either the ionic composition of the flowing Ringer's solution, or by injecting drugs directly into the bath. The juxtaglomerular cells remained viable, as manifested by their exclusion of Trypan blue, for several hours. In contrast, within 1 h the tubular cells generally failed to exclude the dye.

As shown in Fig. 1, the stable resting potentials fell into two distinct populations: a low potential group, with mean −35 mV, and a higher potential group, with mean −70 mV. And, indeed, using a χ^2 test, the data were well approximated using two curves with means -35 ± 8.5 mV (s.d.) and -70 ± 7.9 mV, respectively ($\chi^2 = 15.08$, d.f. = 10, $P > 0.10$); in contrast, the data were poorly fitted by a single curve with mean -54 ± 19.7 mV ($\chi^2 = 37.36$, d.f. = 15, $P < 0.005$). It is possible that the cells with lower potentials represent a less viable group rather than a physiologically distinct population. No obvious morphological differences, however, could be found between the cells, and the whole range of potentials shown in Fig. 1 could be recorded from different cells prepared at the same time.

Since renin secretion is inhibited by increasing K^+ concentrations[6,7], it was of interest to determine whether K^+ had a significant role in determining the membrane potential of the juxtaglomerular cells. All cells that were tested ($n = 11$) depolarised with increasing K^+. Figure 2*a* illustrates the typical response to increased K^+ concentration, and shows depolarisation with 70 mM K^+ and repolarisation when normal Ringer's solution was restored in the bath. The potential was related to K^+ concentration: for cells of group I the relationship was curvilinear, as might be expected from their lower resting potentials[8], whereas for group II cells the relationship was linear (Fig. 2*b*). The slope, 43 mV per tenfold change in K^+ concentration was greater than that for many non-excitable cells[8], but less than if the juxtaglomerular cell were simply a K^+ electrode—that is

$$E_m = 61\ \text{mV}\ \log[K^+]_o/[K^+]_i.$$

Adrenaline has been shown to stimulate the secretion of renin *in vivo*[4] and *in vitro*[9,10]. As shown in Fig. 3, adrenaline caused a small, but statistically significant ($P < 0.005$) hyperpolarisation for cells over the whole range of resting potentials. Since the typical potential change with any mechanical disturbance was depolarisation, it was unlikely that these changes were artefacts. To determine the possibility of an artefact, injections of Ringer's solution into the bath were carried out for six cells. These injections caused either no change or a depolarisation, in sharp contrast to the adrenaline-induced hyperpolarisation ($P < 0.001$). A concentration of 10^{-4} M was used because of its rapid dilution by the flowing bath, and because concentrations of at least this magnitude are needed to stimulate renin secretion *in vitro*[9,10].

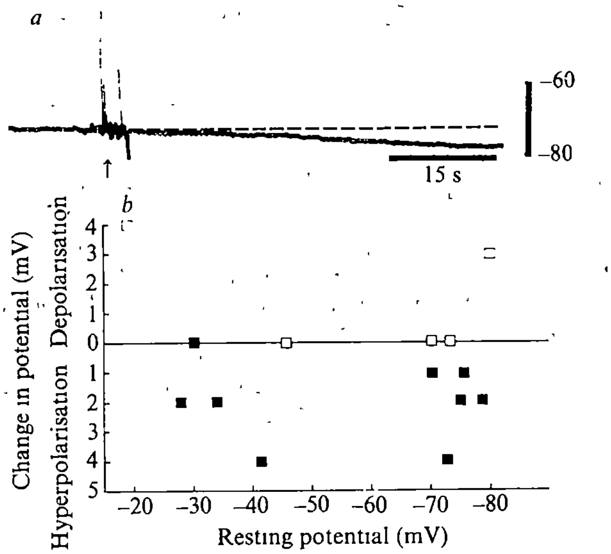

Fig. 3 *a*, Hyperpolarisation of a juxtaglomerular cell by injection (at arrow and artefact) of adrenaline (to an initial bath concentration of 10^{-4} M) into the flowing bath. *b*, Comparison of effects of adrenaline (■) or equal control (□) volume of Ringer's, for cells over the range of resting potentials.

This investigation provides a fresh approach to the study of the cellular physiology of the juxtaglomerular cell. The trials reported in this paper have demonstrated that two substances (K^+ and adrenaline) which are known to affect renin secretion in opposite ways, cause the membrane potential to change in opposite directions. These results, although distinctive, do not imply that either adrenaline or K^+ are the most important controlling elements in renin secretion, or that the membrane potential changes are the cause of subsequent alterations in renin release. Indeed, in other secretory systems, potential changes and secretion may be uncoupled[11].

Note, however, that both the adrenaline- and K^+-induced potential changes are similar to those that occur in smooth muscle cells[12], which juxtaglomerular cells resemble morphologically. One additional feature of the smooth muscle membrane potential is its sensitivity to stretch[12]. In view of the baroreceptor theory of renin secretion[13], it is tempting to postulate a similar mechanical sensitivity for the juxtaglomerular cell membrane potential. Thus, renin secretion could be partially controlled by changes in arteriolar or interstitial pressures near the juxtaglomerular cell, as signalled by changes in its membrane potential.

I thank Dr A. C. Barger for encouragement and assistance. This research was supported in large measure by the Proctor–Wellington Fund and a grant from the USPHS.

19-Hydroxyprostaglandin E_1 as a major component of the semen of primates

As their name implies, prostaglandins were first identified in secretions of the male reproductive tract. In the early 1930s several workers[1–3] showed that human semen could stimulate various smooth muscle preparations, and this activity was ascribed to an unidentified component which von Euler named 'prostaglandin'. von Euler[4,5] then found that a watery alcoholic extract of rhesus monkey seminal vesicles markedly lowered the blood pressure in the rabbit but, unlike human seminal vesicle extracts, it had little or no action on the isolated intestine and the uterus of the rat and other laboratory animals. He therefore postulated the existence of another substance in the monkey which he named 'vesiglandin' and which he suggested could be a component of human seminal 'prostaglandin'.

We have shown[6] that the major prostaglandins present in human semen are two hitherto unidentified compounds, 19-hydroxyprostaglandin E_1 (19-OHPGE$_1$) and 19-hydroxyprostaglandin E_2 (19-OHPGE$_2$), and this has since been confirmed[7]. Human semen also contains appreciable amounts of prostaglandins E_1 (PGE$_1$) and E_2 (ref. 8) which are known to both lower blood pressure and stimulate smooth muscle in test animals. It was therefore interesting to know whether these new 19-OHPGs had any pharmacological activity, and how widely they were distributed throughout the animal kingdom.

Ejaculates were obtained from men, the great apes and various monkeys and domestic and laboratory animals, either by electroejaculation[9], masturbation, or the use of an artificial vagina, and examined for the presence of 19-OHPGE$_1$ and 19-OHPGE$_2$ by gas chromatography–mass spectrometry for identification and gas chromatography alone for quantitation[10]. Table 1 shows that large amounts of these two new PGs were recovered from the semen of man, the chimpanzee, orang-utan, rhesus monkey and stump-tailed macaque, and a trace was obtained from a small and possibly incomplete ejaculate from a gorilla, whereas they were undetectable in the semen of domestic and laboratory animals. Figure 1 shows a gas chromatographic trace of the acidic fraction of rhesus monkey semen, in which 19-OHPGE$_1$ is obviously the main component.

We have already demonstrated that the production of these PGs in men is highly androgen dependent, since the concentrations in the ejaculate fell within 48 h of cessation of testosterone replacement therapy to hypogonadal individuals[11]. To investigate the site of origin of these compounds, we dissected out the complete male reproductive tract from a freshly killed stump-tailed macaque (*Macaca arctoides*) and analysed each of its components. There was an extremely high concentration of 19-OHPGE$_1$ and 19-OHPGE$_2$ in the large seminal vesicles (70 μg g^{-1}; combined seminal vesicle weight 73 g), but none was detectable in the testis, epididymis, vas deferens, ampulla of the vas or prostate. Thus there was sufficient 19-OHPGE$_1$ and 19-OHPGE$_2$ stored in the seminal vesicles to account for

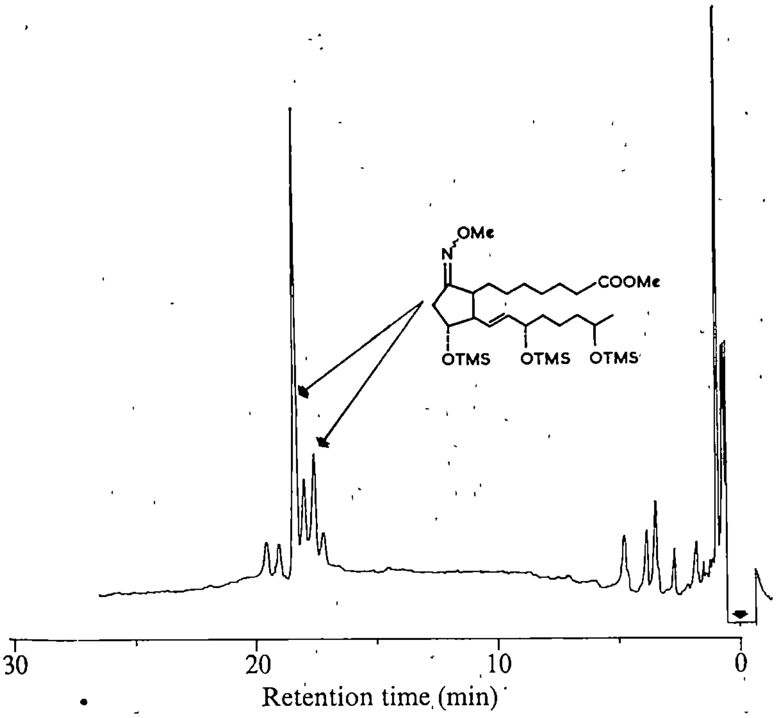

Fig. 1 Gas chromatographic (GC) trace of acidic fraction from semen of *Macaca mulatta*. Coagulated semen (2 g) was stored in methanol at −20° C, homogenised in the same methanol then centrifuged and the methanol evaporated. The residue was treated with 5 ml of a solution of methoxyamine hydrochloride (10 mg ml^{-1}) in pyridinium acetate (1.5 M *p*H 5). The mixture was left in an ultrasonic bath at 60 °C for 40 min then extracted with ether–ethylacetate (3:1); the ethereal layer was evaporated, transferred to a small tube and reacted with diazomethane followed by *bis*-(trimethylsilyl) trifluoro acetamide (20 μl). This solution was injected directly into the GC after 40 min at 60 °C. The trace was obtained from a combined gas chromatograph–mass spectrometer (duPont 490B spectrometer coupled to a Varian 1400 GC) the column was a 25-m SCOT column (SGE Ltd) temperature programmed from 170 °C to 270 °C at 4° per min. Helium carrier gas flow was 3 ml min^{-1}. Detection was by total ion current monitor.

Table 1 Concentrations of 19-OHPGE$_1$ and 19-OHPGE$_2$ in semen

Species	Source of semen	No. of samples	19-OHPGE$_1$ concentration mean (μg ml^{-1})	19-OHPGE$_2$ concentration mean (μg ml^{-1})
Man (*Homo sapiens*)	Masturbation	6	100±47 s.d.	96±43 s.d.
Chimpanzee (*Pan troglodytes*)	Masturbation	2	390	84
Gorilla (*Gorilla gorilla*)	Electroejaculation	1	5	Not identified
Orang-utan (*Pongo pygmaeus*)	Electroejaculation	2	54	Not identified
Rhesus monkey (*Macaca mulatta*)	Masturbation	8	420	84
Stump-tailed monkey (*Macaca arctoides*)	Masturbation	1	780	150
Horse (*Equus caballus*)	Artificial vagina	1	ND	ND
Cow (*Bos taurus*)	Artificial vagina	3	ND	ND
Sheep (*Ovis aries*)	Artificial vagina	8	ND	ND
Pig (*Sus scrofa*)	Artificial vagina	2	ND	ND
Rabbit (*Oryctolagus cuniculus*)	Artificial vagina	3	ND	ND
Chicken (*Gallus domesticus*)	Lumbar massage	1	ND	ND

ND Not detectable, concentration less than 1 μg ml^{-1}.

the amount present in a single ejaculate (Table 1). We examined a series of spontaneous ejaculates produced by one stump-tailed macaque that masturbated 11 times in less than 2 h (Table 2). Since the concentration of 19-OHPGEs did not decrease with time, this suggests that the vesicular store can be replenished rapidly. The high concentration of 19-OHPGE$_1$ in the semen of the stump-tailed macaque has also enabled us to isolate the compound as pure crystals (melting point 129–131 °C) by selective extraction with organic solvents, followed by Sephadex LH20 chromatography.

Dr N. S. Crossley of ICI Pharmaceuticals has synthesised 19-OHPGE$_1$ and 19-OHPGE$_2$ for us; however, these two synthetic compounds are each a mixture of the two racemic forms, [(+) and (−)], and the α and β epimers at C_{19}, whereas the naturally occurring 19-OHPGE prostaglandins are probably the (−)-racemate and the 19βOH epimer[12]. Preliminary evidence shows that synthetic 19-OHPGE$_1$ and 19-OHPGE$_2$ are about a quarter as active as PGE$_1$ and PGE$_2$ in relaxing spontaneously contracting non-pregnant human uterine muscle strips *in vitro*, whereas in contrast to PGE$_1$ and PGE$_2$, they have little or no action on rat uterine muscle *in vitro* (unpublished results of J. A. Russell, P. L. T. and R. W. K.). Since only a quarter of the synthetic material corresponds to the naturally occurring compound, it seems that the 19-OHPGEs are comparable in activity with the PGEs as far as the human uterus is concerned; moreover they are usually present in larger amounts.

Table 2 19-OHPGE concentrations in repeated ejaculates from a masturbating stump-tailed macaque (*M. arctoides*)

No.	Time	Weight of ejaculate collected* (g)	Combined concentration of 19-OHPGE$_1$ and 19-OHPGE$_2$ (μg g^{-1})
1	1100	1.71	461
2	NR	2.17	473
3	NR	0.93	439
4	NR	0.95	189
5	NR	1.07	426

7	1150	0.71	496
8	NR	0.79	383
9	1205	0.73	444
10	1215	0.94	341
11	1250	0.97	433
			Total 4.96 mg

* This is a minimal estimate of the total ejaculate produced since the animal invariably ate some of it before it could be removed from the floor of the cage.

NR, Not recorded.

In contrast to human semen, with its mixture of 19-OHPGEs and PGEs, the semen from the two species of macaque contains approximately 100 times more 19-OHPGEs than PGEs. This could go some way towards explaining the different spectrum of pharmacological activity that von Euler found between human and rhesus monkey seminal vesicles.

Our study certainly emphasises the widespread occurrence of these new 19-OHPGEs throughout the primates, and the high concentrations that are present. It remains to be seen whether their potent smooth muscle relaxing activity is a significant factor in sperm transport through the human female reproductive tract.

We thank Professor T. R. R. Mann and Drs H. M. Dott, C. Polge and W. R. Allen for semen samples from domestic and laboratory animals, Dr P. E. Lake for cock semen and the Royal Zoological Society of Scotland for chimpanzee semen.

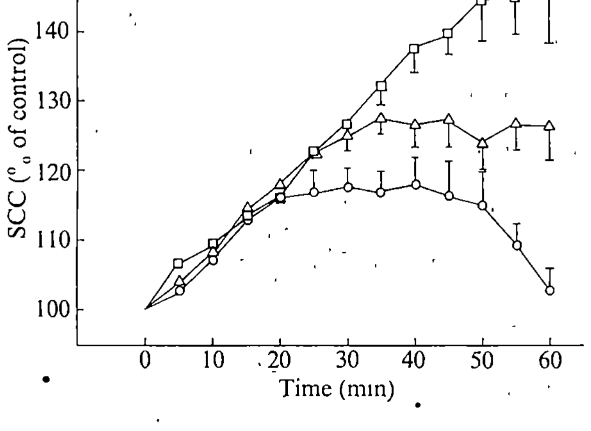
Insulin stimulates active sodium transport in toad bladder by two mechanisms

INSULIN has been shown to increase sodium and potassium fluxes in a series of tissues including muscle[1], and colon[2] and the isolated perfused kidney[3]. Attempts to define the exact mechanisms by which insulin stimulates ion transport in these tissues have been hindered by their anatomical complexity and heterogeneous cell populations. Tracer flux studies, using ^{22}Na, in frog muscle[1] and toad bladder[4] have suggested a direct stimulatory action of insulin on the sodium pump. Preincubation of intact frog muscle with insulin for 1 h has been shown to increase the amount of ouabain binding by this tissue suggesting that insulin unmasks latent sodium pumps in this structure[5]. The urinary bladder of the toad (*Bufo marinus*) has been shown to transport sodium actively from the urinary (mucosal) side to the blood (serosal) side and has been used extensively to study cation transport and the effects and mode of action of numerous hormones and drugs[6–8]. We have now examined the mechanisms by which insulin increases short circuit current (a measure of active sodium transport) in the toad bladder.

To define the effects of insulin on short circuit current (SCC), paired hemibladders were mounted in standard amphibian Ringer's in Ussing lucite chambers and the maximum SCC in response to increasing concentrations of the hormone was determined. Figure 1 shows the results of these experiments. The hormone was added to the serosal bathing media since insulin was without effect when added to the mucosal media. Concentrations of insulin greater than 50 mU ml^{-1} resulted in progressive increases in SCC. The peak response in SCC after addition of 100 mU ml^{-1} of insulin occurred at approximately 30 min and SCC returned to control values within an hour. Higher concentrations of insulin (250 and 500 mU ml^{-1}) resulted in persistently elevated SCC. An early increase in SCC was seen in the first 5 min after addition of insulin. This increase was similar but not identical to the rapid rise observed after vasopressin, a rise in Na transport which has been shown to be mediated by an increase in the cellular levels of cyclic AMP[9]. The prolonged stimulatory effect of higher concentrations of insulin on SCC was analogous to the response observed after addition of aldosterone, a phenomenon which has been shown to be dependent on protein synthesis[8,10].

Fig. 1 Effects of 100 (○), 250 (△) and 500 mU ml^{-1} (□) of insulin on short circuit current (SCC). Values are mean ± s.e. of 10 experiments.



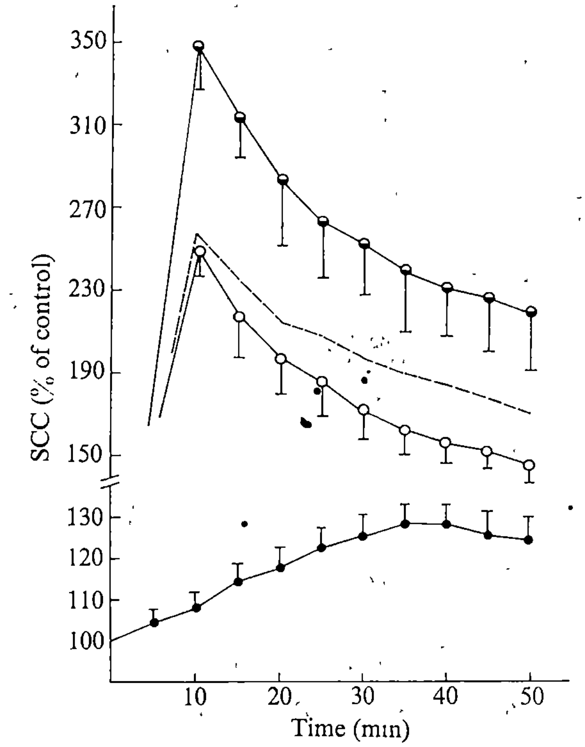


Fig. 2 Addition of 100 mU ml^{-1} of vasopressin alone (○), 250 mU ml^{-1} of insulin alone (●) or vasopressin and insulin (◒) on short circuit current. ———, Arithmetic sum of the effects of vasopressin and insulin when added alone. Values are the mean ± s.e. of 10 experiments.

We next explored the effects of addition of vasopressin and insulin alone and in combination on SCC. These results are shown in Fig. 2. Addition of vasopressin alone (100 mU ml^{-1}) resulted in a characteristic rapid increase in SCC which peaked at approximately 250% of control values. Addition of insulin alone increased SCC by approximately 30% about 35 min after addition of the hormone. When insulin and vasopressin were added simultaneously, at the same concentrations as when added alone, a marked enhanced synergistic response in SCC was observed with values rising to 340% of control. The simultaneous addition of insulin plus vasopressin thus produced an increase in SCC far exceeding the arithmetic sum of the responses observed when each hormone was added alone. In other experiments, a similar enhanced response in SCC was seen in bladders treated with insulin at time zero when vasopressin was added 40 min later. This synergistic effect was not observed, however, when the order of addition was reversed and vasopressin was added before insulin. These data suggest that insulin is capable of unmasking latent or reserve sodium pump sites not normally available to stimulation by vasopressin. An allosteric effect of membrane-bound insulin on active sodium pump sites could account for this phenomenon. An alternative explanation would require insulin to enhance or facilitate the formation of cyclic AMP in response to vasopressin, thereby acting as a modulator of vasopressin activity. To explore this possibility further, additional experiments were conducted and the results are shown in Table 1. The cyclic AMP content of scraped toad bladder cells incubated with diluent (control), insulin 250 mU ml^{-1}, vasopressin 100 mU ml^{-1} and insulin plus vasopressin were studied. Incubation time was 30 min for the experiments reported in column I. In column II the cells were preincubated with insulin for 1.5 h before adding vasopressin for the final 30 min. In neither case did insulin stimulate baseline cyclic AMP concentration nor did it increase cyclic AMP production in response to vasopressin. These data suggest that neither the early nor late stimulatory effect of insulin on SCC is mediated by cyclic AMP and that the enhanced response in SCC seen with the combination of insulin and vasopressin is not dependent on increased production of cyclic AMP. Addition of 0.5 mM cyclic AMP and insulin also resulted in a synergistic

Table 1 Cyclic AMP levels in isolated toad bladder cells

	I	II
	(pmol per mg protein)	
Control	34.3±3.0	22.2±3 4
Insulin (250 mU ml^{-1})	35.5±5.1	23.9±4.4
Vasopressin (100 mU ml^{-1})	72.3±7.2	46.8±4.7
Insulin and vasopressin	76 1±9.1	51.5±6.1

Values are mean ± s.e. of 8 experiments.

enhanced response in SCC which was greater than the arithmetic sum of the increase in SCC observed when insulin and cyclic AMP were added alone. These data support the hypothesis that insulin may act by unmasking latent pump sites or by increasing the sensitivity of existing pump sites to cyclic AMP. Insulin does not seem to modify the binding of vasopressin to receptor sites.

To explore the role of protein synthesis *de novo* in the stimulation of SCC produced by insulin, bladders were preincubated for 1 h in Ringer containing 20 μg ml^{-1} of actinomycin D, a potent inhibitor of messenger RNA (mRNA) synthesis. Figure 3 shows the changes in SCC observed after addition of insulin to bladders incubated for the preceding 60 min with or without actinomycin D. An identical increase in SCC was observed following addition of insulin in both control and actinomycin D-treated bladders in the first 30 min. After 40 min, however, the SCC of actinomycin D-treated bladders declined and reached baseline values by 70 min. The bladders not exposed to actinomycin D showed persistent stimulation of SCC for several hours after addition of insulin.

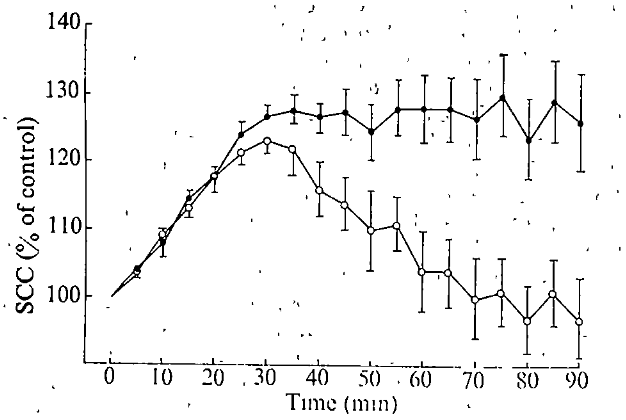

Fig. 3 Effects of addition of insulin at time 0 on the SCC of bladders incubated with (○) and without (●) actinomycin D for the preceding 60 min. Values are the mean ± s.e. of 10 experiments.

The SCC of bladders incubated with actinomycin D alone was no different from that of control bladders incubated without the drug. These data suggest that insulin stimulates active sodium transport (short circuit current) across the toad bladder by two different mechanisms. The rapid initial increase in SCC produced by insulin is unaffected by actinomycin D addition and thus does not seem to depend on protein synthesis. The rapidity of onset also speaks against the involvement of protein synthesis in this phenomenon. This initial phase of increase in SCC produced by insulin is synergistic with the effect of vasopressin, if vasopressin is added after insulin, and suggests that the initial rise in sodium transport produced by insulin may be due to unmasking of latent pump sites within the membrane. The prolonged stimulation of SCC by insulin is inhibited by preincubation of the bladders with actinomycin D. The time course of its appearance and the fact that the persistent elevation of SCC is abolished by an inhibitor of mRNA synthesis suggest that protein synthesis *de novo* is involved in this phenomenon.

It thus seems that insulin stimulates sodium transport in the toad bladder by two different mechanisms: (1) a rapid phase presumably representing "unmasking" of latent sodium pump sites within the membrane, and (2) a prolonged phase of increased sodium transport that requires synthesis *de novo* of protein. The nature and mode of action of this newly synthesised protein(s) on sodium transport are unknown and further studies will be required to elucidate its role.

Diminution of tumorigenesis initiated by 4-nitroquinoline-1-oxide by post-treatment with caffeine in mice

THE potent carcinogen 4-nitroquinoline-1-oxide (4NQO)[1] mimics ultraviolet effects[2,3]. Kondo[4] proposed an idea to test the mutation theory of cancer by comparison of 4NQO carcinogenesis in mice and 4NQO[3] or ultraviolet[5] mutagenesis in *Escherichia coli*. In parallel with 4NQO mutagenesis in *E. coli*[2,3,6], it was concluded that transformation initiated by 4NQO in cultured mouse cells is suppressed by holding in a non-DNA-replicating state[7], due to elimination of 4NQO–purine adducts[8] from DNA by an error-free excision repair[9]. There is another type of repair which works after DNA replication and is assumed to be error prone[5]. Again, in parallel with ultraviolet mutagenesis in *E. coli*[10], Kakunaga[7] has found that transformation of mouse cells by 4NQO is reduced greatly by post-treatment with caffeine. Zajdela and Latarjet[11] reported that ultraviolet-inducible skin cancer in mice is suppressed by the presence of caffeine. The present paper reports that post-treatment with caffeine diminishes 4NQO-initiated lung tumorigenesis in mice.

Young (21-d-old) ICR/Jcl mice (9–11 g), 339 males and 285 females were used (Japan Central Laboratory for Experimental Animals). 4NQO (provided by the late Dr K. Mori, Showa Medical School, Tokyo) was dissolved in propylene glycol and caffeine (Nakarai Chemical Co.) in water. Both chemicals were injected subcutaneously; 4NQO in the right flank of animals with a single dose (12.5 μg per g body weight) and caffeine in the left flank with five doses (100 μg per g body weight for each) at intervals of 6–12 h (Fig. 1). These doses of 4NQO and caffeine are the maximum tolerated doses to young ICR/Jcl mice. As described in Fig. 1, animals were divided into five groups. Groups 1 and 2 received caffeine during the 0–36 h and the 120–156 h after 4NQO treatment, respectively, but group 3 received caffeine during the 12–48 h before 4NQO treatment. Group 4 received an equal volume of water, instead of caffeine solution, during the 0–36 h after 4NQO treatment. Solvent control, group 5, received an equal volume of propylene

*χ^2 test and t test were applied for groups 1–3 against group 4. t test was applied with the Cochran–Cox approximation, if variance ratio was more than F value at 1%. NS, Not significant.

†All 4NQO-treated groups (groups 1–4) developed lung tumours with significantly higher incidence and frequency than solvent control (group 5), ($P < 0.01$) Spontaneous tumour incidence and frequency at week 25 were 2/315 (0.6%) and 0.006±0.005, respectively.

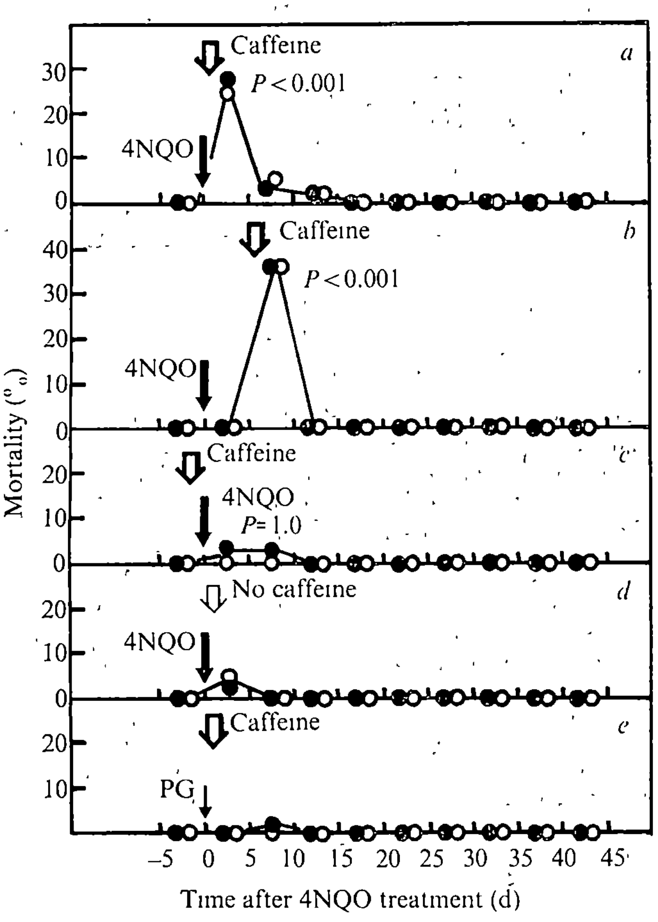

Fig. 1 Enhancement of mortality in 4NQO-treated mice by post-treatment with caffeine Percentage of dead mice (●, male; ○, female) is plotted against days after 4NQO treatment. Lethality of 4NQO-treated mice confined to 2–5 d after caffeine treatment, primarily due to intestinal death Numbers of mice used are given in Table 1 χ^2 test was applied with Yates' correction for groups 1–3 against group 4. *a*, Group 1: five subcutaneous injections of caffeine (100 μg per g body weight for each) were given to young mice 0, 6, 12, 24, and 36 h after a single injection of 4NQO at a dose of 12.5 μg per g body weight ($P < 0.001$) *b*, Group 2: five doses of caffeine were given 120, 126, 132, 144, and 156 h after 4NQO treatment ($P < 0.001$). *c*, Group 3: five doses of caffeine were given 12, 24, 36, 42, and 48 h before 4NQO treatment ($P \neq 1.0$). *d*, Group 4: an equal volume of water, instead of caffeine solution, was given after 4NQO on the same time schedule as in *a*. *e*, Group 5: propylene glycol (PG), instead of 4NQO solution, was given, and then followed by five doses of caffeine on the same time schedule as in *a*.

glycol, instead of 4NQO solution, and caffeine during the following 0–36 h. The mice were maintained on mouse diet CA-1 (CLEA)[12], and killed at week 20 after 4NQO treatment to examine lung tumours as described previously[12,13]. Most lung tumours were papillary adenomas[12,14]. Lung tumour frequencies, defined as average numbers of tumour nodules per lung, were compared statistically among the experimental groups, since the frequency thus defined increased with doses of carcinogens, even in the high dose range where the increase in the tumour incidence defined as fraction of tumour-bearing mice in survivors levelled off[12,14].

Table 1 summarises the results. It will be clear from comparison of groups 1 and 2 with group 4 that in females post-treatment with caffeine during either the early (0–36 h) or late (120–156 h) post-4NQO period suppressed tumour frequency by 60–70%, and that in males caffeine administered during the 120–156 h after 4NQO treatment significantly suppressed the tumour frequency. The tumour frequency in males post-treated with caffeine during the 0–36 h after 4NQO treatment (group 1) was also lower, but not significantly lower, than that of males treated with 4NQO alone (group 4). This will, however, not invalidate the conclusion that caffeine post-treatment suppresses 4NQO-initiated lung tumorigenesis, because the less suppressive effect of caffeine during the 0–36-h period compared with the 120–156-h post-4NQO period was also the case with females (Table 1). Furthermore, it is the rule deduced from 14 sets of our previous experiments with 50–60 young ICR/Jcl mice each, that lung tumour yields are always lower in males than in females after treatment with 4NQO, but not with other carcinogens[12]. Caffeine administered during the 12–48 h before 4NQO treatment gave no statistically significant effects on the 4NQO-induced tumour frequencies in both males and females (groups 3 and 4, Table 1). In parallel with the case of cultured mouse cells[7], post-treatment with caffeine during either the 0–36 h or the 120–156 h after 4NQO treatment, but not pre-treatment, increased mortality in 4NQO-treated mice to about 30% compared with negligible mortality in mice treated with 4NQO alone (Fig. 1). These support the misrepair model[4] in that caffeine suppresses the repairing action of error-prone post-replication repair on tumorigenic and lethal damage produced in daughter DNA by 4NQO damage on template DNA, resulting in decrease of survivors and induced tumours. The lethal and tumorigenic damage in mice is sensitive to caffeine as late as 120 h after 4NQO treatment (Table 1 and Fig. 1), but cultured cells become insensitive to caffeine as early as 48 h after 4NQO treatment[7]. This difference may simply reflect the fact that a considerable fraction of DNA, bearing 4NQO damage, in the stem cells of the lung remains unreplicated for several days, whereas almost all the cultured cells in the growing state go through the phase of DNA replication in about one day after 4NQO treatment. Thus I propose that not only 4NQO-induced pretransformational damage in cultured mouse cells but also 4NQO-induced pretumorigenic damage in mice may be fixed during the first post-4NQO DNA replication period, the fixation being similarly suppressed by caffeine in mice as well as in their cultured mouse cells. It has been reported[15,16] that actinomycin D inhibits skin tumour formation initiated by 7,12-dimethylbenz(*a*)anthracene or β propiolactone when given 0 to 14 d later, provided that actinomycin D is present, which probably works as inhibitor for normal DNA synthesis, during the first post-carcinogen DNA replication. Caffeine is known to slow down greatly the post-replication processes and to inhibit specifically post-replication repair in cultured mouse cells after treatment with ultraviolet[17] or 4NQO (M. Morita and M. Tada, personal communication).

I carried out this work as a member of a cooperative cancer research team headed by Dr S. Kondo with a grant from the Japanese Ministry of Education, Science and Culture.

Inhibition of RNA polymerase as a possible anti-leukaemic action of cytosine arabinoside

Cytosine arabinoside (ara-C, 1-β-D-arabinosylcytosine) has marked anti-tumour and anti-viral activities[1,2], and is currently one of the most successful drugs used to induce remissions in acute granulocytic leukaemia[3]. Its cytotoxic activity is ascribed to its effect of inhibiting DNA polymerase after being phosphorylated intracellularly to its triphosphate derivative (ara-CTP)[4]. Studies with murine leukaemic cells[5] and mouse L cell line have indicated[6], however, that acute cell death induced by ara-C does not completely correlate with the inhibition of DNA synthesis: (1) DNA polymerase activity was rapidly restored after ara-C was removed, whereas cells were still non-viable; (2) the amount of ara-C incorporation into DNA did not correlate with the degree of cell lethality. We have shown previously[7] that ara-CTP could inhibit RNA polymerase II activity from chicken leukaemic cells when the enzyme was purified. This report describes results of our kinetic studies characterising the nature of this inhibition.

Chicken leukaemic RNA polymerase IIa, obtained from glycerol-gradient centrifugation as described previously, was used for the present studies. The effect of ara-CTP on the kinetics of incorporation of CTP into RNA was determined

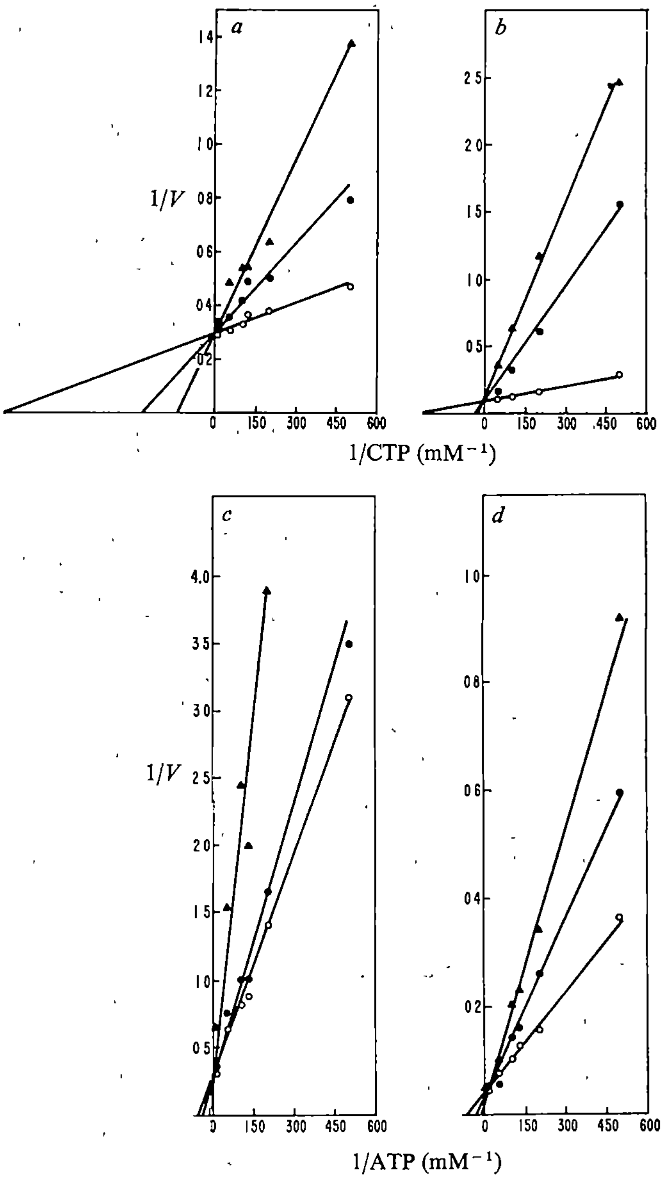

Fig. 1 Effect of ara-CTP and ara-ATP on the kinetics of RNA synthesis (Lineweaver–Burk plot). The reaction mixture (0 1 ml) for chicken leukaemic enzyme (*a* and *c*) contained 50 mM (*p*H 7.9) Tris-HCl, 2 μg pyruvate kinase, 4 mM phosphoenol pyruvate, 1 mM MnCl$_2$, 10 mM KCl, 1 mM dithiothreitol, 40 μg denatured chicken blood DNA (Calbiochem), 2 μg RNA polymerase, and four normal ribonucleoside triphosphates, with or without the addition of drug. The reaction mixture for *E. coli* enzyme (*b* and *d*) was similar to that described above except that it contained RNA polymerase (*b*, 0.25 U; *d*, 0.5 U; fraction IV, Grand Island Biological), 4 mM MgCl$_2$, 1 mM MnCl$_2$, 5 mM dithiothreitol and 40 μg native *E. coli* B DNA (Sigma). The four normal ribonucleoside triphosphates used were 0.2 mM GTP, 0.04 mM UTP and ^{3}H-UTP (1,000 c.p.m. pmol^{-1}); and 0.2 mM ATP and varied CTP concentration (*a* and *b*); 0.2 mM CTP and varied ATP concentration (*c* and *d*). Incubation was at 37 °C for 15 min. The reaction was terminated and the RNA precipitated, filtered and counted as described previously[7]. 1/*v* shown on the ordinates is the reciprocal of pmol UMP incorporated into RNA per 0.1-ml reaction mixture per 15 min. Symbols: *a* (K_i for ara-CTP = 14.9 μM): ▲, 0.1 mM ara-CTP; ●, 0.03 mM ara-CTP; *b* (K_i for ara-CTP = 10.2 μM): ▲, ●, as *a*; *c* (K_i for ara-ATP = 150 μM): ▲, 0.3 mM ara-ATP; ●, 0.1 mM ara-ATP; *d* (K_i for ara-ATP = 77.5 μM): ▲, ●, as *c*. ○, No drug added.

Table 1 Effects of arabinosyl nucleotides on RNA synthesis by chicken leukaemic RNA polymerase II

Added nucleotide	Control	ara-AMP	ara-ADP	ara-ATP	ara-CMP	ara-CDP	ara-CTP	ara-UTP
UMP incorpoated (pmol ml^{-1})	27.5	30.5	22.0	1.60	30.4	26.6	1.70	29.4
% control	100	110	80	5.9	110	96	6.3	106

Chicken leukaemic RNA polymerase II (20 μg ml^{-1}) was assayed in the presence of 1 mM arabinosyl nucleotide as indicated. The assay conditions were similar to those described in Fig. 1, except that all four normal ribonucleoside triphosphates used were 0.04 mM, and that the incubation (0.2 ml) was for 45 min. The arabinose nucleotides were obtained from Terra-Marine Bioresearch, La Jolla, California.

and the results are presented in Fig. 1*a*, using the graphical representation of Lineweaver and Burk[4]. Ara-CTP is a competitive inhibitor for the binding of CTP to RNA polymerase II; K_m (the Michaelis constant) is increased in the presence of the drug without change in V_{max} (the maximum velocity of the reaction). The K_m for CTP and the K_i (enzyme inhibitor dissociation constant) value for ara-CTP inhibition were estimated from 6 determinations to be 1.4±0.5 μM and 14.9±3.0 μM, respectively, for the leukaemic enzyme. A similar study was carried out on *Escherichia coli* RNA polymerase and it was shown that the enzyme was also inhibited by ara-CTP with a K_m (CTP) of 4.2±0.2 μM and a K_i (ara-CTP; from seven determinations) of 10.2±2.7 μM (Fig. 1*b*).

The reported K_i values for ara-CTP inhibition of DNA polymerase (replication enzyme) were 1 μM for calf thymus[4], 8.7±5.2 μM for mouse L cells[6], 18.4±7.9 μM for mouse lymphoma cells[8]. The K_i value reported for Rauscher leukaemia virus reverse transcriptase was 30 μM (ref. 9), and for DNA repair enzyme of isolated hepatocyte nuclei, 500 μM (ref. 10). Our studies with RNA polymerase showed that the K_i value for ara-CTP inhibition for chicken leukaemia enzyme fell in the same range of K_i values for the DNA replication enzyme in mouse L cells and mouse lymphoma cells, and that it was certainly smaller than the values reported for reverse transcriptase and DNA repair enzyme. It indicates comparable affinities of ara-C for the RNA polymerase and the DNA replication enzyme. Because of the competitive nature of this inhibition, the relatively high I_{50} value reported previously[7], could be explained by the high CTP concentration used in the assay system. It would seem that the degree of inhibition by ara-C of cellular DNA compared with RNA synthesis will depend on the physiological (local) concentrations of dCTP and CTP, the concentration of ara-C used, and their individual K_m values. It has been suggested[10,11] that inhibition of replicative DNA synthesis by ara-C could not kill cells and that to achieve cell killing ara-C must be given at a dose high enough to impair DNA repair function. At such a high ara-C dosage, however, inhibition of RNA synthesis has undoubtedly occurred.

The anti-tumour and anti-viral activities of adenine arabinoside (ara-A) have long been recognised[12,13], although data on clinical trials of this compound are scanty. The compound was suggested to have no effect on RNA polymerase activity[14,15], and the inhibition by ara-A of DNA polymerase was shown to be selective[13]. We tested the effects of ara-A on the purified RNA polymerase and found that it inhibited the enzymes by competing with the normal nucleotide ATP. The mean K_m (ATP) and K_i (ara-ATP) values were 17.2 and 150 μM, respectively, for chicken leukaemic enzyme, and were 14.2 and 77.5 μM, respectively, for *E. coli* enzyme (Fig. 1*c* and *d*). These K_i values are in the same range as those reported for ara-A inhibition of DNA polymerase[12].

It is well known that ara-C is rapidly deaminated to uracil arabinoside (ara-U) *in vivo*, and that the latter compound has no pharmacological value[16]. The negative effect of ara-U on tumour cells prompted us to study the effect of ara-UTP on chicken leukaemic RNA polymerase. The results are presented in Table 1. Ara-UTP did not inhibit the RNA polymerase activity, suggesting that the amino group of cytosine or adenine base may be essential for the inhibition. Further studies showed that the inhibition of RNA polymerase activity by ara-C or ara-A was at the triphosphate level of the drugs. Neither mono- nor diphosphates produced the inhibitory effect (Table 1). These findings are in accord with *in vivo* observations[11] that cellular levels of ara-CTP, but not those of the mono- and diphosphates of ara-C, are the determinants of chemotherapeutic efficacy of ara-C against leukaemia. These, together with the ara-U studies, suggest the possibility of considering RNA polymerase inhibition as the target for ara-C action.

This study has described the inhibitory activity of ara-C (or ara-A) on RNA polymerases. Since RNA polymerase II has been suggested as being responsible for messenger RNA synthesis[17], the inhibition of RNA polymerase II by ara-C may result in the decreased 2–7S RNA synthesis[18] and subsequently in an irreversible cell death, as observed previously[5,6,18]. Since ara-CTP has apparent affinity for RNA transcription comparable for DNA replication, inhibition of RNA synthesis must be considered before the mechanisms of this drug can be understood completely.

Similarities in the helical sequences of the repressor-binding sites in the *lac* and λ operators

SEVERAL reports have considered the repressor binding sites in the *lac*[1–3] and λ[4–6] operators. The analysis of these regions has focused on features apparent in the linear sequences such as regions of twofold rotational symmetry, and the 17-base-pair sequence which is largely conserved in the rightward and leftward repressor-binding sites of λ[6]. As these sequences are thought to be wound in the double helical form when they are recognised by repressor[7,8], I have investigated whether any further interesting features could be revealed by such an arrangement.

There are many possible ways of "casting" a sequence on a

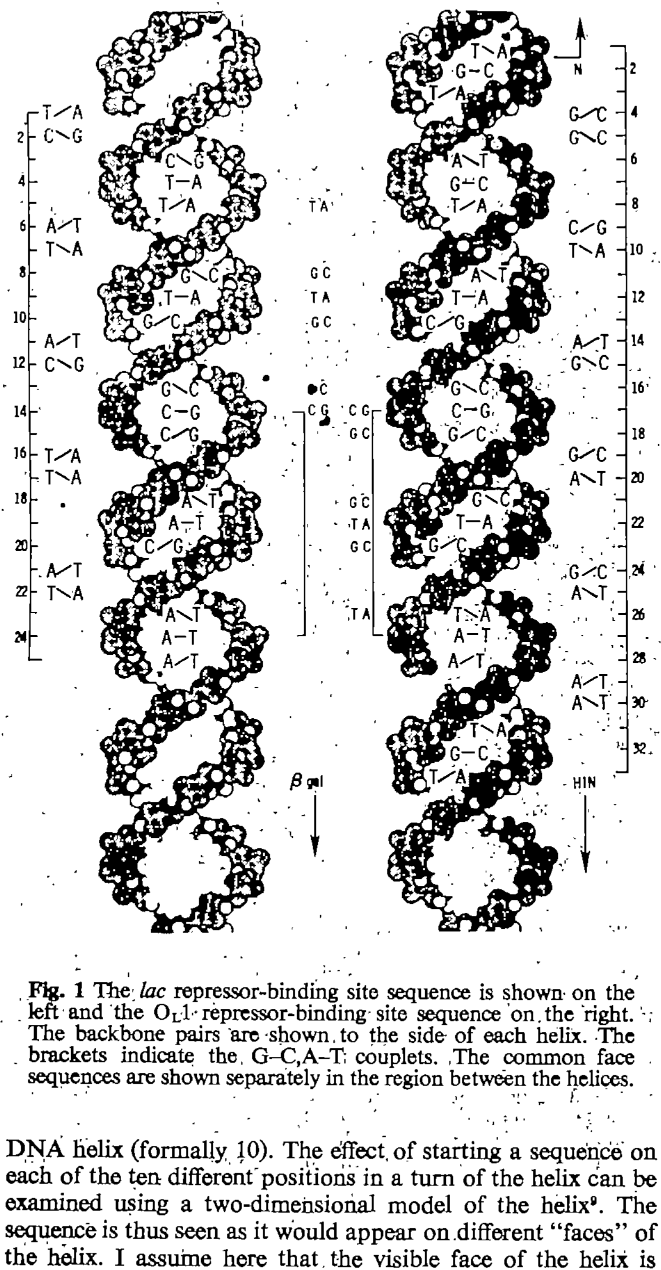

Fig. 1 The *lac* repressor-binding site sequence is shown on the left and the O_L1 repressor-binding site sequence on the right. The backbone pairs are shown to the side of each helix. The brackets indicate the G–C,A–T couplets. The common face sequences are shown separately in the region between the helices.

DNA helix (formally 10). The effect of starting a sequence on each of the ten different positions in a turn of the helix can be examined using a two-dimensional model of the helix[9]. The sequence is thus seen as it would appear on different "faces" of the helix. I assume here that the visible face of the helix is composed of the three base pairs centred in each groove. The two base pairs aligned most nearly parallel to the line of view at each half turn are assumed to be hidden behind the backbone and therefore not seen on the forward face. Thus a "face sequence" is the sequence presented by the base pairs visible in the grooves with the backbone pairs omitted. Therefore, the sequence one sees on a particular face is composed of the three base pairs in the centre of, say, a wide groove, then the three pairs in a narrow groove, then the three in a wide groove, and so on; the two base pairs between grooves are masked and not seen. For the purpose of looking for symmetries, no distinction is made here between wide and narrow grooves, so half the possible castings become equivalent.

When this procedure was applied to the binding sites of *lac*[1] and λ O_L1 (ref. 4), the result was unexpected. There was for each sequence, one "casting" which established two types of homologous features shared by the two repressor-binding sequences on one particular face of the helix (Fig. 1). These are: (1) a face sequence in each comprised of the same six "visible" base pairs with only the 5′–3′ orientation reversed, and (2) a feature which, for lack of an established terminology, will here be called a G–C,A–T couplet; this is defined simply as a succession of three G–C base pairs preceded or followed, at a separation of seven base pairs, by a succession of three A–T base pairs, with the result that one wide groove filled by G–C pairs would have an adjacent wide groove filled by A–T pairs in the helix.

As Fig. 1 shows, the 'upper' half of the *lac* sequence (positions 5–14), excluding backbone positions, is a perfect reflection of the lower part of the λ sequence (positions 17–26). As discussed below, this sequence is largely conserved in the O_R1 (ref. 5) and O_L2 (ref. 6) binding sites in that it forms part of the sequence which Maniatis *et al.* have noted to be repeated in the rightward and leftward λ repressor recognition sites. Considering *lac* and O_L1 sequences alone, the random odds of such a match symmetrically located with respect to the centre of the sequences are less than 1 in 1,000. (The probability of a random match in a sequence of size six is $\sim(1/4)^6$ since the G–C content in *E. coli* and λ DNA is 51%. There are four chances for a match in the 4 halves of the two sequences. The probability of one or more such matches is then $1-P(0)$ or $1-[1-(1/4)^6]^4 = 0.00097$.)

The second homologous feature shared by the *lac* and O_L1 sequences as presented in Fig. 1 is what I have termed a G–C, A–T couplet in each sequence. The central wide groove contains only G–C pairs and the next lower wide groove contains only A–T pairs. The random odds of such matching couplets are $\sim 2(1/64)^2$ or 1 in 2,000. This feature, as noted below, also appears in O_L2, O_R1, O_R2 and O_R3. Alignment of the *lac* and O_L1 sequences, so that this feature is seen in the forward face, defines a helix face with considerable symmetry. For example, the symmetry of the *lac* sequence is still present in this representation. Most of the symmetry properties discussed here are limited to positions 4 to 24, noted by Gilbert and Maxam[1] to show substantial rotational symmetry about position 14 when viewed in the linear form. The two asymmetries previously observed in this rotation are split between the face sequence ($10\nrightarrow18$) and the backbone sequence ($12\nrightarrow16$); otherwise both face and backbone sequences still show rotational symmetry about position 14. It is interesting that the "correction" of the $12\nrightarrow16$ asymmetry is a known constitutive mutation, and a correction of the $10\nrightarrow18$ asymmetry would cause a recurrence in the lower half of the *lac* sequence of the common sequence shared by *lac* and O_L1. On the other hand, the symmetry seen in this view of the O_L1 sequence was not suggested by Maniatis *et al.*[4] but is clearly revealed by this format. In contrast to the *lac* sequence, the symmetry character of the O_L1 sequence when viewed on this face of the helix is not a rotation but a reflection, in the face sequence, with seven of the ten face pairs reflected across the centre. This symmetry extends beyond the homologous regions picked out by Maniatis *et al.*[6]. The backbone sequence shows neither type of symmetry.

It is intriguing that this feature, the G–C,A–T couplet, appears in several other control sequences. The phage fd RNA polymerase binding site[10] has such a couplet at its centre. The CAP sequence starts with two such couplets[2]. One face in the promoter sequence of the *tyr* tRNA gene[11] shows three such couplets out of a possible four for that sequence size; in this case, however, it is a different face of the helix which shows perfect rotational symmetry centred on the rotational axis noted by Sekiya and Khorana[11] (here all asymmetries in the sequence fall on the backbone positions). The sequence for the attenuator region of the tryptophan operon[12] contains a successive series of six such G–C,A–T couplets in a row. This guarantees one such couplet on every face of the helix in the attenuator region.

In Fig. 2, the sequences of the O_L2, O_R1, O_R2, and O_R3 binding sites[5,6] have been aligned such that the G–C,A–T couplet is seen in each. The same alignment shows most of the *lac*–O_L1 common sequence appearing in O_L2 and O_R1; the one change is that T–A at position 22 in O_L1 becomes A–T in O_L2 and O_R1. This is the only change between O_L1 and O_R1 which falls within the recurring symmetrical 17-base-pair regions described by Maniatis *et al.*[6] and is viewed by them as the probable cause of the weaker binding observed with O_R1.

The fact that the G–C,A–T couplet appeared in all these sequences and in several cases was associated with a recurring sequence suggested a search of the only other sequence known

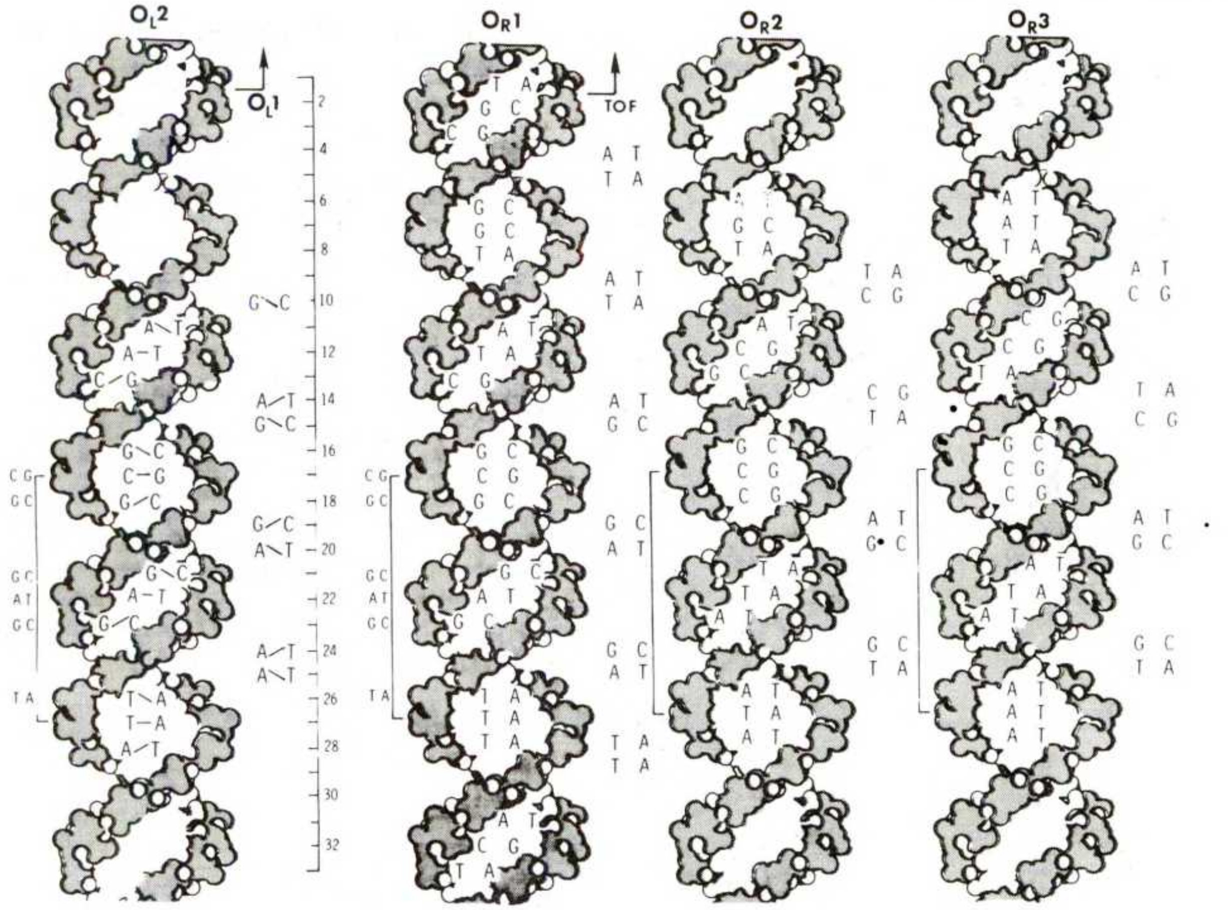

Fig. 2 The helices from left to right represent the repressor-binding sequences of O_L2, O_R1, O_R2 and O_R3, respectively. The common face sequence shared by O_L1, O_L2, O_R1 and the *lac* repressor sequence is shown to the left of the O_L2 helix. The corresponding sequence in O_R1 is shown to the left of the O_R1 helix. The two base pairs hidden by the backbone on each turn are shown to the right of the respective helices. The brackets indicate the G–C,A–T couplet feature in each helical sequence. The dashed A–T at the top of the O_R2 sequence is the same pair shown at the bottom of the O_R1 sequence; the top pair in the O_R3 sequence is the next pair following the pair shown at the bottom of the O_R2 sequence. The sequences shown for O_R1 and O_R3 are on the same face of the helix, when viewed as a continuum; whereas the sequence shown for O_R2 is on a face rotated 108° relative to that shown for O_R1 and O_R3.

to contain a repressor binding site, the 'leader region' of the tryptophan operon[12]. As noted above, the attenuator region is rich in G–C,A–T couplets; there are four additional couplets preceding the attenuator region, the first appearing 13 bases from the starting point of transcription. But only the second G–C,A–T couplet in the attenuator region is preceded by a sequence similar to that seen in the *lac* and λ repressor-binding regions (Fig. 3). The recurring face sequence seen in these five cases is

$$\begin{array}{l} \quad\binom{T}{A}\quad\ \binom{A}{T}\quad\ \binom{G}{G} \\ \mathrm{AA--CTC--GG} \\ \mathrm{TT--GAG--GC} \end{array}$$

The 5′–3′ orientation of the sequence is the same in *trp* and *lac* with the reverse orientation seen in the three λ sites.

The chance occurrence of the juxtaposition of a G–C,A–T couplet with a very similar sequence in all these cases is very low. Neither feature nor the combination of the two, however, provides the symmetry one would expect for recognition by dimeric or tetrameric repressor molecules. The 17-base-pair groups with strong rotational symmetry, observed in the analysis of Maniatis *et al.*[6], almost certainly serve this function. These are shown, in helical form, in Fig. 4. The faces shown here are rotated 36° relative to those shown in Figs 1 and 2 for O_L1, O_L2, and O_R1, 72° for O_R2 and O_R3. Thus the sequence similarities discussed above are seen on the face of the helix which is adjacent to the face in which a rotationally symmetrical group is seen in O_L1, O_L2 and O_R1. The symmetry groups themselves do not fall on a single face of the helix in either the rightward or leftward λ sites, for example, the face shown in

Fig. 3 Partial sequences from the *trp* attenuator region and the repressor binding sites of *lac*, O_L1, O_L2 and O_R1 have been aligned by the position of their G–C,A–T couplets. The base pairs in bold letters represent the "common" sequence; those pairs in light letters are not part of this sequence but are part of the G–C,A–T couplets.

TRP	LAC	O_L1	O_L2	O_R1

Fig. 4 for O_L2 lies at 144° relative to that shown for O_L1.

If the repressor-binding function is conceded to the rotationally symmetrical groups, what function can be suggested for the two recurrent features observed in this analysis? Furthermore, what mechanism would give rise to a sequence, shared, but with reversed 5′–3′ orientation in different cases? A case can be made that the G–C,A–T couplet may be part of a recognition sequence for RNA polymerase. From its appearances in known control sequences, it seems that it may be involved in both promoter and terminator sequences. Though the probability of a G–C,A–T couplet occurring somewhere in a given promoter sequence is high (probability of one or more couplets for a sequence of size *n* is $1-(31/32)^{n-13}$ or 0.42 for an *n* of 30), the probability of finding it in 11 such sequences, often several times over, drops well below 1 in 100,000. It is true that this feature does not always show the same position relative to the starting point of transcription, but the relationship of the initial binding point to the starting point is unclear at this time[6,13,14]. With regard to the terminator regions, the attenuator-terminated *trp* mRNA ends precisely with the last of the G–C,A–T couplets in the attenuator region[12]. A possible terminator region for the *tyr* tRNA sequence reads CCATC – – TTT – – – – – – – CCC on the 5′ → 3′ strand[15]. Here, as in O_L1 and O_R1, ATC appears in the groove preceding a G–C,A–T couplet but the order of the A–T triplet and the G–C triplet is reversed.

How does the "common" sequence fit in? This sequence is juxtaposed with the G–C,A–T couplet only in repressor-binding regions (the claim of the *trp* attenuator region here is tenuous, however) and not in the promoters. The homologous sequence observed by Pribnow[16] in six promoters appears in position 7 to 13 of O_L1 in Fig. 1, not in the common region. It is difficult to see why there should be this sequence appearing with the same 5′ → 3′ orientation in *trp* and *lac* and with the opposite orientation in O_L1, O_L2, and O_R1. Another puzzling observation, the reflection symmetry seen on the O_L1 face in Fig. 1, may hint at an explanation. This symmetry, though definitely non-random (random odds ~7/100,000), would seem of little use to a repressor dimer. If the reflection symmetry of O_L1 were perfect, however, one would have a sequence containing the "common" sequence of the *lac* and *trp* orientation in the upper half and the "common" sequence of the O_L1, O_L2, and O_R1 orientation in the lower half and a G–C,A–T couplet in each direction. Divergence from a common precursor sequence of this type could produce the shared features observed here and might be related to those homologies observed by Pribnow as well. If this evolutionary hypothesis is correct and similarly obtains in eukaryotes, it could provide the molecular basis of an integrator gene[16].

Consider the implications of this hypothesis for the *lac* and λ sequences. In *lac* it looks as though the common sequence is the recognition sequence for repressor; here the sequence has been duplicated in the lower half of the site (in place of the original reflected sequence?); in the λ sites it still forms parts of the basis of the recognition site but with a shift in reading frame to an adjacent face of the helix, preventing heterologous interactions. This view suggests that homologies would exist, as well, in the "dissimilar" halves of *lac* and O_L1. If the upper half of the O_L1 sequence is compared with the lower half of the *lac* sequence after the latter has been rotated 180°, one observes the rather remarkable pattern that there is a perfect match at every other position in the two sequences, that is, *lac* position 23 = O_L1 position 8, *lac* position 21 = O_L1 position 10, and so on.

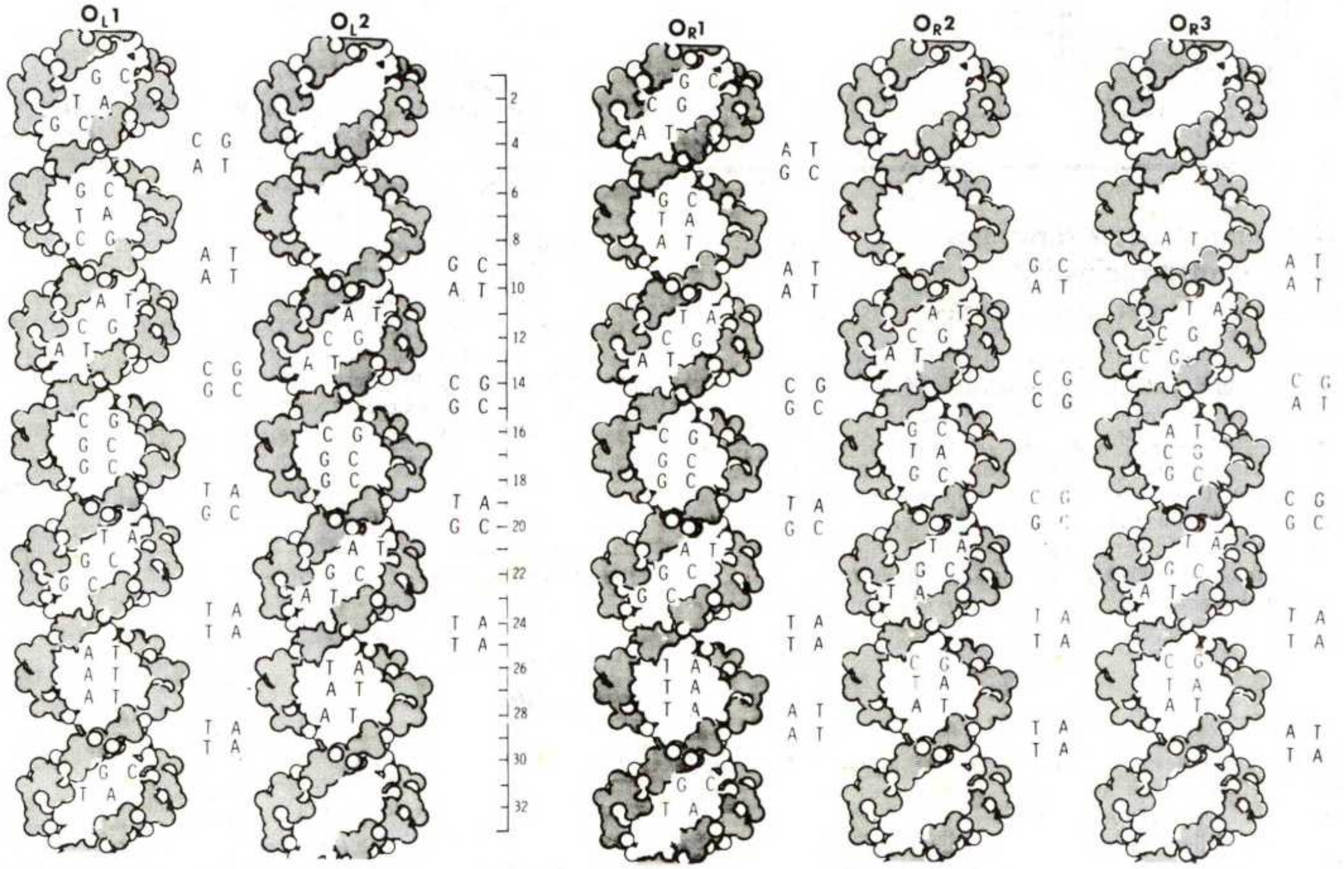

Fig. 4 In this view of the repressor-binding sequences of O_L1, O_L2, O_R1, O_R2 and O_R3, the rotational axis observed by Maniatis *et al.* has been located in the centre of the central wide groove in each case. The face shown here for O_L2 lies at a viewing angle of 144° relative to the face shown for O_L1. The face shown for O_R2 lies at a viewing angle of 144° relative to the face shown for O_R1; that for O_R3 lies at 252° relative to O_R1, 108° relative to O_R2. O_L3 (not shown) lies on the same face as O_L2. The sequences shown are contiguous; for example, the first base pair of O_L2 follows the last shown for O_L1. The rotationally symmetric 17-base-pair groups of Maniatis *et al.* lie in positions 9 to 25. The O_L1, O_L2 and O_R1 sequences have been moved upwards one position relative to Figs 1 and 2, whereas O_R2 and O_R3 have been shifted downwards two positions.

In conclusion, I suggest that synthetic DNA probes of the sequence

$$\begin{array}{lcccccc}
 & (\mathrm{C}) & (\mathrm{C}) & (\mathrm{C}) & (\mathrm{T}) & (\mathrm{T}) & (\mathrm{T}) \\
\mathrm{C\,G\,G\,T\,C\,A\,C\,C\,A\,T} & \mathrm{G} & \mathrm{G} & \mathrm{G} & \mathrm{A} & \mathrm{A} & \mathrm{A} \\
\qquad\qquad\text{and} & & & \text{- - -} & \text{- - -} & & \\
\mathrm{G\,C\,C\,A\,G\,T\,G\,G\,T\,A} & \mathrm{C} & \mathrm{C} & \mathrm{C} & \mathrm{T} & \mathrm{T} & \mathrm{T} \\
 & (\mathrm{G}) & (\mathrm{G}) & (\mathrm{G}) & (\mathrm{A}) & (\mathrm{A}) & (\mathrm{A})
\end{array}$$

in both 5′, 3′ permutations may prove very useful, in addition to that proposed by Maniatis *et al.*[6], in the investigation of promoters, terminators and repressor-binding sites.

Detection of slow rotational motions of proteins by steady-state phosphorescence anisotropy

WE have used the anisotropy of the phosphorescence from intrinsic chromophores of proteins to detect slow rotational motions of the macromolecules in highly viscous solutions. This method has potential for monitoring the mobility of proteins in structures such as membranes and viruses.

Rotational motions of the emitting molecules in a solution result in the depolarisation or loss in anisotropy of the emission. The quantitative relationship between the emission anisotropy observed in conditions of constant illumination and the rotational time is embodied in the Perrin equation[1]

$$\frac{1}{A} = \frac{1}{A_0}\left(1+\frac{\tau}{\theta}\right) \tag{1}$$

When the rotational correlation time θ is equal to the excited state lifetime τ, the anisotropy A decreases to half A_0 the anisotropy for a stationary emitter.

Weber applied emission polarisation[2] to the study of protein hydrodynamics using fluorescent labelled protein molecules. Fluorescence polarisation is widely used in probing the rotational mobility of proteins and the flexibility of their active sites in steady-state experiments[3] and in nanosecond techniques[4-6]. Introduction of a fluorescent label is usually required in that the lifetimes of the intrinsic fluorescence from tryptophan and tyrosine residues are much shorter than the rotational correlation times of most proteins. Rotational correlation times as long as 500 ns have been measured by the use of fluorescence probes with 100–200-ns excited singlet lifetimes[7]. Rotational motions which are much slower than the fluorescence lifetime, however, are difficult to detect.

For access to slower rotational motions a long lived emission is necessary. Whereas long lived phosphorescence is usually quenched in fluid solutions, we have shown that buried tryptophan residues in proteins which are protected from quenching by solvent-mediated processes, phosphoresce in fluid solutions with lifetimes in the millisecond range[8]. As a consequence, rotational motions occurring on this time scale and shorter become amenable to experimental detection. We report here a preliminary study on the use of steady-state phosphorescence anisotropy measurements to monitor rotational motions of proteins.

The tryptophan residues in proteins were excited at 300 nm from a mercury lamp. Phosphorescence was measured on the 0–0 vibronic transition of tryptophan ($\lambda = 410$–415 nm) which has the largest emission anisotropy[9,10]. Measurements were obtained with a phosphoroscope described elsewhere[11], in which both the exciting and emission beams were polarised with Polaroid HNPs linear polarisers. Anisotropy A was calculated from the relationship

$$A = \frac{I_{11} - GI_1}{I_{11} + 2GI_1} \tag{2}$$

where I_{11} and I_1 are the emission intensities polarised parallel and perpendicular respectively to the vertically polarised exciting beam, and G is an instrumental correction factor[12]. The values of A_0 reported are the largest values of A obtained at temperatures where the glass had softened somewhat eliminating strains and cracks, but molecular rotational motions were still insignificant.

The anisotropy of the tryptophan phosphorescence for several proteins and for indole in glycol–H_2O were determined. The values for the anistropy of the 0–0 transition at temperatures below 120 K appear in Table 1. At these temperatures, near the glass transition temperatures of the solvents, molecular rotational times are longer than the 5–6-s tryptophan-triplet lifetime. These values of A_0 therefore, depend only on the electronic properties of the isolated chromophores and the extent of electronic coupling, or energy transfer, between chromophores. The connection between these limiting anisotropies and energy transfer between tryptophan residues in proteins in relation to earlier studies[9], and to observations of heterogeneity in protein phosphorescence spectra[13], will be considered elsewhere.

The rotational correlation time for spherical particles was

Table 1 Limiting phosphorescence anisotropy values A_0 and $T_{\frac{1}{2}}$-values of some proteins in 1:1 propylene glycol–buffer

P_0, the limiting degree of polarisation, is included for comparison with earlier works where the old notation was used. The relationship between anisotropy A and the degree of polarisation P, used in the older notation, is given by

$$\frac{1}{A} = \frac{3}{2}\left(\frac{1}{P} - \frac{1}{3}\right)$$

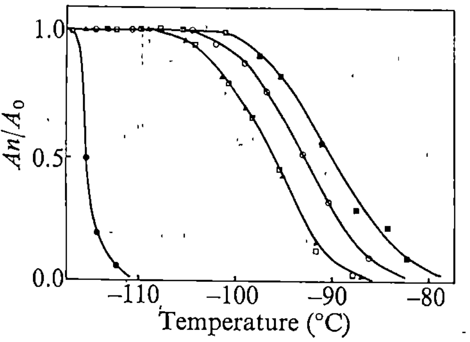

Fig. 1 Relative anisotropy of tryptophan phosphorescence as a function of temperature for globular proteins in 1:1 propylene glycol–phosphate buffer (0.05 M, pH 7). □, DNase I (Worthington); ▲, bovine carbonic anhydrase (Sigma); ○, bovine serum albumin (Worthington), ■, alcohol dehydrogenase from horse liver (Worthington). The anisotropy curve of indole (●) in the same solvent is included for reference All were at 10^{-4} M. In independent experiments *An* varied by less than 10%.

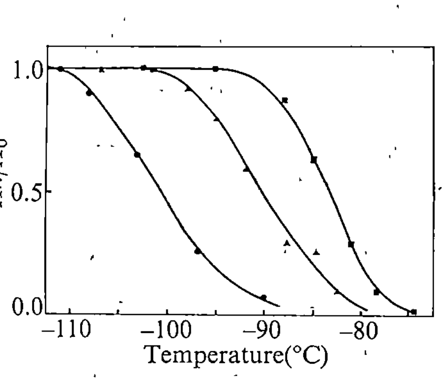
shown by Einstein[14] to be equal to $v\eta/kT$ where v is the volume of the particle, η is the viscosity and k and T are the Boltzman factor and temperature (K) respectively. In polar solvents at low temperatures there is a steep dependence of viscosity on temperature, so that the temperature dependence of the rotational correlation time reflects principally changes in viscosity. As the viscosity of the glycol–H_2O solvent decreases at higher temperatures, rotational motions of proteins manifest themselves with a decrease in the magnitude of A. Equation (1) shows that A becomes a measure of the relative mobility of various proteins if the lifetime remains constant. The triplet lifetimes, however, decrease at warmer temperatures and vary from protein to protein. Each of the anisotropy values, therefore, was corrected to the value An it would have at a fixed lifetime, arbitrarily taken as 3 s.

Figure 1 shows the variation of An with temperature for indole and for several proteins. The decline in phosphoresence anisotropy is observed at relatively low temperatures, or high viscosities. The temperature $T_{\frac{1}{2}}$ at which An/A_0 is reduced to one half is compared with the molecular weight of the protein in Table 1. As the volume of globular proteins increases with molecular weight, there is a concomitant increase in the temperature at which depolarisation occurs. The trend shown by molecular volumes compared with $T_{\frac{1}{2}}$ indicates that it is rotational diffusion of the entire macromolecule, rather than independent motions of the aromatic side chains, which is the dominating factor in depolarising the intrinsic phosphorescence of proteins. That the temperature–anisotropy profiles depicted in Fig. 1 for various proteins reflect a viscosity-dependent process is confirmed in Fig. 2. As the solvent viscosity is increased from ethylene glycol–H_2O to propylene glycol–H_2O to glycerol–H_2O, there is a corresponding increase in the temperature range for which depolarisation occurs with a given protein. In addition, experiments (to be published) in which phosphorescence depolarisation is followed as a function of time at a given temperature, unambiguously establish rotational motions as the origin of these transitions.

Fig. 2 Relative anisotropy of tryptophan phosphorescence as a function of temperature for alcohol dehydrogenase from horse liver in solvent mixtures of different viscosity. ●, Ethylene glycol–phosphate buffer (1:1); ▲, propylene glycol–phosphate buffer (1:1); ■, glycerol–phosphate buffer (2:1)



When the present steady-state method of measuring phosphorescence anisotropies is used, the rotations of even relatively large proteins must be slowed down by means of high viscosities to observe the depolarisation. The technique suggests itself as a method for measuring rotational motions of larger macromolecular complexes or of proteins embedded in media of high viscosity where the relaxation times can be expected to be long. Figure 3 illustrates the feasibility of using phosphorescence anisotropy to monitor the rotational mobility of membrane and viral coat proteins. The emission anisotropy for proteins in rat glomerular basement membrane (GBM), human erythrocyte ghosts and the coat of S-13 bacteriophage are plotted as a function of temperature along with the data for indole.

In contrast with the behaviour of the soluble proteins and the glycoprotein in GBM, the tryptophan phosphorescence of erythrocyte ghosts depolarises in stages rather than in a single transition. With increasing temperature an initial loss of anisotropy occurs at a viscosity at which soluble proteins (molecular weight 60,000–80,000) undergo depolarisation. The remaining anisotropy of the phosphorescence from the ghosts decreases slowly with increasing temperature. Only at much lower viscosity, about 0 °C, is most of the anisotropy lost. The data suggest that some proteins are highly constrained through interactions between macromolecular components although others are relatively free to undergo independent rotational motions, and probably correspond to specific types of membrane proteins at the surface. Selective removal of particular proteins[15] followed by phosphorescence measurements would establish the mobility of various membrane

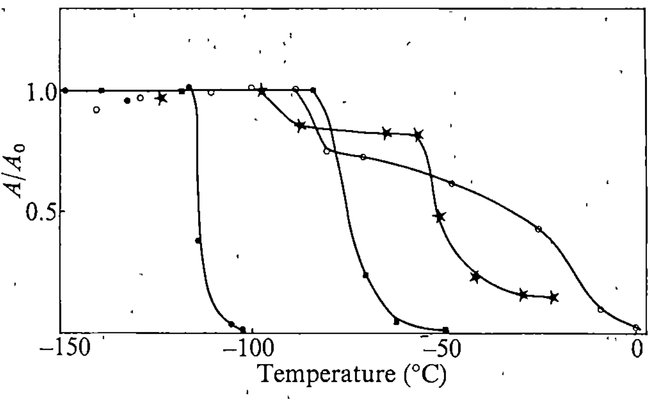


Fig. 3 Relative anisotropy of tryptophan phosphorescence as a function of temperature for biological structures suspended in propylene glycol-phosphate buffer (1:1). ■, GBM from rat kidney. They were prepared as previously described[23], in the laboratory of Dr N Kalant at the Lady Davis Institute for Medical Research. ★, S-13 bacteriophage viruses, a gift of Dr J. H. Spencer, Department of Biochemistry, McGill University. The method for growth, collection and purification has been described before[24]. ○, Human erythrocyte ghosts were given by Dr Kahlenberg and were prepared by the method of Dodge *et al.*[25]. With these suspensions the O_2 concentration of the solvent was reduced by bubbling the samples with highly purified N_2 (Union Carbide, Canada, 99.997% N_2) after which the 5-mm outer diameter, round, Spectrosil quartz sample cells were sealed. ●, Indole anisotropy curve in the same solvent is included for reference.

proteins and contribute to the elucidation of their role in membrane structure.

There is a similar discontinuous temperature profile of the phosphorescence anisotropy of the coat proteins of S-13 bacteriophage. The data establish that in the sample investigated, several rotational correlation times are involved. While the results may reflect some independent motion of the individual coat proteins in the virus capsule, due to the rather harsh deoxygenation treatment of this sample (bubbling with N_2) the observed heterogeneity probably arises from damaged and aggregated phage particles. The depolarisation profile is included to reflect the ability of the technique to detect heterogeneous rotational correlation times and to follow the motion of large macromolecular complexes. The anisotropy–temperature profile for GBM from rat kidney reveals that tryptophans are not rigidly fixed within the structure in that loss of anisotropy is observed at a temperature characteristic of soluble proteins (molecular weight ~ 100,000). GBM is composed primarily of collagen and one or more glycoproteins[16]. The glycoproteins therefore cannot be rigidly fixed within the insoluble basement membrane matrix but must have considerable rotational mobility of their own.

Several features of this technique for monitoring rotational motions of proteins are noteworthy. (1) Rotational motions are detected by the use of the depolarisation of the emission from intrinsic chromophores in proteins, thus avoiding labelling of proteins with probes. There are no concerns about the extent of perturbation to the system and the possibility of independent motions of the labelling group itself. A perturbation has been introduced instead with the use of glycol–water solvents. Studies of the biological activity[17,18] and the X-ray analysis[19,20] of proteins in these solvents, however, suggest that the perturbation is small.

(2) In the investigation of more complex systems involving two or more proteins, such as with the erythrocyte ghost membranes, the use of the intrinsic emission offers the possibility of resolving the rotational correlation time into contributions from individual proteins. Selective observation of particular proteins is also possible. With structures such as GBM the tryptophan phosphorescence arises only from the glycoprotein component[21] in that tryptophan is generally absent from collagen[22].

(3) The method is useful for investigating slow rotational motions. The functioning of proteins not only as soluble cellular entities but within macromolecular complexes and in insoluble structures, such as membranes and muscle fibres, makes necessary the development of techniques to elucidate the structure and dynamics of such systems. We feel that phosphorescence anisotropy measurements can contribute to the understanding of the molecular basis of the function of such systems.

Errata

In the article "Eukaryotic DNA replication complex" by V. M. Genta, D. G. Kaufman, W. K. Kaufman and B. I. Gerwin (*Nature*, **259**, 502; 1976) in the last paragraph, lines 8–13 should read . . . the observation of ATP-dependent DNA synthesis in M-band fractions isolated from sea urchin embryo nuclei[14]. Since nuclear membrane is largely confined to the LB (unpublished observation), the result reported here differs from studies involving the M-band technique[14–16] because . . .

In the article "Dissociation of response to injected gonadotropin between the Graafian follicle and oocyte in pigs" by R. H. F. Hunter, B. Cook and T. G. Baker (*Nature*, **260**, 157; 1976) the first entry in the 7th column of Table 1 should read 81.2% and not as printed.

In the article "Gibberillic acid enhances the level of translatable mRNA for α-amylase in barley aleurone layers" by T. J. V. Higgins, J A. Zwar and J. V. Jacobsen (*Nature*, **260**, 166; 1976) Figs 1 and 3 have been transposed. The legends are correct as they stand.

In the article "New H_2O celestial sources associated with H II regions in the Southern Hemisphere" by P. Kaufmann *et al.* (*Nature*, **260**, 306; 1976) the second entry in the 1st column of Table 1 should read 330.9–0.4 and not as printed.

In the article "Effect of surface roughness on rolling friction and adhesion between elastic solids" by G. A. D. Briggs and B. J. Briscoe (*Nature*, **260**, 313; 1976) the first line under the equation in the first paragraph should read : where σ is the distribution of asperity heights . . .

Nature Index and Binders

The **Index** for 1975 is now available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £7.00 for four (a year of *Nature* fits into four binders).

Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

matters arising

Polymerisation and the solar neutrino problem

JACOBS[1] has questioned the efficiency of the helium flushing method for extracting Ar^+ ions produced in the reaction

$$\nu + {}^{37}Cl \rightarrow e^- + {}^{37}Ar^+$$

He suggests that Ar^+ ions could induce polymerisation in the liquid C_2Cl_4 and get trapped before they are neutralised by capturing electrons, and consequently all the Ar^+ ions produced in the above reaction are not detected.

Tetrachloroethylene is an unsaturated molecule which undergoes polymerisation, when irradiated by MeV γ rays, at the rate of $\sim 2.1 \times 10^{-10}$ mol ml^{-1} s^{-1} (based on the dose rate of 1.5×10 eV ml^{-1} s^{-1} and the polymer yield in the radiation experiments)[2]. It is known that halogenated ethylenes undergo predominantly free-radical polymerisation, the cationic initiation of the chain is less likely because of the presence of electronegative groups in C_2Cl_4 leaving an electropositive carbon atom at the polymerisation site. Even if Ar^+ can initiate polymerisation, the rate will be much smaller than that quoted above for γ rays. On the other hand, since the electron affinity of Ar^+ is high, the Ar^+ radical produced by the solar neutrino can be neutralised at a very fast rate. The electron transfer between the neutral radical and the positively charged ion is diffusion controlled with the rate constant 10^9–10^{10} l mol^{-1} s^{-1}, while the rate constants of generalised polymerisation[3] are of the order of 1–30 l mol^{-1} s^{-1}. It is clear there will be negligible trapping of Ar^+ ions through polymerisation in the tank.

The foregoing arguments receive indirect but unambiguous support from two experiments: (1) Barabanov *et al.*[4] have measured the relative efficiency of removing a small number of ^{37}Ar atoms by helium purging in liquid C_2Cl_4 and in solid C_6Cl_6 by irradiating both the substances with fast neutrons from a PuBe source. They find that for the same number of fast neutrons, the same number of ^{37}Ar atoms is produced. Considering the different physical and chemical properties of C_2Cl_4 and C_6Cl_6, the probability of identical rate of trapping is surely negligible. (2) In the helium-purging efficiency experiment of Davis[5], liquid C_2Cl_4 was irradiated with neutrons from an RaBe source to get an apparent ^{37}Ar production rate per incident neutron of 7.5×10^{-7}. If chemical trapping is important, the true production rate should be at least an order of magnitude higher than the observed one. The cross sections for the nuclear reactions

$$n + {}^{35}Cl \rightarrow {}^{35}S + p \text{ (fast)}$$
$$\hookrightarrow p + {}^{37}Cl \rightarrow {}^{37}Ar + n$$

are sufficiently well known to render a theoretical calculation of the true production rate of ^{37}Ar possible; we find it to be $\sim 4 \times 10^{-7}$, in reasonable agreement with Davis' measurements.

We may add to these the very careful analyses by Wolfendale *et al.*[6] and by Cassiday[7] of the cosmic ray-induced background in Davis' experiment. These analyses lead to values for the photonuclear cross section which are in substantial accord with other cosmic ray and accelerator measurements. If the normalisation of the background at the depth of 25 m.w.e. (metres water equivalent) is wrong as implied by Jacobs, this would hardly have been the case. The conclusion thus seems inescapable, that chemical trapping of any kind—polymerisation or other chemical process—is of negligible significance in Davis' experiment.

JACOBS REPLIES—In a brief communication[1] I explored the logic of the possibility that the solar neutrino problem might be caused by the chemistry of the solar neutrino experiment. I concluded that this chemical hypothesis was viable only if $^{37}Ar^+$ became 'chemically trapped' in Davis' system; five mechanisms for trapping the argon in C_2Cl_4 were suggested.

Banerjee *et al.*[2] criticise one of my trapping mechanisms—induced polymerisation in the liquid tetrachloroethylene—and imply by heuristic arguments that Davis' neutron-irradiation test[3] and the cosmic-ray background test[4,5] completely rule out the possibility of any significant 'chemical trapping'. I suggest that the conclusions of Banerjee *et al.* are comfortably plausible, but they are by no means logically inescapable.

Induced polymerisation of C_2Cl_4 is the least tenable of my suggested trapping mechanisms; the large atomic radius of chlorine will hinder the formation of any long chain polymer[1]. It is much more probable that the argon is 'chemically trapped' in a small bound molecule or ion–molecule. One could just as easily interpret the results of Barabanov *et al.*[6] as positive support for the formation of $ArCl_n$, with $n = 2$, 4 or 6.

Order-of-magnitude arguments are unsafe in this controversy. The uncertainties intrinsic to present-day solar models can easily render acceptable a theoretical solar neutrino rate as low as 4 SNU (ref. 7), whereas Davis' latest two runs (36 and 37) indicate an experimental rate of $\sim$4 SNU—with a 1σ upper limit of $\sim$1.5 SNU for the average of runs 21–37 (ref. 7; estimated by eye from their Fig. 2). Thus, 'chemical trapping' need not hide 9 of every 10 argon atoms produced by solar neutrinos, but could well conceal only 60% of the argon on average.

Therefore, order-of-magnitude (or even crude qualitative) agreement between theory and experiment in some of the crucial tests[3-5] is not sufficient to eliminate the chemical hypothesis—only precise quantitative matching can do that. Finally, I conclude again that my chemical solution to the solar neutrino problem remains a viable alternative.

Sub-microscopy porosity and superfluid ^4He

VAN Brakel and Heertjes[1] have reported on transfer phenomena in porous media, using the capillary rise of a wetting liquid. I would like to add to this by mentioning a phenomenon apparently similar to capillarity, although fundamentally different: the behaviour of superfluid ^{4}He in narrow gaps. This might contribute to the knowledge of transfer phenomena.

The behaviour of superfluids is not as well known as capillarity of a normal viscous wetting liquid. The viscosity of superfluid helium is zero. This provides a method[2] to detect and to estimate the size of sub-microscopic pores in solid materials as well as in small, packed grains. Those materials with small enough pores and through which only the superfluid helium flows are called superleaks.

When liquid ^{4}He is cooled to a temperature of 2.17 K, the λ point, there is a phase transition, and some of the liquid becomes superfluid. As the temperature decreases further, the proportion of superfluid increases. The temperature at which the superfluid starts to flow through a superleak is called the onset temperature and is always below the transition temperature. The difference between the two temperatures is the 'depression of the transition temperature'. The smaller the pores the lower the onset temperatures.

The channels through a superleak are not uniform but are at random, interconnecting each other. If φ_m is the minimum diameter along a connection path, then the largest φ_m of all possible paths determines the onset temperature, because in that diameter superfluid movement will occur first, that is, at the highest temperature below the λ transition. This is a 'size effect' and arises from interactions between excitations of quasi particles of the liquid helium and the solid. When the temperature is high and the gap or diameter is small, the interaction is equivalent to the presence of viscosity. The number of excitations diminishes with the temperature.

To estimate the widths of the gaps, or the 'diameters' of the pores through which the superfluid penetrates the superleaks, the following two relationships between the depression ΔT_λ of the transition temperature and the width d of those gaps are used

$$\Delta T_\lambda \simeq -\frac{2\times10^{-14}}{d^2}\ \mathrm{K}$$

$$\text{or } \Delta T_\lambda \simeq -\frac{2.5\times10^{-11}}{d^{3/2}}\ \mathrm{K}$$

if d is expressed in cm. The first relationship was derived by Ginzburg and Pitaevskii[3] and the second, which seems to be more consistent with the experimental data, by Mamaladze[4]. It was, however, pointed out[5] that the width of a parallel-sided channel, which probably occurs most frequently, is $2d$. Using this latter criterion and the two expressions given above, the width of the channels in a granite and a limestone, which were found to be superleaks, was estimated for both between 34 Å and 22 Å (ref. 6) and the onset temperatures measured were 1.48 K and 1.45 K, respectively.

Antibiotic resistance in laboratory workers

RECENT publications by Williams Smith[1] and Anderson[2] have been concerned with the ability of *Escherichia coli* K12 to survive in the human alimentary tract. This is a matter of importance since a detailed knowledge of the behaviour of this much used *E. coli* strain is needed to assess the potential hazard of many genetic engineering experiments.

In this department we have monitored the faecal flora of laboratory workers engaged in work with R-plasmids to see whether they have ever excreted the K12 strains with which they were working, or other *E. coli* carrying plasmids which were being studied in this laboratory. Most of our experiments have involved a restricted number of R-plasmids (Table 1) in *E. coli* UB1139, a nalidixic acid-resistant derivative of *E. coli* K12.

A total of 52 samples was taken from the two individuals under study during a period of 184 d. Suspensions of faecal material in physiological saline were plated on McConkey agar to determine the total coliform count, and on agar containing either ampicillin (25 μg ml^{-1}), streptomycin (10 μg ml^{-1}), tetracycline (25 μg ml^{-1}), chloramphenicol (25 μg ml^{-1}) or nalidixic acid (30 μg ml^{-1}). Resistant colonies arising on these plates (if any) were then tested for indole production in peptone water, and for acid+gas production in McConkey broth after overnight incubation at 44 °C (refs 3 and 4). If available, ten resistant colonies from each plate were O-antigen typed[5] and tested for the transferability of their resistance patterns by mating with a standard *E. coli* R$^-$ (ref. 5). In all, 590 isolates were examined in this way.

A total of 38 R-plasmid carrying *E. coli* have been isolated so far, and seven different resistance patterns have been encountered (Table 1). None of these resistant *E. coli* was UB1139, nor were the resistance patterns encountered those of the plasmids used for experimental purposes.

The workers concerned in these studies used conventional procedures for testing low-risk bacteria[6,7]. Mouth pipetting was not used but experiments were conducted in the open laboratory. These results therefore reinforce the views of Williams-Smith[1] and Anderson[2] that *E. coli* K12 lines are unlikely to establish themselves as major components of the faecal flora of workers handling these bacteria so long as reasonable laboratory procedures are used.

Table 1 Comparison of the resistance patterns of the plasmids isolated from faecal samples with the patterns of the experimental plasmids used by the workers concerned

Faecal samples		Experimental plasmids	
Pattern	No. of times isolated	Plasmid	Pattern
Tc	23	R1*drd*19.K1	Kn
Sm Su	3	R46	Tc Sm Sp Ap Su
Tc Su	1	R55-1	Su Cm
Sm Ap Su	1	R64-11	Tc Sm
Tc Sm Su	8	R100-1	Tc Sm Su Cm
Tc Sm Ap Su	1	R388	Su Tp
Tc Sm Ap Su Cm	1	R391	Kn
		R751	Tp

Total number of isolates examined: 590. Abbreviations for resistance markers: Tc, tetracycline; Sm, streptomycin; Ap, ampicillin; Su, sulphonamide; Cm, chloramphenicol; Sp, spectinomycin; Kn, kanamycin; Tp, trimethoprim.

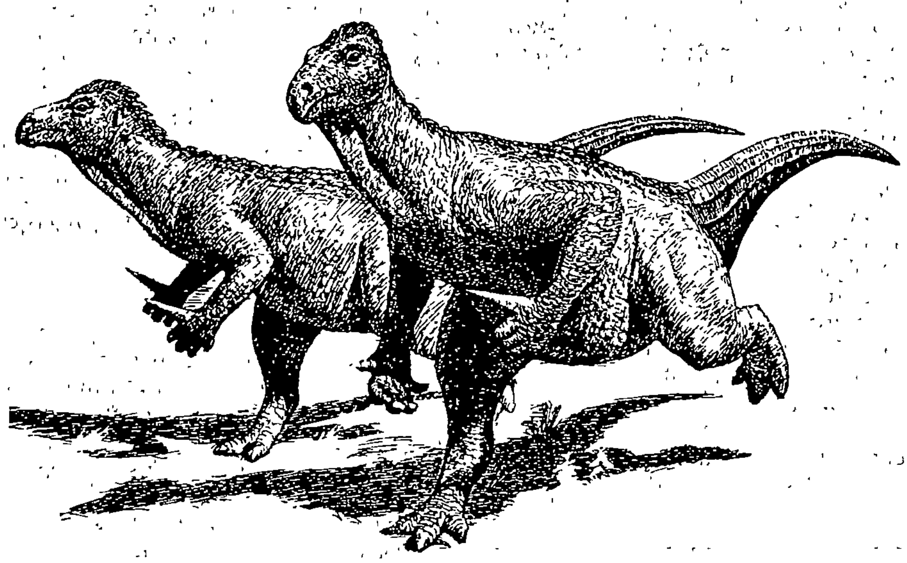
Dinosaur teleology

L. B. Halstead

FOR 140 million years the dinosaurs dominated the continents, then 64 million years ago they suddenly disappeared. These animals have always been accepted as the acme of the world of cold-blooded reptiles. In recent years, however, R. T. Bakker has been arguing that their former success was a consequence of their high metabolism and fast energy production (*Nature*, **238**, 81–85, 1972). He considered that they were warm-blooded in the same sense as birds and mammals, maintaining a constant internal temperature (homoiothermy) by means of their own internal activity (endothermy) Adrian Desmond's *Hot-Blooded Dinosaurs** is a fascinating account of the history of the study of dinosaurs and the changing views of their physiology, culminating in a vigorous exposition of Bakker's ideas. As an exercise in evangelism it is exemplary.



Desmond uses the old legal trick of the leading question How could *Tyrannosaurus* have engaged in lengthy gladiatorial combats with *Triceratops*, if they had not had a high metabolic rate? How could *Struthiomimus*—the ostrich dinosaur—have maintained a speed of 80 km h^{-1} with the physiology and energy output of a lizard? The answers quite clearly are that they could not; but what Desmond fails to establish is that such behaviour actually took place or was even necessary

All the evidence marshalled to support the notion of dinosaur endothermy is capable of alternative interpretations. The stance and gait of dinosaurs with the limbs positioned beneath the body is comparable to that found in birds and mammals This stance seems to be associated with endothermy today. There is therefore a *prima facie* case that the energy requirements may have been the same; yet the crocodile's high walk is not evidence for endothermy—there is an advantage in an upright posture *per se*.

Much emphasis has been made of the different predator–prey ratios between living ectothermic and endothermic populations. If one examines mammalian ratios of kg predator/kg prey, it can be seen that this changes from small animals to larger. The 'endothermic' situation with the dinosaurs could be interpreted as a direct consequence of their large size.

Perhaps the most striking similarity between dinosaurs and mammals is found in the microstructure of their bone. The laminar bone of sauropod dinosaurs is indistinguishable from that of some of the larger artiodactyls and it is presumed that this indicated a similar metabolism. Such microarchitecture may in fact be simply due to the rate of bone formation and is thus characteristic merely of large animals. The large dicynodonts with their sprawling gait (and therefore not comparable in terms of their locomotion to the dinosaurs) have the identical bone histology The evidence for endothermy from bone histology is not particularly convincing

The existence of dinosaurs in latitudes that were situated in the Cretaceous Arctic would seem at first glance to be strong evidence for endothermy. To speak of the Arctic at the time of the dinosaurs is a little misleading as there were no polar ice caps The temperature of the Cretaceous seas at differing latitudes has been ascertained from oxygen isotope studies and the mean sea level air temperatures subsequently calculated The range from Equator to Arctic was 31–14 °C. It is not unreasonable to imagine the odd dinosaur surviving such conditions

The final piece of argument concerns the first bird *Archaeopteryx* and the pterosaurs. Both types of animal originated from the same basic stock and the birds seem to be directly descended from the dinosaurs Birds and pterosaurs had an insulating covering as did the advanced paramammals and primitive mammals In all these groups, it is accepted that they possessed a high metabolic rate and were genuine endotherms. Desmond contends that as *Archaeopteryx* was skeletally similar to small theropod dinosaurs and possessed feathers primarily for insulation, then perhaps such a covering was a common feature of all these animals.

Once the premise that dinosaurs must have been endotherms is accepted, it is but a short step to remove them from the Reptilia and place them in a new class, the Dinosauria, which includes the birds Aves (Bakker and Galton, *Nature*, **248**, 168–172, 1974). Desmond for his part proposes the new superclass Endosauropsida to encompass the classes Dinosauria (including Aves) and Pterosauria.

The case for dinosaur endothermy has certainly not yet been convincingly established and, even if it were, there would still be no justification for such a drastic restructuring of the classification of the vertebrates Even the man in the street has some inkling of what a bird is and in no sense does this equate with dinosaurs Brontosaurs and

---

**The Hot-Blooded Dinosaurs*: *A Revolution in Palaeontology* By Adrian J. Desmond Pp 238. (Blond and Briggs: London, November 1975.) £5.95.

Dr Halstead is a reader in geology and zoology at the University of Reading, UK.

blackbirds have precious little in common beyond sharing an ultimate common ancestor. The evolutionary line of the mammals can be traced back to the paramammals, but this is not a sound basis for terming the mammal-like reptiles 'mammals', nor for including the mammals in the Paramammalia. The fact that we can now begin to indicate lines of descent is not a licence to redraft the classification.

The conclusions drawn by Desmond run far ahead of the available evidence A great deal more work will be required before such notions of dinosaur endothermy can be taken seriously. There can be little doubt, however, that the dinosaurs were warm-blooded. The dinosaurs achieved a passive type of homoiothermy by being large; their surface–volume ratio would have ensured a fairly constant internal temperature. All the features that have been used to attribute endothermy to the dinosaurs can more easily be interpreted as being a direct consequence of their size.

It is a pity that Desmond's undoubted literary talents were not used in a more deserving cause than promoting hot-blooded dinosaurs. □

Synaptic receptors

Synaptic Receptors: Isolation and Molecular Biology. (Modern Pharmacology–Toxicology: A Series of Monographs and Textbooks.) By Eduardo de Robertis. Pp. xiv+387. (Dekker: New York, 1975.) $29.50.

In those synapses with chemical transmission, the transmitter substance acts on the postsynaptic membrane by combination with synaptic receptors. Within the last ten years, our knowledge of these receptors has advanced from a condition in which their existence as discrete structures was far from established to a situation in which several have been isolated. Their isolation is the subject of Dr de Robertis' book.

Synaptic receptors, as constituents of membranes, are amphipathic and there are, broadly speaking, two approaches to their isolation. The first uses detergents in aqueous solution to counteract their hydrophobicity and effect solubilisation. The second approach seeks to take advantage of this hydrophobicity by extracting receptors into nonaqueous solvents of low polarity. Dr de Robertis has played a dominant role in the development of the latter approach, whereas most other work has concentrated on the former. Recently, Barrantes *et al.* (*Nature*, **256**, 325–327, 1975) have shown that, at least in the case of the acetylcholine receptor, there is nothing in common between the material isolated by these two methods. This casts a long shadow over the book, for in spite of a superficial balance, it is, in fact, an apologia for Dr de Robertis This should surprise no one for Dr de Robertis' prolificity is truly remarkable, having isolated some half dozen receptors from twice as many tissues.

The need for an expensive monograph at the present time is open to the strongest doubt, more so since Dr de Robertis has displayed the virtue of brevity in a subsequent review covering the same ground (*Rev. Physiol. Biochem. Pharmac.*, **73**, 9–38; 1975). The book contains a quite incredible number of typographical errors from the merely irritating to the downright misleading.

Until such time as our knowledge of synaptic receptors enables distinction between the permanently valuable and the ephemeral, a book of this kind is prey to premature obsolescence and, at the price, just not worth it.

David Green

Conceptual shorthand

Transport Phenomena in Medicine and Biology. By M. Min-Shing Lih. Pp. xviii+531. (Wiley–Interscience: New York and London, 1975.) £14.70.

This book gives a very clear presentation of the mathematics necessary to describe—with a fair degree of rigour—the underlying physics involved in physiological processes concerned with transport of mass, momentum and energy. The author is to be complimented on achieving his declared aim of demonstrating how the mathematical conceptual 'shorthand' of physics can reduce the apparent phenomenological diversity of physiology. From the start the emphasis is on translation from the real world to the mathematical model, solution of the problem and back to the real world to present the answer in physical terms. The mathematics is continuously related to reality so that an experimentalist has his interest maintained and is carried along with the argument. This is done in a direct and refreshingly conversational way, producing more the flavour of a verbatim record of a colloquium than a concise university text.

With such a discursive style the author does well to contain his subject within 500 pages. The first five chapters present the mathematics necessary for a proper description of material processes in terms of continuum physics Chapters 6, 7 and 8 show us how to apply the mathematics to changing conditions as diverse as pulsatile blood flow, body heat loss, placenta mass transport and gastric acid analysis. Chapters 9 and 10 are specifically dedicated to haemorrheology—the non-Newtonian behaviour of blood as a suspension of cells flowing through narrow vessels—and oxygen transport This last chapter is an impressive discussion of a vital process, including examples of varied problem solving from membrane blood oxygenators to the oxygen–tension profile in the cornea.

We are told that the original manuscript was 'test-used' in a Chatauqua-type programme, and I would agree that the final book is very well suited for this self-help with guidance type of learning. The comprehensive presentation of 'Mathematical Background' in Chapter 2 makes the book self-contained. The reader is taken from functions and variables (p16) through to the tensor and its operations (p96), and by this time is ready to accept quite naturally the need for a tensor as a description of the stress on an element of fluid. I particularly liked the use of small print flow diagrams to illustrate on one page a single application of the mathematics being discussed. All of the mathematical development is integrated with the rest of the book through the use of problems.

Because of the excellent integration I wondered if it might not be difficult to easily 'dip' and use parts of the book as a companion text in an undergraduate course—say haemodynamics. For example, the pursuit of generality in the development of the mathematical models means that to arrive at a particular point such as the description of pulsatile flow in a pipe seemed to be longer than Womersley's direct approach. The very applied flavour, however, of the maths makes the attempt an attractive/worthwhile proposition. Certainly I have not found any more suitable text for that type of course.

Some of the material in this book will be familiar to any teacher in this field and even the organisation may in part be already in use. Yet the whole achievement of keeping the practical biomedical quality of the mathematics always so apparent makes this a most welcome book. It will certainly be a great help in courses at final special honours or MSc level in this country. Although the fly-leaf suggests it is an ideal text for the student I do not believe that it is an easy book for the unaided beginner. For the postgraduate student and the biomedical researcher it should handsomely repay the investment of time necessary to come to terms with this very able and challenging presentation.

R. G. Gosling

Chemical Fortran

Fortran IV in Chemistry: An Introduction to Computer-assisted Methods. By G. Beech. Pp. x+303 (Wiley: London and New York, October 1975.) £8.75.

UNDERGRADUATE chemistry courses have so far not shown as much response to the advent of the computer as engineering courses, and they do not reflect its importance as a research tool. It is still possible to teach both theory and laboratory techniques without reference to the computer; the main impetus towards Fortran programming and computer-assisted techniques lies in the knowledge that nearly every chemistry graduate soon becomes involved with computers. Dr Beech's book will be invaluable to those responsible for the introduction of these methods at undergraduate level, and essential reading to undergraduates and research students meeting them for the first time. Perhaps the most striking feature of the book is the care with which scopic data (including curve addition and reduction), crystal field simula- the chemistry and the underlying mathematics are developed as well as the computing. The operation of the programs listed is always fully described in the text.

An elementary knowledge of Fortran is assumed. The first chapter gives those elements not met on a first programming course, and those which may depend on the particular machine used. Next, normal numerical and statistical methods are given, including non-linear equations and a particularly clear account of matrix operations and eigenvalues. Practical examples of the application to experimental data are taken from chemical kinetics, electrochemistry, thermal analysis, multicomponent spectroscopic data and mass spectroscopy. The next chapter covers a very wide range of computer simulations of experimental observables: modelling simple kinetic and radiochemical systems (including Monte Carlo techniques), thermodynamics and equilibria, crystal lattice energies, statistical mechanics, spectrotions and nuclear magnetic resonance line splitting and intensity. Theoretical topics treated include particle-in-a-box (one dimensional with bond length alteration, and two dimensional) and atomic and molecular orbitals (LCAO and Huckel calculations). In this section, emphasis is rightly placed on plotting out the results.

Data acquisition by analogue to digital instruments is described, followed by data processing (including convolution smoothing and baseline corrections), illustrated by application to nuclear magnetic resonance spectra. Complex data systems are described for mass spectrometry, gas chromatography and γ-ray spectrometry. The book closes with a useful review of the literature, including handling chemical information on the computer. Each chapter is followed by problems and a bibliography. The book is well produced, and in view of its extensive coverage, good value. It is warmly recommended for both undergraduate and postgraduate use. **B. P. Levitt**

Changing role of ion beams

New Uses of Ion Accelerators. Edited by J. F. Ziegler. Pp. xii+482. (Plenum: New York and London, 1975.) $33.60.

THE current state of world economics demands that equipment, manpower and money are used as efficiently as possible. Nuclear physics has long been singled out as one of the 'big science' areas and more than a generation of expansion has provided a legacy of ion accelerators of which the low energy machines (that is about 5 MV and below) are used increasingly today in fields far removed from the compilation of nuclear structure data. But the story now is not merely one of keeping highly specialised machinery occupied. So interesting and valuable have the applications of ion beams to materials science and solid-state physics turned out to be that many Van de Graaff accelerators, for example, are now used exclusively in analytical experiments complementing (or replacing) more well established techniques. An analogous situation exists in the new field of ion implantation where exciting property changes are induced with ions usually below 500 keV in a variety of materials. The result is that nuclear physics laboratories are undergoing a metamorphosis towards solid-state applications which encompass physics, chemistry, materials science and metallurgy.

This book covers new developments in analytical methods, such as Rutherford backscattering, channelling, nuclear reactions and characteristic X rays for composition analysis, as well as ion implantation and ion-induced X rays. The editor deserves praise for welding the wide-ranging subject matter so satisfactorily; and it is perhaps significant that nearly four-fifths of the book relates to analytical techniques since this is the area in which ion accelerators are making immediate impact. The previous volume—which had a similar title—appeared eight years ago It was an excellent monograph which should have been more widely disseminated and its publication set the stage for constructive interaction between accelerator users and other physicists. It is encouraging to see how much ground has been covered in the intervening period and it is interesting to note the change of emphasis In the present volume, for example, nuclear astrophysics and beam foil spectroscopy give way to superconductivity, corrosion studies and pollution species detection.

The principal value of this book is the bringing together of the detailed procedures for backscattering and X-ray data collection and analysis, as well as up-to-date overviews of current developments in ion implantation and X-ray excitation theory. It is a rare thing to find accounts written from what is clearly first-hand experience of the systematics of establishing a first-class analytical service using an accelerated beam of protons or helium ions. Inevitably in a book consisting of contributed chapters there is duplication but the essentials are there, and numerous real-life examples are included. Surprisingly there is very little reference to the ion implantation of semiconductors. Perhaps it was felt that this important field (virtually synonymous now with advance in device technology) receives adequate cover elsewhere. As semiconductor implantation, however, has provided the bread and butter of the industrial side of ion implantation for many years, and is likely to continue doing so, an omission of this sort is regrettable. It is unfortunately made all the more obvious since the contributed chapter on superconductors is wrongly labelled 'semiconductors' in the text! Rutherford backscattering should be referred to as such to distinguish elastic Coulomb interactions from inelastic reactions arising within the nucleus (nuclear backscattering). Although they receive attention in separate chapters, the two are referred to a little indiscriminately elsewhere. Having said that, the treatment and power of such methods of analysis (and the two chapters on ion-induced X-ray physics) are excellently covered.

Accelerator users, present and intending, should reach for this volume No-one contemplating an integrated analytical programme or materials project with solids should be ignorant of the applications of ion beam machines and the growing expertise which surrounds them It is a pity that oversights in production and a lack of standardisation of diagrams detract slightly from an otherwise well conceived book.

N. E. W. Hartley

Spin labelling

Spin Labelling: Theory and Applications. (Molecular Biology: An International Series of Monographs and Textbooks.) Edited by Lawrence J. Berliner. Pp. xiii+592. (Academic: New York and London, January 1976.) $49.50; £25.55.

SPIN labelling is an obviously attractive technique. It is relatively easy to attach a spin label to a protein or to insert it into a membrane to act as a reporter group. Furthermore, the electron spin resonance spectra obtained are often aesthetically very appealing. But as with much modern art, the apparent surface simplicity is said to hide a deep inner meaning, which can only be properly discerned by the educated eye. In this book, a number of dedicated spin labellers try, successfully, to pass on the secrets of their art.

Probably the most useful part of the book for the experimentalist is the second half, in which applications of the technique are discussed. Four chapters are concerned with membrane studies, a reflection of the fact that it is in the field of membranology that spin labelling has proved most fruitful. Particularly useful are discussions by J. Seelig, O H. Griffith and P. Jost on the measurement of spin label order parameters, the overall conclusion being that simple measurements taken directly from the spectra usually give as good results as complex computations.

Two chapters deal with enzyme studies, but it is clear that here spin labelling has, in general, been rather less successful, in spite of the synthesis of a wide range of spin labelled compounds. The technique can be used to obtain distance information, but this is of course, information about the distance to an >N—O group rather than to a part of the native enzyme. Most enzyme studies have, however, been of a much more qualitative nature, merely looking for changes in the spectrum following some perturbation of the system.

A further two very useful chapters provide details for the preparations of spin labelled compounds and discuss instrumental aspects of obtaining electron spin resonance spectra. The first part of the book is the theoretical section containing chapters on general magnetic resonance theory by P. L. Nordio, on the theory of slow tumbling of spin labels by J. H. Freed and on the theory of biradicals by G. R. Luckhurst.

The only criticism that can be levelled at the book is that it does not meet its claim to be accessible to readers from medical and biological backgrounds. A quick survey of my medical colleagues showed that few knew what quantum mechanical operators or expectation values were, and such knowledge is assumed at the beginning of chapter two. It is a pity that the book does not include a non-mathematical discussion of the basis of electron spin resonance, since, in fact, the latter chapters show that detailed understanding of the theory is not necessary for its application to biological problems. Nevertheless, this is certain to become the spin labellers' benchside book, even if they do have to steal the library copy. **A. G. Lee**

Stimulus for ecologists

Ecological Animal Parasitology. By C. R. Kennedy. Pp. ix+163. (Blackwell Scientific: Oxford and London, 1975.) £3.50.

IN recent years a number of excellent books have been published on the general ecology and population biology of animal species with approaches ranging from the completely theoretical to practical treatments of field study problems. The ecology of two particular groups of organisms—protozoan and helminth parasites—has, however, received very little attention in general ecological texts, host–parasite relationships often being briefly dismissed by reference to the population equations of Lotka and Volterra.

Such treatment seems surprising, particularly when considered in relation to the economic importance of many host–parasite interactions. A careful examination of the parasitological literature reveals, however, that our knowledge of the ecology of the majority of parasitic organisms is very limited indeed. This unhappy state of affairs has undoubtedly arisen as a result of the complexity of many parasite life cycles, which may involve more than one species of host and many distinct parasite populations compounded by the difficulties in measurement and observation created by the intimacy of the relationship between host and parasite.

Clive Kennedy's new book is a welcome addition to the sparse literature on ecological aspects of parasitolgy. After a brief and perhaps rather superficial introductory chapter on the nature of parasitism, parasite population growth and host–parasite systems, the following four chapters are concerned with the concepts of host specificity and intra- and interspecific competition, the biology of host location and the dispersal and fecundity of parasites. Four of the remaining five chapters, constituting the major part of the book, deal in a fair amount of detail with the population biology of parasites within intermediate hosts, and poikilothermic and homiothermic definitive hosts. The contents of these chapters, reflect to a large extent the information available in the research literature, although they are somewhat biased towards the author's own interests in helminths and in particular parasites of fish. In the last chapter, perhaps the most stimulating of the book, the author attempts to come to terms with the dynamic aspects of the relationship between host and parasite populations. Some of the more quantitative attempts to model the population dynamics of host–parasite interactions are discussed, although it seems surprising that the pioneering and highly relevant work of V. A. Kostitzin 40 years ago is ignored

This book will be of more general interest to students of parasitology than modern day ecologists since the author has not really achieved his stated objective of interpreting animal parasitology in the light of current ecological ideas and concepts. For example, many rather important ecological topics such as the relationship between stability and complexity in host–parasite systems and the importance of time delays and genetic factors in population interactions are completely ignored. Furthermore, the author himself seems to be rather confused by certain ecological concepts, such as the role played by density-dependent factors in the regulation of population growth. He frequently refers to specific types of host–parasite interactions as "fundamentally unstable". The reader is first of all unaware of what the author means by stability and in addition is left to wonder how such interactions persist in the world today in the absence of regulatory mechanisms operating on population growth. In certain cases confusion is created by contradictory statements within the same paragraph. The author implying in one instant that mortality of parasites within poikilothermic hosts is a non-seasonal parameter and then going on to state that temperature influences the rate of loss of adult parasites from the host.

Many of the confusing discussions within this book are no doubt due to the lack of quantitative ecological information available in the parasitological literature. As an undergraduate text this book will be of value, and it may stimulate some of the more quantitatively minded ecologists to turn their attention to this fascinating field

R. M. Anderson

Talking to computers

Conceptual Information Processing (Fundamental Studies in Computer Science, Volume 3.) By R. C. Schank. Pp. viii+374. (North-Holland: Amsterdam and Oxford, 1975.) Dfl.75; $31.25.

How can we get computers to understand natural language? One way is to restrict conversation to a very limited domain such as noughts-and-crosses or the world of children's blocks and then to try to devise programs that will go through most of the mental operations that human beings perform when they talk to each other about such topics. In spite of some promising developments, the disadvantages of this approach are obvious: change an aspect of the simulated world—introduce a baby to play with the blocks—and sooner or later the semantic machinery will be unable to cope. An alternative method is to restrict not the topic of discourse but what the programs do. Mechanical translation, the white hope that became a white elephant, was a lesson in the dangers of an extreme version of this approach. Nevertheless, Roger Schank has opted for a wide range of discourse at the cost of limited comprehension, and the present book describes his work in great detail down to three chapters by his students based on their PhD theses. They have contrived some ingenious programs that will generate a list of paraphrases of a sentence or draw plausible inferences from it, for example, given: "John said he killed himself", their system responds: "Dead people can't talk." The drawback is, of course, that the programs are not really demonstrating a full mastery of language. They could not describe a dead man even if they had eyes to see.

The choice at present seems to be either articulate conversations with an idiot savant who knows only how to pile up wooden blocks, or the inferential responses of a deaf, dumb and blind kid who cannot even play a pinball machine. Neither alternative promises to deliver us an intelligent talking computer by the year 2001. Perhaps we should treat computers like babies and provide them with senses and voices, the ability to learn how to represent the world and to reflect on their own processes, and then talk to them for a few years **P. N. Johnson-Laird**

Manipulating plant growth

Environment and the Experimental Control of Plant Growth. (Experimental Botany: An International Series of Monographs.) By R. J. Downs and H. Hellmers. Pp. vii+145 (Academic: London and New York, November 1975.) £4.50; $12.50.

MANIPULATING the environment is a technique used by experimental and applied botanists for many years in their search towards an understanding of plant growth, and the use of sophisticated controlled environment facilities has recently increased. The authors of this book have drawn on their considerable experience with such facilities to provide a monograph that will be welcomed by many researchers in the field. Their object was to collate information on environmental factors controlling plant growth and the methods of controlling these factors in turn, to enable biologists to understand what is required in the design and use of the facilities, in order to obtain acceptable degrees of control. In doing so, the authors have produced the first major book on the subject in over ten years since L. T. Evans' *Environmental Control of Plant Growth.*

There are chapters covering temperature, light, the gaseous environment, and water and nutrients. Each begins with definitions, followed by methods of measurement and design of facilities, and examples of the influence that each factor has on the development and growth of plants. The technical information is presented with clarity. The physiological data is necessarily rather limited, but each chapter is concluded by a comprehensive reference list. The value of the book lies in its considerable amount of practical advice based on the authors' experiences, with emphasis on the problems that may be encountered. The book is concluded by chapters discussing the controlled environment in relation to the natural environment, and the various types of facilities available. The authors are directors of the South Eastern Plant Environment Laboratories in North Carolina, and naturally stress the advantages of phytotrons since a number of facilities are available and visiting workers are encouraged there. Their book will, however, prove especially useful to those with more limited facilities and little experience. **S. M. Thomas**

Look—no maths

Electrons in Metals: An Introduction to Modern Topics. By C. M. Hurd. Pp. ix+331. (Wiley-Interscience: New York and London, December 1975.) £9.95; $19.90.

DR HURD'S book is an ambitious project—the descriptive treatment of the major properties of electrons in metals without the use of mathematics. The author sets out to lead beginners in the subject through the tangled web of quasiparticles, Fermi surfaces and Kondo effects to gain at least a qualitative overview of the theory of metals. To do this the author has developed what would, at first sight, seem to be a logical framework, in that he starts with an atomistic view so as to relate the various types of metals to the periodic table. He goes on, for what is the largest section of the book, to treat the electrons as a fluid with increasing complexity, from the single-particle model to Bose condensation and superconductivity, before introducing the atoms back into the problem for a general review of cohesion and electron transport in metals.

A very large part of metal physics is covered at a fairly elementary level but this book suffers, however, from a number of major faults, which are inherent in this format. If one is to have a qualitative discussion of fairly sophisticated concepts it is necessary to provide a framework as simply and as early as possible. In the standard textbooks this would be achieved by either reference to the interplay between experiment and theory, which led to those concepts, or through a sufficiently simple model of a real metal that could be modified as one progressed in understanding. Neither of these has been followed by the present author and the simple single-particle model, on which the major part of the understanding of the electronic theory of metals can be based, is left until the final chapter. This means that many of the concepts, and indeed technical jargon, receive only the briefest mention on their initial appearance and the reader is constantly being referred forward to the later chapters. This would not necessarily be fateful, but coupled with the emphasis in large parts of the earlier parts of the book on the exception rather than the rule (as in, for instance, assymmetric scattering of electrons by impurities) must lead to terrible confusion for the beginner.

In general, although it does contain some very good non-mathematical descriptions of complex phenomena, this is not a book I would recommend for anyone without a good grounding in solid-state physics. **J. C. Inkson**

obituary

Dorothy Wrinch was born in Rosario, Argentina, on September 13, 1894 and died very recently on February 17, 1976 at Falmouth Hospital (Massachussetts). She was a brilliant and controversial figure who played a part in the beginnings of much of present research in molecular biology.

Her father was Hugh Edward Hart Wrinch, an engineer, and her mother, Ada Soutar. She was educated at Surbiton High School and won a scholarship to Girton College, Cambridge, where she read mathematics—she was a Wrangler in 1916—and moral sciences. She was appointed to a lectureship in pure mathematics at University College, London, in 1918 and became the first woman ever to receive a D.Sc. from Oxford (1929). In the early 1920s she was one of a brilliant circle of mathematicians and physicists, among her friends were Dora Black and Bertrand Russell, whom she introduced to each other. In 1922, she married John William Nicholson, FRS, then a fellow of Balliol College, Oxford, and well known for his work on atomic structure. The marriage became more and more unhappy as his mental state deteriorated; it was finally dissolved in 1937 leaving Dorothy with one daughter, Pamela. From 1922 until 1939 Dorothy Wrinch lived mainly in Oxford, holding various research fellowships and a lectureship and tutorship in mathematics at Lady Margaret Hall and Somerville College. In 1939 she took Pamela to America where she met and married, very happily, Otto Glaser, Professor of Biology at Amherst, and spent the rest of her life in the USA, holding appointments in mathematics and physics at Amherst, Smith and Mount Holyoake until she retired to Woods Hole, which she greatly loved.

Until 1932, Dorothy Wrinch's research work was all in the field of pure mathematics, particularly classical analysis. In 1930, she turned towards biology and set herself seriously to study the facts of elementary biology and chemistry by attending courses in Vienna and Paris during her sabbatical terms. She then began to seek for mathematical solutions to the problems she found, particularly of the structure of chromosomes, including nucleic acids and proteins. It was the properties of protein films that first suggested to her that peptide chains should be polymerised into sheets, by links between CO and NH groups to which she gave the name 'cyclol'. Folding the sheets then gave her a beautiful series of closed octahedra and other solid figures, built of definite numbers, *n*, of amino acid residues; one series has the general formula $72n^2$. These provided an attractive explanation of many recent observations on proteins, for example, the limited number of sizes of protein molecules found by Svedberg's early ultracentrifuge measurements. When Bergmann and Niemann in 1937 deduced from chemical analysis that egg albumin had 288 residues in the molecule, the exact number required for the second member of the above series, 72×2^2, Dorothy Wrinch felt her hypothesis had been strikingly verified. The coincidence was extraordinary. Her infectious enthusiasm carried many with her: almost all the participants of the first Cold Spring Harbour Symposium on proteins in 1938 and, most notably, Irving Langmuir Her explanation of the first X-ray evidence on the structure of insulin positively encouraged others to take up the study of protein crystal structures, W. L. Bragg and David Harker among them. (Bragg used her version of the insulin Patterson maps as one of the illustrations in his last book.)

Gradually and relentlessly, after the war, chemical and crystallographic work proved that protein molecules did not have the cyclol structure. Yet many of Dorothy Wrinch's geometrical instincts and deductions were, in general terms, correct. The structures of protein molecules are *not* based on simple parallel arrays of peptide chains, yet the packing of molecules within the insulin unit cell *is* octahedral in character, there are patterns of close packed units over closed surfaces in many spherical viruses, even the 'cyclol' link itself sometimes exists, for example in the ergot alkaloids. This pleased her—she found it very hard to give up the cyclol theory as a whole. She maintained to the end of her life a strong interest in crystallography and in biology; the book she wrote at the request of her crystallographer friends on *Fourier Transforms and Structure Factors* is still very useful. And in old age she came again to Oxford to talk over the structure of insulin.

I like to think of her as she was when first I knew her, gay, enthusiastic and adventurous, courageous in the face of much misfortune, and very kind. **Dorothy Crowfoot Hodgkin**

Dorothy Wrinch's early work was in pure mathematics, with occasional excursions into philosophy. She helped with the proofs of the 1920 edition of Whittaker and Watson's *Modern Analysis*. She wrote papers on mathematical logic in the tradition of Whitehead and Russell and, in the early 1920s, a number of papers on hypergeometric functions and problems in classical mechanics. She and I published four joint papers in the Philosophical Magazine on the theory of scientific method. I should like to put on record my appreciation of the substantial contribution she made to this work, which is the basis of all my later work on scientific inference.

We also had a joint paper on the seismic waves from the Oppau explosion of 1922, which was the first co-ordination of seismic data with the structure of the upper layers inferred from geological evidence by Suess.

Every cow carries a government health warning

Coronary heart disease (CHD) is a major cause of death in middle and old age in the UK and many other western countries. For instance, in the age range 45–54 years, 39% of all male deaths and 12% of all female deaths are from CHD. Since 1950 death rates from CHD have increased consistently for men; the death rate is 60% higher in that same age range now than it was 25 years ago. Strangely, there is no evidence of a similar trend for women.

In the light of these and similar figures many countries have looked at ways in which the incidence of CHD might be reduced. A working party of the Royal College of Physicians of London and the British Cardiac Society has just issued the latest assessment, which will be distributed widely to general practitioners (*Journal of the Royal College of Physicians*, **10,** 213–275). It deserves to be read by scientists too, not just for the factual content but also as an example of a rather good blend of science and commonsense.

The report comes out unambiguously against major investment in more after-the-fact services which "cannot hope to achieve a major reduction in the overall burden of CHD in the community". Preventive measures against a disease with palpable environmental factors are, however, spelt out in considerable detail. They include stopping smoking, monitoring blood pressure whenever possible, changing diet and increasing physical activity (including "getting breathless some time every day"). Probably the most controversial of these suggestions, all of which have been floating around for a long time, is the fairly explicit talk of dietary adjustments. The recommendations are made, the report says, because plasma lipid levels in the UK indicate a population generally at risk.

Fat in the diet, it is recommended, should be reduced from its present average contribution of 42% of the total calorie intake to around 35%. Saturated fats (which at present constitute half of this contribution) should be particularly reduced, to be replaced in part by polyunsaturated fats. What this means is less meat and egg yolks, more poultry and fish; less butter, more soft margarine high in polyunsaturated fats; corn oil, sunflower oil and safflower oil, not hard margarines and lard; cream and top of the milk are to be avoided, vegetables and fruit encouraged. In fact all that one's instincts say, except in the case of dairy products.

Readers from overseas, particularly from the United States and Australia, can be forgiven a certain wry amusement at this point that at last the UK is starting to publicise what has been common knowledge for many years. The word "polyunsaturated", surely the most scientific word the layman will ever need to take into his vocabulary, was sufficiently well know as early as 1970 for the Massachusetts Heart Association to be distributing leaflets to all homes asking: "Will your children remember your tasty meals, low in saturated fats and cholesterol?"

Why has it not been possible for similar exhortations (perhaps a touch less ham-fisted) to be made in Britain, and why has a major manufacturer of polyunsaturated margarine had till recently to pursue publicity for his product by unconventional means? (Not, it should be said, that it took more than a day after the report's appearance before perfectly explicit advertisements were appearing.)

Part of the answer may be in genuine scientific doubt, not so much about the role of unsaturated fats in raising plasma cholesterol levels, nor even about the correlation between cholesterol levels and the risk of CHD, but concerning the value of lowering plasma lipid levels by dietary change in trying to reduce CHD. The report itself cautiously concludes that there is "probably sufficient evidence . . . to make dietary recommendations in the hope of affecting a degree of prevention". Not, it must be admitted, the most gripping of cases.

But it is not the medical science so much as the sacred cow that has held things up. The dairy industry could be hit hard by dietary changes if the nation took them seriously—less meat, less butter, little cream. Small wonder that the issue has been carefully skirted in Whitehall for as long as possible, and small wonder that the National Dairy Council was quickly out fighting.

The publication of this report must not herald the start of some form of public relations war between rival products each of which will doubtless (such is the nature of the scientific literature) be able to marshal cast-iron evidence for its own point of view. The onus is on the Department of Health and Social Security to ensure that knowledge is diffused into the community rather than thrown at the citizen by interested parties. What is needed is a clear statement of the meaning of the scientific words and a relaively low-key assessment of the risks, followed by a requirement that advertisers state the contents of their product simply. □

Taking the naturalness out of natural disasters

Phil O'Keefe, Ken Westgate and **Ben Wisner** argue the case that disasters are more a consequence of socio-economic than natural factors

THE MEDIA continually present us with graphic accounts of natural disasters—the Bangladesh cyclone, the Nicaraguan earthquake and the African drought are just some of the recent examples of catastrophes that caused much death and destruction. Since the beginning of 1976, we have already had detailed accounts of floods in Venezuela, Australia and Indonesia, famine in Niger, landslides in Ecuador, drought in Malaysia and the mammoth earthquake in Guatemala. It is difficult to gather global information on the frequency and, more importantly, the impact of these disasters. But a set of global statistics from all available resources has recently been compiled.

The Disaster Research Unit at the University of Bradford has collected data from international organisations, government departments, academic institutions and insurance companies. The information was confused because most institutions recording disaster data had an implicit role in the disasters and their aftermath which coloured their recording. For example, the international and governmental organisations were chiefly concerned with disasters in which aid was being donated, academic institutions were primarily interested in recording unusual phenomena which might not necessarily be disastrous, while insurance companies only recorded information directly related to their business. In spite of the data's unreliability, several tendencies can be observed.

The most important tendency is an increase in the occurrence of disasters over the last 50 years. Figure 1 shows this increase from 1947–70 of large-scale disasters, that is, those disasters covering more than a ten-degree square on a world map and where damage exceeds $1 million. This tendency is paralleled by an increasing loss of life per disaster. The greatest loss of life per disaster is observed in underdeveloped countries, and there are general indications that the vulnerability of these countries in particular is increasing. Such conclusions clearly require further explanation.

Disaster marks the interface between an extreme physical phenomenon and a vulnerable human population. It is of paramount importance to recognise both of these elements. Without people there is no disaster. The two elements are basic to an explanation of an increase in the occurrence of disasters. No major geological or climatological changes over the last 50 years adequately explain the rise. There is little argument about geological change, but there has been much mystifying argument about climatic change, especially following the prolonged drought over the African and Asian continents. But no firm conclusion can be drawn about changing climatic conditions from available evidence. Randall Baker at the Development Studies School of the University of East Anglia recently reviewed all the evidence of climatic change in Africa, and offered the Scottish judgment of "case not proven". Even if some long-term change was observable it would not explain the increase in disaster occurrence observed in the data.

If it is accepted that there has been no major geological and climatological change in recent years, then it can be assumed that the probability of the extreme physical occurrence is constant. If the probability is constant, then logically the explanation of the increasing numbers of disasters must be sought in an explanation of the growing vulnerability of the population to extreme physical events. Ongoing research suggests that some radical rethinking on the nature of "natural" disasters is necessary.

Searching for water in Ethiopia.

It is known that the frequency of natural disasters is increasing especially in underdeveloped countries. Indeed, the increased vulnerability of people to extreme physical events can be seen as intimately connected with the continuing process of underdevelopment recorded throughout the world. As population continues to expand, and as resources continue to be controlled by a minority, the real standard of living drops for much of the world's population. This population is increasingly vulnerable to environmental variation as the process continues. Paul Richards of the Environmental Unit in the International African Institute recently emphasised this in his introduction to *African Environment: Problems and Perspectives:* " . . . just as natural processes such as lack of rainfall affect social structures", he argued, "so social processes such as economic 'development' can affect natural systems, 'causing' famine and soil erosion for example". He went on:

> "[I]n a continent where international ties of dependency, massive international labour migration and multinational companies prevail and in a world where growth does not necessarily mean development, and development does not necessarily bring enrichment or an increase in personal happiness, the ultimate cause of environmental problems may well be traceable to the structural imbalances between rich and poor countries and we would be right to replace the term *natural* with the more appropriate term *social* or *political* disaster".

These suggestions would strike the Guatemalan peasant as commonsense. The recent earthquake there is no longer identified as a natural event—the local inhabitants who survived are referring to the event as a "classquake". It is a view which reflects their broad experience. That experience is the basis for an explanation of their general plight in terms of a process, not of development, but of underdevelopment —a process which their increasing vulnerability reflects. Instead of moving independently (as one school of thought argues) from a state of undevelopment to development along the lines that the now-developed west has already done, Third World countries (says an alternative, radically opposed school) have in fact been moving retrogressively from a state of undevelopment to one of underdevelopment, in a process of "marginalisation" which is not so much separate from as the price of the west's development in an increasingly inter-

dependent world. As this has happened, the relatively deprived sectors of the populations within these countries have become even worse off.

The reality of this situation is shown in Figure 2. It is the poorest countries which tend to suffer most disaster strikes. This point ought to encourage precautionary planning to mitigate the effect of future disaster. Such precautionary planning needs to be totally integrated into planning for real development, which means the necessary concentration on the vulnerability of a population to future disaster can only be done successfully through an understanding of the marginalisation process. Emphasis on precautionary planning does not, of course, make unnecessary the valuable action invariably mounted in the aftermath of a disaster: in fact, the formation of the London Technical Group, which supplies accurate technical reports on the position after disasters and generally provides expertise on relief measures, is to be warmly welcomed. In the long run, however, precautionary planning would be more beneficial than relief work, since it would aim to consider and alleviate the causes and not merely the symptoms of disaster.

Successful precautionary planning, then. in focusing on the population's vulnerability, depends upon the identification of cultural attitudes towards the use of indigenous resources at local and regional levels, and the incorporation into development planning of strategies to mitigate disasters; precautionary planning should be seen as the insurance chapter in any development plan. The aim would be to raise the standards of life of people currently ill-placed to resist disasters because those standards are too low. The average "cost" of a disaster strike, a rather meaningless concept when the range of impact is so great, is about $20 million. It is sufficient to say that more than $1,100 million was spent on disaster assistance in 1973; and 96 countries of the world had less than this amount of resource capital as GNP in 1973. The time is ripe for some form of precautionary planning which considers vulnerabliity of the population as the real cause of disaster —a vulnerability that is induced by socio-economic conditions that can be modified by man, and is not just an act of God. Precautionary planning must commence with the removal of concepts of naturalness from natural disasters. □

High technology protectionism

Colin Norman reports from Washington on US efforts to control the export trade in strategic technology being stimulated by the era of "détente"

A REPORT which has so far received scant public attention, but which is now being closely studied in the Pentagon, contains a number of startling and disturbing recommendations for controlling trade in high technology goods between western nations and the Soviet Union. Prominent among them is the suggestion that the United States should apply tough sanctions against any country—including America's European allies—which passes potentially strategic technology to a communist country. It also recommends that the Department of Defense should keep a close watch on government-to-government scientific exchange agreements and that it should keep its eye on the training of people from communist countries at major institutes and universities in the United States.

The report, published by the Defense Science Board (DSB), a top-level Pentagon advisory group, is the latest in a series of outpourings of concern that the United States' lead over the Soviet Union in strategic areas of technology is gradually being whittled away by commercial sales of computers, electronic goods and similar items. Such trading has mushroomed in the past few years through the establishment of the Nixon-Kissinger policy of detente with the Soviet Union.

The DSB report, prepared at the request of senior Pentagon officials and written by a task force headed by J. Fred Bucy, vice-president of Texas Instruments, argues that national and international arrangements for controlling east–west trade have not been effective in preventing strategic technologies from leaking eastwards through commercial channels. It therefore argues for a new approach, including some harsh sanctions to prevent such transactions.

Trade between the United States and communist countries has been controlled since the beginning of the cold war by a mechanism operated by an office in the Department of Commerce called the Office of Export Administration (OEA). A company wishing to export a strategically sensitive product or technology, as defined in a document known as the Commodity Control List, must apply to OEA for a licence. The application is reviewed by an interagency committee composed of representatives from the Departments of State, Defense, Commerce, the Energy Research and Development Administration, and the CIA. Approval is given only to those transactions deemed unlikely to improve the Soviet Union's military capabilities.

A measure of western conformity in such matters is provided by an arrangement known as the Consultative Group Coordinating Committee (CoCom), consisting of representatives from NATO member countries, excluding Iceland but with the addition of Japan. CoCom maintains a list of restricted products similar to the US Control List, and its members have informally agreed to follow similar procedures in licensing exports to communist countries.

Although both the US Commodity Control List and the CoCom list have recently been brought up to date—during the height of the cold war they were said to contain such strategic items as brassieres and wigs—the DSB task force suggests that they still contain many products of little military value. Instead of wasting time on such items, the task force suggests that the list should be drastically shortened and more effort should be put into curtailing the transfer of vital design and manufacturing knowledge. Particularly close attention, it indicates, should be paid to deals involving the transfer of turnkey factories, products requiring sophisticated maintenance and operating information, and items resulting from a revolutionary technological advance.

The report argues that controls have broken down in recent years because "CoCom members have perceived less of a need to maintain strict controls while the opportunity for individual gain through the sale of technology to communist countries has increased. As a result, strategic technology has been transferred to communist nations through CoCom-sanctioned exceptions, ambiguous interpretations of lists, and, perhaps, conscious violation of CoCom agreements". The task force therefore suggests that the United States should try to bully CoCom countries into adhering to export control agreements by imposing "a sanction on any CoCom country that fails to control a specific technology, by restricting the flow of know-how in that technology to the offending country".

Another reason why controls have broken down, the task force argues, is that firms in some countries which import US technology promptly re-export it to the Soviet Union, in violation of international agreements. Though the United States already attempts to stop such transactions by blacklisting firms thought to be engaging in such practices, the task force argues that some strong-arm tactics are in order here, too. "A nation that allows strategic technology to be passed on to a communist country should be restricted from receiving further technology of US origin", it states.

Moreover, the task force suggests that the United States "should release to non-allied, non-communist countries only the technology we would be willing to transfer to communist countries directly". In that regard, the task force states that "of particular concern is the acquisition of high technology know-how by nations of the middle east, and the assimilation of know-how by nations of Western Europe that are not members of CoCom—principally Switzerland, Sweden and Austria".

Though the bulk of the report deals with transfer of strategic technology through commercial channels, it also notes that recent scientific exchange agreements between the United States and the Soviet Union have greatly increased the movement back and forth of scientists between those two countries. Such agreements, Bucy notes in a covering letter to the report, are potentially "an area of concern".

The task force, finally, comes up with a recommendation that the Department of Defence should conduct a "comprehensive study of active mechanisms for transferring technology that are beyond the normal scrutiny of export control administration", and that it should develop recommendations for "monitoring and controlling them". Among such mechanisms, the task force lists "the use of US citizens as consultants for key technologies by communist countries", "the participation of US citizens as principals in firms established outside the US and engaged in transferring embargoed technology and products to communist nations", and "the training of citizens from communist countries at the more significant laboratories of US technical institutes and universities".

The task force report was approved for publication by Malcolm Currie, Director of Defense Research and Engineering, which suggests that it at least has his general approval. An internal task force has now been established in the Pentagon to evaluate the report and to recommend if, and how, its recommendations should be implemented. ☐

USSR

Conditions on educational success

The Soviet Union's Five-Year Plan for 1976–1980 will make increasing demands upon the higher educational system. Vera Rich looks at what new degree regulations being introduced could mean for Soviet science

By 1980 the Soviet economy will require 9.6 million "specialists" and 11 million persons with higher educational qualifications in order to attain the envisaged levels of economic growth and technological expansion. Hardly surprising, then, that considerable attention is being paid to problems of streamlining and improving the Soviet education system, particularly in the higher echelons; but a review of the method of awarding higher degrees is producing changes which can only be regarded as worrying.

The degrees of Candidate of Science (roughly equivalent to PhD) and Doctor of Science are not awarded by the Universities, but the Ministry of Education; Universities and Research Institutes make the necessary recommendations, but the confirmation is by no means automatic. The body which assesses the recommendations and awards degrees is the Higher Qualifications Commission (*Vysshaya Attestatsionnaya Kommissiya*, VAK) of the Ministry.

On January 1 of this year, however, new regulations came into force, introducing a major reorganisation in both the structure of VAK and its operation which must, inevitably, reflect on the whole structure of Soviet research and the academic establishment. According to Professor V. G. Kirillov-Ugryumov, the Chairman of VAK, in a recent *Pravda* interview, these changes are not merely of an administrative nature; they also have a qualitative significance. The status and "potentialities" of VAK have been extended. Requirements have been raised regarding the level of qualifications and, consequently, on entry into a scientific career.

In its reorganised form, the administration of VAK will be in the hands of a Plenum, a Presidium and a "College", in whose work leading scientists and specialists will participate. There are to be 34 councils of experts dealing with the principal lines of research, and also some 500 "specialised councils" for assessing degree theses, 150 of these councils being entitled to deal with Doctoral degrees. The Presidium and "College" of VAK have been operating since May 1975, and the first session of the Plenum met last July, but the establishment of the councils is not yet complete, although it is hoped to have them all fully organised by June of this year.

Regarding the "qualitative" changes, the new regulations, says Professor Kirillov-Ugryumov, will demand a higher standard in the theses submitted, and the postulants themselves will also have to meet certain more stringent requirements. The new regulations require that they should "combine a profound professional knowledge with a mastery of Marxist-Leninist theory, and with the convictions of an active builder of communist society".

Courses in political theory and participation in practical "community activity" have always formed a *de facto* compulsory part of Soviet higher education, but the student body and even the staff have tended to regard them as a necessary chore demanding little more than their physical presence. Hitherto the Soviet educational system, although Party-orientated, has permitted a certain number of non-Party scientists to rise to considerable academic heights (Academician Sakharov being the most notable example). The new stress on the political outlook for higher degree postulants, in which their "community and political activity" as well as their scientific knowledge is taken into consideration, and the presence of Party and trade-union representatives on the "specialised councils", suggest that these days may be over, and that the non-Party element in science will gradually be phased out.

Significant, too, is the fact that almost all Professor Kirillov-Ugryumov's comments on the "distinguishing features" of the new regulations deal with these political aspects, on the academic side he notes merely that all exemptions from the examinations for the degree of Candidate and other "weaknesses" of the existing system will be eliminated, and that a higher standard will be demanded from the "official opponents" in the formal defence of doctoral theses.

Although the new regulations had not been published at the time of their introduction (a booklet of the full text is promised), their content and implications were well-known in Soviet academic circles some months in advance. As early as August 1975, reports from dissident sources were affirming that, under the new system, from 1985 onwards no non-Party member would be able to hold a major academic or scientific post, so that students wishing for a successful career in science would be well-advised to take steps to enter the Party ranks (via the Komsomols) at their earliest opportunity.

Politically speaking, the new emphasis on *partiinost'* does make a certain amount of sense—it was precisely the participation by the non-Party scientists that gave the dissident movement its real strength and significance. Scientifically speaking, however,. while the new regulations may, in Professor Kirillov-Ugryumov's words, reflect a "qualitative" change, historical parallels would suggest that it is one which, in the long run, could be detrimental to Soviet science as a whole. ☐

ITALY

Trieste still troubled

Gillian Boucher reports from Trieste on the threat facing an international institution supported by funds from diverse sources

The International Centre for Theoretical Physics at Trieste is threatened with a serious cut in funds which, if not compensated by money from other sources, could result in its closure. What is in jeopardy is the contribution from the United Nations Development Programme (UNDP), which was to have provided nearly one-fifth of the 1976 budget of $1.2 million. UNDP provides funds for specific scientific activities: the regular programmes on solid state physics and applied mathematics. Since an irreducible 35% of the total budget goes on overheads, cutting out UNDP support would mean an enormous reduction in the scientific work of the centre.

Disaster almost struck just before Christmas when the centre received a cable from UNDP announcing that no money would be available for the course (then due to start in three weeks' time) on the interaction of radiation with condensed matter, and that the sum for the 1976 mathematics course would be halved. Fortunately the centre had in writing UNDP's previous promise to support these courses, and managed to persuade UNDP that it was impossible to cancel the solid state course. Funding for the course was restored 17 days before it began, but the cuts for next autumn's mathematics course remain.

More serious is the likelihood that UNDP funds will soon dry up altogether. UNDP has been suffering badly from inflation and from the failure of some countries, notably the USA, to pay up. Its projected shortfall for 1976 of $100 million means cutting back on many projects, and Trieste is a likely victim. Trieste is also likely to be hurt by the growing proportion of UNDP funds being assigned to individual nations rather than international projects.

The centre has always found living with UNDP a precarious business: meetings and courses have to be planned two years ahead while UNDP commits itself for only a year at a time. The Swedish International Development Authority, which provides the bulk of the funds to support the centre's Associates (scientists from less developed countries who come to do research at the centre three times in five years for up to three months at a time), also votes funds annually More stable are funds from the Italian government (currently providing $350,000 a year) and the International Atomic Energy Agency (IAEA) ($225,000 a year), which votes funds on a two-yearly basis. To ease planning headaches and reduce the "rampant feeling of uncertainty" among the centre's small technical staff, an *ad hoc* consultative committee did in fact report to IAEA last summer that the unstable UNDP contribution should be taken over by the centre's stable sources of income

With luck that is what will now happen. IAEA and UNESCO have recently expressed a wish to compensate the centre if UNDP funds dry up, and are proposing to increase their funding to $450,000 and $300,000 respectively Two potential problems seem to have been overcome The first was that the IAEA contribution has been no greater than that of UNESCO since 1970, the year in which UNESCO first became a major source of funds IAEA has however now agreed that its contribution need not be fixed at the UNESCO level, and indeed that with UNESCO's current impoverishment such a rule would be absurd. The other difficulty was that UNESCO's policy has been to fund a project for no more than 10 years, after which other sources of income (primarily national governments) are supposed to have been found But there is now hope that the rule will change, as the committee studying it recently reported to UNESCO that it is outdated, a relic of the era of centres set up by regional bodies. Certainly it would be shortsighted in the extreme to apply the rule to a centre used by over 50 nations, most of them poor.

There should thus be no fundamental difficulty The centre's well-being will depend upon the attitudes of those attending the imminent executive board meetings of IAEA and UNESCO and their general conferences in September and November of this year. At Trieste there are worries particularly about Britain's representative at UNESCO, Sir Harold Thompson, who is likely to repeat his view that Trieste is eating up too large a slice of UNESCO's $1 million basic science cake, and may sway some of the Commonwealth countries. Ironically, at the same time that British scientists have provided the strongest support for Trieste and the backbone of its teaching, the British government, through the international agencies, has caused it great worries.

If the proposed increases are approved by IAEA and UNESCO the centre will be slightly better off than at present but will of course have to exist at this level of funding through the next four years' inflation. Next year is in any case bound to be a messy one because the present uncertainties about money make planning almost impossible. But this year's programme is the largest ever and it is hoped at least to maintain the present level of activity: three 3-month courses and around 1,000 scientists passing through each year. New ideas are being tried; this summer there is a science teaching programme designed in particular for those scientists whose backgrounds are so weak that they cannot benefit from the other activities of the centre. The emphasis of the centre is on science at all cost; two of the three senior administrators as well as several secretaries have recently been made redundant, with the inevitable result of reduced efficiency and some discontent among the remaining staff.

If the UNDP funds are not replaced by those from IAEA and UNESCO, the centre's director Abdus Salem would prefer it to close rather than to continue with a grotesquely reduced programme. Closure would be a tragedy. The centre educates, stimulates and boosts the morale of thousands of physicists from less developed countries, providing them with the sort of contact with their peers which any American or European scientist takes for granted. And it is really very cheap: its running costs are the equivalent of less than 1% of Britain's SRC budget. ☐

JAPAN

China energy link weakens

JAPAN'S energy policy still accords an essential role to oil, even though the crisis precipitated in 1973 showed it to be the most vulnerable of the industrialised countries because of its great dependence on oil imports. Like those countries, however, Japan is now having to cope with an emerging glut of oil, and in the last couple of months relations with one comparatively new supplier in particular appear to have changed.

The supplier is the People's Republic of China, with which the level of Japan's two-way trade last year reached a record $3,800 millions The two countries began their oil trade in 1973, and last year oil produced almost half of China's export earnings from Japan.

In January there were reports, viewed at the time rather sceptically by Japan's refiners and electricity companies, that China might buy over 60% more steel from Japan in return for Japan increasing its purchases of Chinese oil from 8 million tonnes last year to 10 million in 1976.

The following month, however, before any 1976 agreement was concluded, China advised Japan that its February shipment would be halved The same was expected for March as well, and one theory had it that supplies were being diverted to North Korea. When the first contracts were finally agreed in early March, the trend was confirmed: one of Japan's two major importing consortia agreed a 12½% cut. The other principal buyer has since contracted to take a 30% reduction. Japan's total imports of Chinese oil are thus unlikely to exceed 6.1 million tonnes, although there are options which, if exercised, would boost the total to 1975 levels.

It now appears that the February reductions merely anticipated the smaller contracts, and that the reductions themselves simply reflect Japan's oil needs at the present time (with the fact that China's oil is more expensive and less easily processed also playing a part). China may still be hoping to cash in on any upturn in Japanese demand, and might then be looking to offer longer-term oil contracts in return for the Japanese steel it now seems to want and which Japan's steel companies (shareholders in the oil importing consortia) are keen to sell. For the moment it is China's political upheavals which may preclude immediate progress on this.

IN BRIEF

Kissinger on sea law

Dr Henry Kissinger has urged the United Nations Law of the Sea Conference, now in the middle of its latest session in New York, to reach an early agreement, and has made suggestions to this end. Agreement was near on issues like the 200-mile economic zone and a 12-mile territorial limit, and on the continental shelf and protection of the marine environment, but, he said, the critical issues still to be settled concerned exploitation of deep sea beds, on which the USA's proposals were for an international sea bed resource authority, and arrangements for compulsory and impartial settlement of disputes. There was also the matter of marine research within the 200-mile zone. (The US Senate passed a bill at the end of last month to establish such a zone off its coasts; it gives fishing priority to Americans and requires foreign vessels to obtain permits.) Dr Kissinger said the various issues were linked: failure to agree on them could eventually lead to war.

Energy consumption down

Figures released in the last fortnight confirm that total energy consumption in both the United States and the United Kingdom has been falling, and for essentially the same reasons. Apart from a stimulated interest in energy conservation and the benefits of a comparatively mild winter, the chief factors responsible for the reduction in both countries have been higher energy prices and the industrial recession. The US figures reveal a 2.5% drop last year (4.8% over the last two years), while Britain experienced a 4.5% fall in the winter months of November, December and January. Oil consumption was down 5% in Europe and 1% in North America last year.

Middle East nuclear weapons

A report that Israel has an arsenal of 13 locally-made atomic bombs, decried in the Israeli press as speculation and part of a propaganda campaign by US officials favouring American arms supplies to Arab countries, provoked a response from Egypt's President Sadat last week on his visit to Italy as part of a European tour. He said he did not know if the rumours were true, but warned that Israel would have to face the consequences if it used nuclear weapons in the Middle East.

Conferring doubt

KENNETH MELLANBY

As money to support scientific research becomes scarce, it is right that we should scrutinise spending on what may possibly be fringe activities. Today a great deal which might go to pay salaries or to buy equipment is spent on organising meetings and conferences, and in paying the travelling and other expenses of those who attend. This can only be right if the scientists who attend these conferences do better research as a result. No one seems to have studied the "cost-effectiveness" of the scientific meeting.

Before the last war most of us seldom expected a grant and we went to conferences in our own countries or abroad at our own expense; if a small sum of money was available, it was received with gratitude and divided among a group of colleagues who gladly made up the balance out of their own pockets. Now most scientists expect the fullest public support, and there is even trade union pressure to insist that all shall receive the maximum government rate for the country visited, even if this is excessive, and even if poorer colleagues are denied a share of their costs. The total sum involved is substantial.

I would not deny that some conferences are fully justified; I think that they can be easily identified Thus I personally gained a great deal from a Ciba Foundation Guest Meeting convened in January 1966 by Dr T. A Quilliam of University College, London, on the apparently restricted subject of "The Mole; its adaptation to an underground environment". Some of us, all actively working with this animal, met for two days of papers and discussions. Most of the work described had not yet been published Everyone was interested in everything that was said, and all could enter fully into the extended discussions.

Another equally valuable, though slightly larger meeting was an Advanced Study Institute, sponsored by NATO, and organised by my colleague Dr N. W. Moore at Monks Wood Experimental Station in July 1965 Its subject was "Pesticides in the environment and their effects on wildlife". About 75 scientists, including the majority of those from all parts of the world who were actively researching in this field, met for a fortnight to compare notes Most of the papers dealt with unpublished material. Everyone was deeply concerned in the subject and able to contribute something useful to the discussion.

Thus it would appear that small, highly specialised meetings can be successful, and helpful to research I fear that the same cannot be said for the enormous international gatherings arranged by many learned societies. Here few papers contain anything new. Most of the speakers read a paper as a condition of receiving a grant. Many of those supported by public funds are absent from most of the sessions. Sometimes it is an opportunity for younger scientists to see and hear some of the elderly savants who may already possess legendary reputations, but unfortunately they often discover that their idols have tongues of clay.

It may be admitted that the public sessions of large conferences are unproductive, but it is suggested that the informal contacts, in the bar and elsewhere, justify the expense I cannot confirm this I have asked many colleagues whether they can honestly say that such contacts have ever had a major and productive effect on their research So far no one has given me an example. Contacts between working scientists are undoubtedly important, but large meetings with their social distractions may be the worst places for them to take place. The distractions may be fun, but why should they be enjoyed at the taxpayer's expense? The money could probably be better spent sending young and productive scientists on visits to selected laboratories ●

Incubator contamination

SIR,—Tissue cultures usually require a CO_2-in-air incubator to maintain the proper *p*H in the medium. When chemicals are introduced into the culture to test for their carcinogenic or mutagenic activity, potentially hazardous materials might be volatilised and released through the incubator vent.

Air from an incubator (37 °C) containing four large covered dishes, each of which held three smaller covered dishes containing about 50 μg of safrole in 8 ml of medium, was drawn through a bed of activated charcoal. The charcoal was treated with CS_2, and the eluate was analysed by gas chromatography. The concentration of safrole in the gases vented from the incubator was about 2×10^{-2} parts per 10^9.

Concentrations of such magnitude may prove to be insignificant, but investigators should be aware of this possible source of contamination. A partial solution to potential exposure of personnel may be achieved by connecting the incubator vent to an exhaust system (for example, an operating chemical fume hood) by large-bore tubing. This expedient will, however, neither prevent the release of potentially contaminated air into the laboratory each time the incubator is opened, nor eliminate the possibility of transmission of volatilised material from one dish to another within the incubator.

Angling right

SIR,—Kenneth Mellanby (March 4, page 7) is right to claim that anglers are responsible for the continued existence of the large quantity and good quality of freshwater fish in parts of the United Kingdom, particularly in England where the need to pollute is greatest.

In earlier and cleaner times, when fish were threatened by over-harvesting, 74 Angling Societies in London were the principal supporters of the Mundella Bill for the Preservation of Non-migrating Fish in England and Wales. It became law in 1878 (though not before jealous rows between the larger of the Societies and after fierce debates on whether or not to include a close season for the migrating species), and for the first time curbed the netting and marketing of "white fish", which by that time had reached wholesale proportions in the effort to feed fresh protein to a growing population.

Once refrigeration, Argentine beef and New Zealand lamb became available the pressure on freshwater food eased dramatically, and it is rare to meet anyone in this country who enjoys aromatically baked pike, grilled perch or the carp, once the favourite of the abbots. All three species are the equal of the salmon and infinitely superior to the pathetic offal-fed restaurant trout.

Today, as Mellanby emphasises, the danger is pollution in all its many and sometimes subtle guises, and it is curious how long it was before anglers organised themselves in a co-operative to spread the risk of the cost of bringing a Common Law action against interference of any kind with an established fishery. John Eastwood founded the Anglers Cooperative Association in 1948, and it has since won costs and compensation in almost a thousand cases of pollution, losing one on a technicality.

Science indicators

SIR,—It is often asserted that science ranks with politics at the bottom end of public esteem. But the survey conducted for the National Science Foundation in the US (March 18, page 184) discerned a remarkably favourable attitude toward science and technology among Americans. The survey found that 75% of the American public believes that science and technology have changed life for the better; a similar survey conducted in 1972 discovered that only 70% then held that belief. In addition, scientists and engineers were ranked second and third respectively in terms of occupational prestige—below doctors, but above ministers of religion. Businessmen ranked lowest.

As for the impact of science and technology, there seems to be a certain amount of ambivalence. Some 57% of the respondents said they think that science and technology have done more good than harm, while 31% said they believe the beneficial and harmful impacts are evenly balanced. Only 2% believe that science and technology have done more harm than good. By far the most frequently cited benefit was improvements in medical care.

When asked whether social control over science and technology should be increased, 28% of the respondents replied that it should, while 46% said they believe the degree of control is about right.

The results of the survey also conflict sharply with the popular belief that young people are particularly turned off by science and technology—the attitudes of people under thirty differed little from those of elders.

Mass and weight

SIR,—The introduction of the SI system of units presented a great opportunity to clarify the difference between the concepts of mass and weight. It is thus disappointing that the use of the word kilogram has already in common parlance become associated with weight rather than mass. This is illustrated in the jingle put out by the British Metrication Board which you quote in an example in Competition 6 (March 18, page 188).

Although in most cases weighing is merely a convenient way of determining mass and "weights" used with balance-type instruments are calibrated in mass units, it would have been preferable, for example, to express the contents of a jar of jam as net mass 453 g rather than net weight, as has become the custom. The widespread television coverage of space flights has well illustrated the concept of weightlessness and it should no longer be difficult even for children to appreciate the distinction between mass and weight.

The JPU in modern science

SIR,—D. Fraser is to be congratulated for his valuable concept of the JPU (Just Publishable Unit) presented in *Nature* (Correspondence, March 11). A more conservative measurement, however, is the JXPU (Just Xeroxable Published Unit), which may be defined as the smallest amount of published information normally considered worthy of xeroxing. An example being D Fraser's correspondence.

news and views

Ball lightning

from P. C. W. Davies

REPORTS of unusual aerial phenomena always attract great interest, are surrounded by folklore and superstition and irritate scientists who find them hard to explain. By far the most common such reports concern luminous spherical or ellipsoidal objects which appear without warning, often move through the air erratically, and disappear without trace, sometimes explosively. Each year, hundreds of eye witness accounts of such events are reported to local newspapers, the police and even military authorities. Occasionally the accounts are published in scientific books and journals, and several have appeared in *Nature* in the past few years When the events occur during adverse weather conditions they are often called ball lightning The invention of a precise name is somewhat misleading because it suggests that these phenomena are well understood. They are not. Indeed, so puzzling and bizarre are the properties attributed to these luminous balls that many scientists have preferred to deny their existence.

For the theoretical physicist, the hardest thing to swallow is that the balls are often said to be encountered inside closed, or nearly closed, structures. One spectacular report appeared a few years ago of a luminous sphere moving down the inside of an all-metal aircraft in flight. More frequently, witnesses claim to observe ball lightning inside their own homes.

One particularly alarming account of such an event is described by M. Stenhoff of Royal Holloway College, London University, in this week's issue of *Nature* (page 596). The case is particularly intriguing because the single witness, a lady living in the English Midlands, was able to produce material evidence in support of her story During the course of her unnerving experience, the witness claims she was struck full in the body by a blue sphere of light, which totally disintegrated her clothing at the centre of impact The dress she wore has a hole several centimetres across Surprisingly, she sustained little physical injury, complaining only of a burning sensation in her wedding ring when she instinctively brushed the object away.

Taken at face value, this report highlights the hazards surounding the present lack of understanding about these phenomena It is not at all clear, for example, that conventional lightning precautions are of any use against such things, or indeed that ball lightning actually has any direct connection with ordinary lightning. None of the several theories which has been proposed in recent years accounts for the properties of the luminous spheres completely satisfactorily. The most difficult part is to explain how they can remain coherent, stable and luminous for durations up to, apparently, some minutes. There is also the peculiar kinematic behaviour—in many cases the balls are said to move upwind, and even trail along beside aircraft travelling at several hundred m p.h. through the air. Electrical explanations based on ionic recombination fail to explain the long lifetimes. Various plasma theories have been published, but run into problems of stability. Even nuclear theories have been tried They would predict that the Midlands lady should be suffering from radiation sickness. Perhaps the most imaginative suggestion of all is that micrometeorites of antimatter are responsible!

One of the most promising theories is due to the Russian physicist Peter Kapitsa, who has proposed a model based on the existence of UHF electromagnetic waves produced by an ordinary lightning strike A standing wave pattern could then be created under some circumstances, which might then ionise the air in the region of an antinode, thus producing a luminous patch which could be sustained in energy by the external field. This theory certainly accounts for many of the enigmatic properties of the luminous balls, but is not completely convincing. It seems likely that some nonlinear, coherent electromagnetic process which is still not understood is regularly taking place in the atmosphere.

As always with transient aerial phenomena, scientific progress is hampered by lack of precise observational data Accounts often reflect the beliefs and perceptual distortions of the witnesses. In addition, the usual unreliability of the human memory for accurately recalling details of speeds, sizes, durations and so on makes any theorising based on random narrative evidence from the general public particularly risky.

The present unsatisfactory situation would be greatly improved if the aura of mystery and superstition surrounding unusual aerial events were dispelled. Good, detailed eye-witness reports of luminous balls are frequently made by competent observers such as airline pilots, but are rarely passed onto scientists. Instead many of them find their way into military files, where they are shrouded in a ridiculous secrecy. (Incredibly, the British Ministry of Defence continues to deny scientists access to their accounts of these events.) With proper cooperation between scientists and the public, particularly the local press, and the civil aircraft authorities, it would be possible to follow up ball lightning reports rapidly, enabling tests for radioactivity and so forth to be carried out. One sensible improvement would be for the Meteorological Office to draw the public's attention to the existence of this potential hazard, particularly during stormy weather, and request detailed reports. ☐

A hundred years ago

A CORRESPONDENT, Mr. F. Green, writing from Cannes, France, states that on the 8th instant, for the first time this year, he heard the Cuckoo in a valley amongst mountains sixteen miles to the westward of that place. The first time last year that he heard it in the same neighbourhood was on the 10th of April.

ON April 2 at 5.55 a.m., an earthquake was felt at Berne. Two movements took place from east to west. The duration at was two seconds; doors were opened, and church bells were rung by the shocks. In Neufchatel a strong detonation was heard; the oscillation was very strong in the lowest part of the city, and clocks struck the hour before the appointed time. Persons who where in the streets declared that warm wind was blowing for some seconds. A few hours afterwards a rain-spout occurred near Mainz, in Rhenish Hesse. A number of houses were struck by a thunderbolt and ignated, many others were flooded by the water falling from the mountains, and people drowned by an instantaneous flood.

Order and spacing of ribosomal RNA genes

from Benjamin Lewin

THE first system to be defined in which a large precursor RNA is processed to much smaller mature molecules was that of rRNA synthesis in eukaryotic cells; as early as 1966, Greenberg and Penman (*J. molec. Biol.*, **21**, 527–535) reported that a label in nucleolar RNA first enters a 45S species in HeLa cells and only later is found in 28S and 18S rRNAs. Since then it has become apparent that the 45S RNA contains the sequences of both the 28S and 18S RNA molecules, which together occupy about 7,500 nucleotides of its total length of 14,000 bases.

In bacteria the situation at first appeared to be different, with the 16S and 23S rRNAs each apparently transcribed independently, although their genes were located adjacent on the chromosome. But the isolation of an *E.coli* strain lacking a processing enzyme allowed Nikolaev, Silengo and Schlessinger (*Proc. natn. Acad. Sci U S A.*, **70**, 3361–3365; 1973) and Dunn and Studier (*ibid.*, 3296–3300) to isolate a 30S precursor molecule that contains both sequences.

How are the mature rRNA sequences organised within the precursor? In bacteria the sequences 5′ 16S–23S–3′ is generally agreed on the basis of the relative sensitivity of 16S and 24S RNA synthesis to inhibition by rifampicin (for example Doolittle and Pace, *Proc. natn. Acad. Sci. U.S A.*, **68**, 1786–1790; 1971). In eukaryotes the evidence has been conflicting although up to now it was generally held to favour the reverse order. In particular the identification of distinct secondary structure of the various rRNAs and their precursors in the electron microscope and the determination of polarity by digestion with a 3′ exonuclease, suggested that the 5′ end of the 28S molecule coincides with the 5′ end of the 45S precursor (Wellauer and Dawid, *Proc. natn. Acad. Sci. U.S A.*, **70**, 2327–2831; 1973). This seemed to be the definitive answer and a similar organisation for *Xenopus* 40S precursor was suggested by the same authors (*J. molec. Biol.*, **89**, 379–396; 1974).

But two recent experiments using different techniques suggest the opposite conclusion. Hackett and Sauerbier (*J. molec Biol.*, **91**, 235–256; 1975) inhibited RNA synthesis in L cells by ultraviolet irradiation. The irradiation causes transcription to terminate at damaged sites in DNA; the farther a gene lies from its promotor, the more likely it becomes that a terminating event will occur before its transcription is completed The pseudo-first order loss of 45S RNA as a function of ultraviolet dose confirmed that each gene for the precursor represents an individual transcription unit with its own promotor. The target size of the 18S cistron suggested by these experiments was about 4,000 nucleotides, just twice the length of the 18S RNA molecule. This suggests that a spacer of 2,000 nucleotides lies at the 5′ end of the 45S precursor, followed by the 2,000 nucleotides of the 18S sequence. The target size of the 28S RNA was 11,000 nucleotides; since the molecule is 5,500 nucleotides long, it must begin at a point 15,000 nucleotides after the end of the 18S RNA This leaves a distance of 3,000 nucleotides at the 3′ end of the 45S RNA, which must be part of the discarded sequences. The target size of the 32S precursor, the immediate precursor of 28S RNA, is the same as that of the 28S molecule; this suggests that the 32S precursor is adjacent to the 18S sequence, so that the 45S RNA has the structure:

$$5'\ \underset{\text{Spacer}}{\longleftarrow\!\!-\!\!-}\times\underset{\text{18S}}{-\!\!-}\times\overset{\text{32S}}{\underset{\text{28S}}{\longleftrightarrow}}\underset{\text{Spacer}}{-\!\!-\!\!\longrightarrow}\ 3'$$

Another approach to analysing sequence organisation has been taken by Liau and Hurlbert (*J molec. Biol.*, **98**, 321–332; 1975). The mature 28S and 18S RNA molecules are methylated on the 45S precursor, when only these sequences gain the methyl groups. The relative amounts of methylation of the two mature molecules are different, so that methylation could be used to identify the parts of the 45S precursor carrying these sequences. The experimental problem is to obtain identified fragments of the 45S molecule. Liau and Hurlbert generated suitable conditions by incubating Novikoff rat tumour nucleoli in the absence of nucleotides; this prevents elongation of polynucleotide chains, generating a series of incomplete precursor molecules of varying lengths starting from the 5′ end, which are methylated *in vitro*. The 18S methylation pattern is found in the shorter transcriptions and the 28S pattern is seen in the longer molecules.

One of the most satisfying conclusions to be drawn is that the same relative organisation of mature rRNA sequences within the precursor is seen in bacterial and eukaryotic systems. The smaller molecule precedes the larger, although more extensive spacer sequences have evolved in the eukaryotic systems. It seems clear that the relative locations of the 18S and 28S RNA sequences seen in the HeLa and *Xenopus* precursors by electron microscopy are indeed correct; but the polarity is reversed. The explanation seems to lie in the use of the exonuclease to determine the polarity of the RNA; clearly in the system used, the 5′ rather than the 3′ end must have been digested, perhaps by some contaminating enzyme.

What is the function of the spacer regions in the common precursor? Little information is available on the extensive spacers of the eukaryotic precursor, but the striking observation that a tRNA gene lies between the 16S and 23S sequences in an *E.coli* unit has been reported by Lund *et al.* (*Cell*, **7**, 165–177; 1976). The *E.coli* genome possesses several copies of the genes for rRNA, organised in transcription units that display the sequence 16S–23S–5S RNA (with the assignment of the 5S RNA to the end of the unit being less certain than the tandem arrangement of the 16S and 23S sequences). The transducing phage $\lambda rif^{d}18$ carries one of the sets of the genes for 16S and 23S RNA, as well as genes for some RNA polymerase subunits, ribosomal proteins, and a protein synthesis factor. When cells are infected with this phage, the synthesis of two small RNA species is greatly stimulated: one is 5S RNA and the other is $\mathrm{tRNA}_2^{\mathrm{Glu}}$. Where is the tRNA gene located? By showing that a radioactively labelled $\mathrm{tRNA}_2^{\mathrm{Glu}}$ molecule could hybridise to a phage DNA deleted for the 23S sequence, but could not hybridise to a phage DNA where the deletion extended from the 23S sequence into the 16S sequence, they were able to conclude that the gene for the tRNA must lie between the genes for the 16S and 23S RNAs (Yamamoto, Lindahl and Nomura, *Cell*, **7**, 179–190; 1976). This location was confirmed by Wu and Davidson (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 4506–4510; 1975). in experiments utilising a new technique for visualising RNA–DNA duplex regions formed along a single strand of DNA.

An obvious question is whether this form of organisation is seen in all the 16S–23S transcription units of the bacterial genome. Lund *et al.* (*op. cit.*) examined the transducing phage $\phi 80 rif^{r}$, which also carries an rRNA transcription unit, and showed that it is homologous with the $\lambda rif^{d}18$ phage over most of the bacterial sequences except for 310 base pairs between the 16S and 23S rRNA sequences. This means that the internal spacers are different in the two transcription units. When cells are infected by $\phi 80 rif^{r}$ $\mathrm{tRNA}_1^{\mathrm{Ile}}$ is synthesised, and Lund *et al.* have confirmed that its gene seems to lie within the spacer region. At least two of the rRNA transcription units of *E.coli* therefore possess a (different) tRNA sequence; whether the other (approximately 5) units also carry tRNA sequences remains to be established. What function in bacterial protein synthesis might be served by this coupling is not yet clear, although it seems to have the consequence that the tRNA coded with the rRNAs is synthesised in large amounts (both $\mathrm{tRNA}_2^{\mathrm{Glu}}$ and $\mathrm{tRNA}_1^{\mathrm{Ile}}$ are among the

---

The Red Queen lives

from Leigh Van Valen

When the Red Queen heard of her reported dethronement (Hallam, *Nature*, **259**, 12–13; 1976), she smiled from her throne and said, "As Mark Twain remarked on a report of his death, I find the report somewhat exaggerated".

One side of a controversy is often convincing until the other side appears. Hallam primarily based his conclusion on two recent papers of Salthe and Sepkoski; my response to these has not yet been published and will be part of a broader discussion For now I summarise my comments on the points Hallam discussed.

There are several possible hypotheses to explain the law of constant extinction, which produces a linearity of the survivorship curves of adaptively similar groups on a semilog plot. One is the Red Queen's Hypothesis, that the sum of absolute fitnesses in a community is constant. Another, used by Raup *et al.* (*J. Geol.*, **81**, [for 1973], 525–543; 1974) in their simulations and which I call the Field-of-Bullets Hypothesis, is that the probability of extinction is constant for all groups at all times. This hypothesis is unlikely (Van Valen, *Evol. Theory*, **1**, 1–30; 1973; *Nature*, **257**, 515–516; 1975). A third hypothesis, which Salthe (*Paleobiology*, **1**, 356–358; 1975) proposed and which may be called the Hypothesis of Triviality, is that any reasonable pattern of causation leads to near linearity and so no specific explanation is appropriate. There are several problems with the Hypothesis of Triviality, but it would seem to be disproved by the existence of a few systematically non-linear survivorship curves. That such deviations from linearity have known no possible particular explanations (Van Valen, *Evol. Theory*, **1**, 1–30; 1973) merely accentuates their reality. Simpson (*Tempo and Mode in Evolution*; 1944) used a phenomenon equivalent to part of this exceptional non-linearity as the basis for distinguishing what he called bradytely and horotely as more or less discrete evolutionary modes. Horotely is intimately related to linearity or survivorship curves.

Sepkoski (*Paleobiology*, **1**, 343–355; 1975) in fact claims that most of the curves are non-linear and that the distribution of the lengths of stratigraphic units produces a bias that gives spurious linearity. However, the main result of this bias, when I apply my methods to his simulations, is a reduction in the proportion of bradytelic taxa that are identified, rather than a qualitatively false conclusion of linearity and homogeneity. Sepkoski's analyses were mostly of situations more extreme than the ones I used and most of his results have little bearing on mine. I originally excluded some data from any analysis because of related inadequacies. There are many kinds of inaccuracies involved in my analysis, some as yet unpublished, but none known to me seriously affect the predominant linearity of the curves.

The Red Queen's Hypothesis is ecological and does not depend on the linearity of taxonomic survivorship curves which served as midwife. Her domain is less than universal and may be empty: the hypothetico-deductive method is weak, and the sort of facts from which the hypothesis may be deduced are as yet only suggestively available. But the Red Queen is rather flexible, as a runner should be, and her domain may yet include much of evolution.

more abundant of the *E.coli* tRNAs). The processing of the transcript of the complete unit releases four RNA species, in the order 16S, tRNA, 23S, 5S RNA; the enzyme that appears to undertake this reaction is ribonuclease III and by showing that a deletion phage lacking the end of the 16S sequence can still generate 23S and tRNA sequences, Yamamoto *et al.* (*op. cit.*) were able to infer that the complete precursor sequence is not required for proper processing. This supports the idea that processing can occur before transcription has been completed. ☐

Nuclear charge distributions

from P. E. Hodgson

NEW measurements of the cross section for the elastic scattering of electrons by lead have recently cleared up an outstanding discrepancy concerning the charge distribution in the interior of the nucleus. It has for a long time been uncertain whether there is a dip or a hump in the middle of ^{208}Pb, and it has now been established that there is a small hump.

At first sight this result seems surprising. We know that the protons in the nucleus repel each other by their electrostatic charges, and this might lead us to expect a dip in the charge distribution in the middle of the nucleus. We must however think of the protons as occupying shell model orbits, and the total charge distribution is found by adding the squared moduli of the wavefunctions of the protons in all the occupied orbits. Now the wavefunctions of the protons in S-orbits, with zero orbital angular momentum, have a finite value at the centre of the nucleus, whereas the wavefunctions of protons in all other orbits are zero at the centre. The value of the charge density at the centre of the nucleus thus depends quite critically on the number of protons in S-orbits. In lead the protons in the 3S orbits have the smallest binding energy, and so we might expect that these form a hump at the centre of the charge distribution, and this hump is indeed given by most calculations of the charge distribution of lead, for example those made using the Hartree–Fock theory.

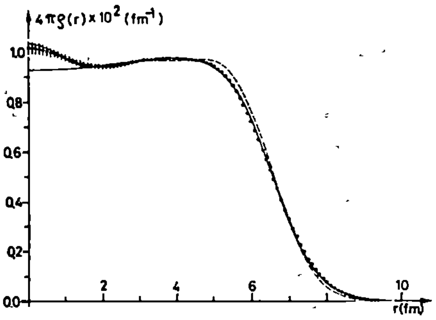
Until recently, however, the experimental determinations of the charge distribution have tended to give a small central dip, and this could not be reconciled with the theoretical result. There was however some uncertainty about this because of the difficulty of obtaining the charge distribution from the measurements of electron scattering.

Electrons only interact with the nucleus throughout their electromagnetic field, so if we scatter electrons by nuclei we should learn about the charge distribution of the nucleus. Unfortunately, although it is possible to calculate the scattering from a known charge distribution, it is not easy to reverse the calculation and obtain the charge distribution from the electron elastic scattering cross section Some quite sophisticated techniques have been developed to do this, and the differences between them account for much of the uncertainty about the form of the charge distribution in the centre of the nucleus.

The simplest method is to assume a suitable analytic form for the charge distribution and then vary its parameters to optimise the fit to the electron elastic scattering cross section. One of the most popular forms is the Fermi function $[1+\exp\{(r-R)/d\}]^{-1}$ which is uniform in the interior and falls rapidly to zero around the radial distance R, the steepness of fall depending on the parameter d. This was soon found to be insufficiently flexible, so it was multiplied by various polynomials such as $(1+wr^2)$, which makes it possible to introduce dips and humps in the interior.

Many analyses were made in this way, and it was often possible to obtain excellent fits to the scattering cross sections, but there was some doubt about the interpretation of the resulting charge distributions. It was realised that the scattering is most sensitive to the charge distribution in the 'knee' region at the surface of the nucleus, and the parameters are largely determined by the behaviour of the assumed charge distribution in this region, so that it is dangerous to assume that this gives us reliable information about the charge distribution in other regions such as the centre of the nucleus.

Much effort has therefore been devoted to the development of the so-called model-independent ways of determining the charge distribution from the scattering cross sections. Some of these use a series of concentric shells of charge, and adjust the densities of each, while others express the charge distribution as the sum of a series of terms each consisting of a suitable function of the radial distance, with different ranges and coefficients. Some important work of this type has been done by Friedrich and Lenz (*Nucl. Phys*, **A183**, 532; 1972) and Friar and Negele (*Nucl. Phys*, **A212**, 93; 1973), so that it is now possible to obtain the charge distribution without making any unduly restrictive assumptions about the form of the distribution.



The charge distribution of lead, as determined experimentally and by Hartree–Fock calculations. The experimental points correspond to the analysis of the Mainz data, the dashed line to the calculations of Vautherin and Brink using the Skyrme force, and the full line the result of an analysis using a three-parameter Fermi distribution that does not give an acceptable fit to the electron scattering data.

The new measurements that have recently been made to resolve the difficulty about the charge distribution in the centre of lead are due to the group of Professor Ehrenberg at the University of Mainz (Euteneuer, Friedrich and Voegler, *Phys. Rev. Lett.*, **36**, 129; 1976). They scattered electrons of 120, 200 and 290 MeV from lead, and analysed the results using a very flexible expansion of the charge distribution in terms of a series of spherical Bessel functions of various ranges. Their results, as shown in the figure, provide definite evidence in favour of a hump in the centre of the nucleus, in accord with the theoretical calculations.

This work shows how accurately we now know the charge distribution of some nuclei. There still remain some uncertainties, especially in the region of low densities at the edge of the nucleus, and this will doubtless be the subject of further studies using electrons of higher energies. ☐

Role for histone H1 in chromatin condensation?

from Tom Barrett

THE lysine-rich histone H1 is the most unusual of the five major histone species found in eukaryotic chromatin In contrast to the other histones which show a strict sequence conservation over a very long evolutionary period, the amino acid sequence of histone H1 varies to some extent (Rall and Cole, *J. biol. Chem.*, **246**, 7175; 1971). Its molecular weight (about 23,000 daltons) is greater than that of the other major histone species H2A, H2B, H3 and H4. It contains a very high proportion of basic amino acids; approximately 25% of the molecule is composed of lysine residues. It is the most readily removed of all the histone species in spite of its very basic charge and can be washed off chromatin with 0.5 M NaCl. Immunological studies have shown that its antigenic determinants are more available in native chromatin than are those of the other histone species. In percentage terms its immunological availability at 9.6% is considerably greater than that of the next most available histone—H2B at 3.2% (Goldblatt and Berstin, *Biochemistry,* **14,** 1689; 1975). Crosslinking experiments performed on chromatin show that histone H1 does not readily form complexes with other histones but rather forms H1 oligomers (Thomas and Kornberg, *FEBS Lett.,* **58,** 353; 1975).

These differences are highlighted by the fact that histone H1 is not required for formation of the characteristic bead-like structures, called ν bodies or nucleosomes, found in native eukaryotic chromatin. Nucleosomes consist of a histone core made up of two each of the four histones H2A, H2B, H3 and H4 associated with approximately 200 base pairs of DNA. Recent neutron diffraction studies indicate that the DNA is wound in a superhelix around the outside of this histone core (Baldwin *et al., Nature,* **253,** 245; 1975; Pardon *et al., Nucl. Acids Res.,* **2,** 2163; 1975).

Chromatin condensation

Since histone H1 is not involved in the formation of the basic nucleosome structure of chromatin its function must be independent of that of the other histone species. There is strong evidence that histone H1 is responsible for chromatin condensation. In dilute buffer solutions chromatin forms a viscous gel which contracts to a maximum of 10% of its original volume as the ionic strength is increased. Increasing the ionic strength above a certain level causes the chromatin to expand again as the histone H1 begins to dissociate from it. The release of H1 from chromatin is governed by the effective ionic strength of the cationic component of the salt, 0.5 to 0.6 M being the critical concentration for release of H1 (Bradbury *et al., Eur. J. Biochem;* **57,** 97; 1975). These authors have made an extensive nuclear magnetic resonance (NMR) study of histone H1 both in free solution and in chromatin under various ionic conditions. In ^2H_2O virtually all the H1 resonance spectrum can be seen but the signals are broader than those of isolated H1. Addition of salt causes the resonances to broaden until a concentration of 0.4 M salt is reached when the spectrum begins to sharpen. When 0.5 to 0.55 M is reached the H1 spectrum is fully developed with a marked increase in the intensity of the lysine resonances. Broadening of the peaks thus corresponds with the contraction of the chromatin gel. The contraction of the chromatin gel is not observed with H1-depleted chromatin. Spectra obtained for H1–DNA complexes are identical in nearly all respects with those obtained for chromatin under the same solvent conditions. The main difference is that the spectrum for the H1–DNA complex is not as broad as that of chromatin at low ionic strength and is evidence that there are more free H1 lysine residues in the complex than in chromatin. Probably one third of the lysine residues in the complex are free in these conditions in spite of the very high positive charge on the lysine molecule. The authors suggest that the addition of salt causes a structural change in H1 and/or reduces the repulsion between the DNA molecules, allowing them to approach each other more closely and bind the free end of the H1 molecule. In chromatin the other histone molecules are present and act to reduce the high charge on the DNA molecules.

Both the crosslinking experiments and the NMR resonance spectra indicate that in chromatin histone H1 is not associated with the other histones but is bound directly to the DNA. Structurally, histone H1 consists of an apolar-rich central region—residues 40 to 75—a short N-terminal end and a long C-terminal end rich in basic residues. The central apolar region is probably the site where the histone H1 molecules interact with one another. The long C-terminal end is the most basic region of the molecule and is probably the main site for the interaction of H1 with both free DNA and chromatin DNA (Bradbury *et al., Eur. J. Biochem;* **52,** 605; 1975). It has been reported recently that the aggregation of DNA molecules by histone H1 is much greater with superhelical DNA, irrespective of the sign of the superhelical turns, than with open relaxed DNA (Bottger *et al., Nucl. Acids Res.,* **3,** 419; 1976). Since the DNA in the nucleosome appears to be supercoiled around the histone core this structure would favour the interaction of histone H1 with the DNA.

Whether or not histone H1 is associated with the DNA wrapped around the nucleosome proper or to the DNA linking adjacent nucleosomes is not certain. A recent paper by Varshavsky *et al.* (*Nucl Acids Res.,* **3,** 477; 1976), however, lends support to the latter idea. They purified nucleosome monomers on sucrose gradients and on subsequent electrophoresis on polyacrylamide gels found two discrete types of nucleosome. The first contained all five histones associated with 200 base pairs of DNA, whereas the second lacked histone H1 and contained only 170 base pairs of DNA. They could also distinguish three types of dimer containing 0, 1 and 2 molecules of histone H1 respectively. They suggest that H1 is bound to a short (30 base pair) terminal stretch of nucleosomal DNA which can be removed by nuclease treatment, probably as a H1–DNA complex, without significantly disturbing the basic nucleosome structure.

Chromatin transcription

Histone H1 is absent or very much reduced in concentration in chromatin that is being actively transcribed. Calf thymus chromatin can be resolved into two fractions by chromatography on ETCHAM-cellulose. The first fraction to elute contains histone H1 whereas the second fraction is depleted in H1. This H1-depleted fraction is enriched in RNA polymerase binding sites and presumably corresponds to the active chromatin (Simpson, *Proc. natn. Acad. Sci., U.S.A.,* **71,** 2740; 1974). Using a different technique whereby Mg^{2+} is used to precipitate the condensed or inactive chromatin fraction, Gottesfeld *et al* (*Proc. natn. Acad. Sci. U.S.A.,* **71,** 2193; 1974) separated a soluble nucleoprotein fraction from rat liver chromatin. This fraction was enriched several-fold in transcribed DNA sequences and histone H1 was virtually absent. In the inactive, highly condensed chromatin of nucleated erythrocytes an additional histone species, histone H5 is present. In many respects H5 is similar to H1 and removal of both these histones from erythrocyte chromatin causes it to expand and resemble the uncondensed fraction of rat liver chromatin. Histone H1 seems to substitute equally well for H5 in the condensation of erythrocyte chromatin. It is probable that the highly condensed state of erythrocyte chromatin is not due solely to the presence of the erythrocyte-specific histone H5 but rather to a greater saturation of the H5 binding sites in erythrocyte chromatin. Reeck (*Arch. Biochem. Biophys.,* **172,** 117; 1976) could detect no H5-depleted regions analagous to the H1-depleted regions in calf thymus chromatin. In fact during the erythrocyte maturation process the concentration of H5 increases in parallel with a decrease in RNA synthesis (Billet and Hindley, *Eur. J. Biochem.,* **28,** 451; 1972).

There is good evidence that the other histone species are present in actively transcribed chromatin. The presence of nucleosomes on DNA does not seem to block its transcription. Lacy and Axel (*Proc. natn. Acad. Sci. U.S.A.,* **72,** 3978; 1975) isolated monomeric nucleosomes from rat liver chromatin and found that a further 46% of the DNA in the monomers could be digested. Analysis of the reassociation kinetics of the resistant DNA revealed that most, if not all, the genomic sequences were involved in this basic subunit structure and that virtually all the liver sequences transcribed into nuclear RNA were present in the nucleosomal DNA.

It appears that the histones act in two distinct ways to fold the DNA molecule in chromatin. First, the four histones H2A, H2B, H3, H4 form an octameric protein core around which the DNA is supercoiled. This results in a 7-fold contraction of the DNA but does not block transcription. Second, histone H1, when present, further condenses the nucleohistone and in so doing makes it unavailable for transcription. ☐

Active Mercurian dynamo unnecessary

from Peter J. Smith

According to measurements made recently by Mariner 10, the planet Mercury has a magnetic dipole moment of about 5×10^{22} gauss cm^3 (5×10^{18} A m^2), which is more than three orders of magnitude smaller than that of the Earth and over 10,000 times larger than the upper limit of the lunar dipole. But what is the origin of Mercury's magnetism? The maximum field observed in the vicinity of the planet by Mariner 10 was 400 nT which, being 20 times greater than the interplanetary field, led Ness *et al.* (*Nature*, **255**, 204; 1975) to rule out induction processes as a source. It seems more likely, therefore, that the field is of internal origin.

And of the various theoretically possible internal sources, Ness and his colleagues favoured a currently active dynamo in what would have to be a very large iron–nickel core. They tentatively rejected remanent magnetisation of parts of the planet on the grounds that it is "difficult to construct a plausible sequence of events leading to the model in which the Mercurian magnetic field is explained in [those] terms". Moreover, shortly before this, Runcorn (*Nature*, **253**, 701; 1975) had shown that the external dipole moment of a shell magnetised in the field of an internal dipole which has since disappeared is apparently zero.

But according to Stephenson (*Earth planet. Sci. Lett*, **28**, 454; 1976), remanent magnetism as the source of Mercury's dipole moment cannot be rejected so easily. His new analysis indicates that an outer magnetised shell will give rise to a residual dipole moment if there is a difference in permeability between the shell and the planetary interior or between the shell and free space. Assuming the Mercurian surface rocks to be similar to those of the Moon, it may then be shown that a magnetic shell could quite easily account for the observed dipole moment without invoking ancient magnetising fields of more than a few gauss, an iron content of more than a few percent, or a shell thickness of more than a few tens of kilometres.

In short, contrary to previous belief, it is not necessary to conclude from the magnetic field observations that Mercury still has an active dynamo. The internal source options remain open.

The illogic of conservation

from Peter D. Moore

It is difficult to be objective, or even rational, about conservation. This is especially true in situations where the conservationist is concerned with the continued survival of a species whose population has fallen to a critically low level. When the very existence of a species is threatened then the conservationist does have sound reason on his side, for extinction, and the depletion of the world's genetic resources which this represents, cannot be regarded dispassionately, yet in practice the attitudes of those who seek to guard the world's wildlife are often far more parochial and far less guided by logic than is normally supposed.

It is this criticism which John Gooders (*Brit Birds*, **69**, 16; 1976) has recently levelled at ornithologists. He believes that a disproportionate amount of concern and money is spent upon preserving isolated colonies of bird species in the peripheral areas of their global range simply because they are rare there and because the birdwatcher in the street has a consuming interest and is therefore willing to spend money on propping up rarities, even if they are common elsewhere in the world. Certainly it is not difficult to find examples of this kind of behaviour on the part of British birdwatchers. Gooders quotes such birds as the snowy owl (*Nyctea scandiaca*), osprey (*Pandion haliaetus*) and avocet (*Recurvirostra avosetta*) all of which are widespread globally and are far from being a threatened species and yet which have received an inordinate amount of attention from British ornithologists because they have recently been able to invade, or reinvade, these islands as breeding birds. Would we not do better, Gooders argues, to concentrate on our ornithological resources which are truly of international importance, particularly in the conservation of such habitats as our estuaries which are vital for many species of wildfowl and wader.

One must sympathise with Gooders' view, and it is true that the British are not alone in this parochial attitude, nor is it confined to the ornithologists. In Estonia biologists pride themselves on having the mute swan (*Cygnus olor*) as a breeding species and avidly protect the single Soviet site where the cross-leaved heath (*Erica tetralix*) is found growing (the species is abundant in more oceanic areas of western Europe). The Norwegians take delight in the gorse effort in trying to rid himself of the same species. The British botanist (*Ulex europaeus*) which just maintains itself in the south-western parts of their country, whilst the British hill farmer spends much time and fervently defends the few British plants of the military orchid (*Orchis militaris*) yet the plant is relatively frequent in parts of central Europe.

Indeed, the botanist is probably more regionally orientated than the ornithologist; the old county boundary is often his horizon. The Kentish man is proud of bog asphodel (*Narthecium ossifragum*) because it is rare in the south east of Britain, though common in the west, and in what was Warwickshire the crowberry (*Empetrum nigrum*) is prized, having only one station in the county, yet it is common further north

But we can really expect more of mortal, irrational man? Can one really expect people to be concerned about species which may be threatened on a global scale and yet, for them, will never be more than a picture in a wildlife magazine? For the panda, or the tiger it may be possible, but for the bald ibis unlikely. The average subscriber to conservation bodies and fund-raising organisations cannot think in international terms because his main concerns are with the local situation. His reasons for desiring conservation are not coldly scientific but are aesthetic and emotive. ☐

V. R. Switsur & A. P. Ward

Radiocarbon Dating Research Laboratory, University of Cambridge, UK

Radiocarbon dates from excavations at the prehistoric Maya site of Cuello, Belize, indicate occupation around 2600 BC *in calendar years, antedating the hitherto earliest known occupation of the Yucatan Peninsula by some 1,700 yr and demonstrating that sedentary pottery-using communities in the Maya lowlands may be as early as any in Mesoamerica.*

WE report here a series of radiocarbon determinations which place the origins of Maya settlement and civilisation in the Yucatan Peninsula back in the third millennium BC, some 1,700 yr earlier than the first occupation known until now[1]. Dating of the early phases of occupation of the Maya site of Cuello indicates a sedentary pottery-using settlement there by 2,000 yr b.c., in radiocarbon years, 2600 BC on the basis of the bristlecone pine calibration of radiocarbon chronology[2].

Background

Maya civilisation flourished in the Yucatan Peninsula and the adjacent highlands and Pacific slope through most of the first millennium AD, the Classic Period of greatest florescence being defined by the existence of dated inscribed monuments at about AD 250–900. Before this was a Preclassic or Formative Period going back to the earliest sedentary settlement of the Maya area and Mesoamerica generally, and formally defined as beginning in 2000 BC when it succeeded the long Archaic Period[3].

During the Formative Period, settled village agriculture became the major means of subsistence in Mesoamerica, with the use of pottery beginning between 2,500 and 2,000 yr b.c., in highland and Pacific Mexico. On this base, complex societies arose towards the end of the second millennium BC, and the Olmec civilisation emerged in the Gulf Coast lowlands of Mexico after 1,200 yr b.c. The earliest evidence for settlement in the Yucatan Peninsula and Usumacinta basin to the east is based on a single radiocarbon date of 660 yr b.c., 850 BC on the bristlecone pine calibration (UCLA-1,437; 5382b 2,610±75 yr b.p.) from the earliest Real Xe phase of the occupation of the major site of Seibal, Guatemala[1], which had Olmec associations. The determinations listed below demonstrate the contemporaneity of occupation of the Maya lowlands with the Olmec to the west, and, in the priority of the earliest date, provide another possible source for Olmec culture.

Cuello

The Cuello site, located in northern Belize at approximately 18°05′N, 88°35′W, is one of a number of Maya ceremonial centres excavated over the period 1973–75 by the Corozal Project, a joint venture of the British Museum and Cambridge University. Excavations in 1975 (supervised by Pring) revealed a deep stratigraphic sequence in Operation 17B of plaster platforms and midden deposits with bedrock at ~4.70 m below ground level; the middens contained partially burnt wood which has been used for the bulk of the radiocarbon determinations reported here, although one date (Q-1,476) is directly associated with a burial. The determinations were carried out at the University of California (UCLA) by Berger and at Cambridge University by Switsur and Ward. The radiocarbon determinations were all carried out using gas proportional detectors filled with purified carbon dioxide produced by the oxidation of the specimens of partially burnt wood from the excavations. The samples were all rather small, and where they yielded insufficient gas for filling the counters, additional radioactively inert carbon dioxide was added. Each sample contained traces of plaster, and this was eliminated by treatment with dilute mineral acid. The calculated radiocarbon dates quoted are based on the 'Libby' half life for radiocarbon of 5,568±30 yr.

All of the samples relate archaeologically to the Formative Period, before the institution of the practice of erecting dated stone monuments, and thus no equivalent dates in the Maya calendar are quoted, although for purposes of articulating the Christian and Maya calendars, we accept the Goodman–Martinez–Thompson correlation.[3] Dates in calendar years BC are quoted here on the basis of the MASCA calibration and that recently advanced by Clark[4], and together with the radiocarbon determination, excavation level and associated ceramic complex are displayed in Fig. 1. Determinations for the upper part of the stratigraphic sequence (levels 1–14) were made at Cambridge, those for the lower part (levels 15–28) at UCLA; the two series are mutually consistent.

The uppermost levels (1–2) of the excavation Operation 17B contained material of the Early and Late Classic Periods (AD 250–900), overlying a plaster floor (3) which covered a sequence of Formative Period deposits[5]. Levels 3–5 contained pure Late Formative ceramics of the Cocos Chicanel ceramic complex and levels 6–8 Cocos material mixed with ceramics of the

Fig. 1 Radiocarbon dates from Cuello, Belize. The dates are ranged against a scaled stratigraphic diagram (left) and major period and ceramic complex designations. Dates considered archaeologically unacceptable are printed in smaller type.

preceding Lopez Mamom complex. A date for a sample of burnt wood from level 6 of 2,125±100 yr b.p., 175 yr b.c. (Q-1558) falls well within the accepted span of 300 BC–AD 250 for the Late Formative Chicanel sphere, and the calibrated date is close to the radiocarbon result.

Levels 9–12 contained Middle Formative Lopez ceramics mixed with those of the Early Formative Swasey complex. The result of ^{14}C determination for a small sample of burnt wood (which had to be diluted with inert CO_2 for counting) from level 12 yielded a date of 2,680±200 yr b.p., 730 yr b.c. (Q-1559), calibrating to ~910 BC. The formal lower limit of the Middle Formative has previously been interpreted as ~800 BC, but the Real Xe material from Seibal also has a calibrated radiocarbon date beyond this limit (of ~850 BC); consequently on the basis of the chronometric evidence we propose that the limit should now be taken as at least 1000 BC.

Apart from a pit (level 21) penetrating down through levels 13–26 and containing Lopez complex ceramics, and a burial (level 14) cut into the plaster platform level 13, all subsequent stratigraphic levels in the excavation contained ceramics of only the Early Formative Swasey complex, the first indisputably Early Formative material to be found in the Maya Lowlands.

Level 14, a grave containing a single burial with three pottery vessels and a block of flint in place of a skull, yielded a sample of burnt wood from which a date of 2,970±160 yr b.p., 1,020 yr b.c. (Q-1476) was obtained, calibrating to ~1275 BC. Levels 13, 15 and 16 were three superimposed plaster surfaces, below which, level 17, of occupation debris, yielded a further sample of burnt wood giving a date of 3,000±160 yr b.p., 1,050 yr b.c. (UCLA-1985a), calibrating to 1320 BC; the Cambridge and UCLA dates for these two closely spaced levels are mutually consistent.

Levels 20 and 22 each yielded a very small burnt wood sample, which were amalgamated to give a date of 1,140±100 yr b.p., a.d. 810 yr (UCLA-1985bc), calibrating to AD 820. This date lies in the Late Classic Period, and is not archaeologically acceptable in view of the association with Early Formative ceramics. The level immediately below, 23, yielded a burnt wood sample which gave a date of 1,700±60 yr b.p., a.d. 250 yr (UCLA-1985d), calibrating to AD 280. This date falls at the end of the Late Formative, and is again archaeologically unacceptable on the basis of the associated ceramics. Both UCLA-1985bc and UCLA-1985d are also out of sequence with the later dates Q-1558, Q-1559, Q-1476 and UCLA-1985a, and the earlier date UCLA-1985e, which are consistent with each other, the stratigraphic sequence and the associated ceramics. We must therefore set aside these dates, and suggest that later disturbance, natural or anthropogenic, brought xylic material into these early levels; excavation of a larger area of the site in 1976 may provide evidence of this postulated disturbance.

Level 28 was a primary midden containing large quantities of Swasey Complex pottery, mollusc shells, animal bones and carbon flecks. It was sealed by the unbroken superimposed plaster surfaces levels 26 and 27, and partly overlay a rough limestone surface (level 31), which together with the rest of the midden deposit rested on the old land surface, level 32. The midden was 25–30 cm thick over the whole area of the excavation and represents the debris from a substantial and undoubtedly sedentary occupation of the site. A sample of burnt wood gave a determination of 4,000±155 yr b.p., 2,050 yr b.c. (UCLA-1985e), calibrating to ~2600 BC.

In another excavation at the site, Operation 17C, a major building recently half-destroyed by bulldozing for road metal was found to date to the terminal phase of the Late Formative, ~AD 200–250, on ceramic evidence. A construction level (12) yielded a sample of burnt wood which gave a determination of 930±85 yr b.p., a.d. 1,030 yr (UCLA-1985f), calibrating to AD 1,050. This date is archaeologically unacceptable, and could have resulted from either root penetration when the site was abandoned after the Late Classic collapse of Maya civilisation[6], or from an archaeologically undetected phase of Postclassic activity at the site.

Below the structure, in a level (37) of occupation material overlying limestone bedrock, a sample of burnt wood was recovered which gave a determination of 3,180±195 yr b.p., 1,230 yr b.c. (UCLA-1985g), calibrating to 1520 BC. This gives an approximate date to a burial sealed by level 37 and lying in a pit cut into bedrock, which was accompanied by five pottery vessels[5].

Discussion

The six acceptable determinations from the Cuello site together document a Formative sequence which, at its latter end, is compatible with what is already known about Maya Lowland and Mesoamerican chronology, but which, at its beginning, takes the prehistoric occupation of the Yucatan Peninsula back well into the third millenium BC. Although no other site in northern Belize has so far yielded similarly early radiocarbon dates, ceramics of the Swasey complex, which we must date to roughly 2,000–1,000 yr b.c. or 2600–1250 BC, have been recovered in Corozal Project excavations from three other sites, Nohmul, San Estevan and Santa Rita, mixed with later material but clear evidence of occupation at this early date. The existence of intensive agriculture utilising man-made raised fields along river and swamp margins a few km to the west by the end of the Swasey phase, is indicated by a radiocarbon date of 1,110±230 yr b.c. (I-7877A) for a trimmed post associated with such fields, calibrating to ~1400 BC, and maize pollen from a core taken at Laguna de Cocos may date to ~1800 BC[7]. In addition a possible early lithic site has been reported at Richmond Hill (D. Puleston, unpublished) only 3–4 km from the Cuello site, and although it remains undated at present an association with the Swasey phase inhabitants of Cuello is possible.

Data from pollen cores taken from Laguna de Petenxil in El Peten, Guatemala, 150 km south-west of the Cuello site, have suggested an agricultural occupation of that region ~2,000 yr b.c. on the basis of radiocarbon determination Y-1285 of 3,990±160, 2,040 yr b.c., calibrating to ~2590 BC[8], and this, has been extrapolated on the basis of sedimentation rates to suggest possible human interference with the vegetation of Peten ~4,000 yr b.c. (F. Wiseman, unpublished). This last proposal is still speculative; the Petenxil determination is, however, consistent with those from Cuello, and sedentary agricultural occupation of several areas of the rainforest zone by 2500 BC now seems likely. Such a date would accord with the still contentious glottochronological date for the splitting off of the Mayan language group.

On a broader Mesoamerican basis the radiocarbon chronology for Cuello may be compared with those for the Olmec area and the Central Mexican highlands. The latter part of the Swasey phase as defined by UCLA-1986g, UCLA-1985a and Q-1476 overlaps within 1σ the Bajio, Chicharras and San Lorenzo phases of the major early Olmec site of San Lorenzo Tenochtitlan[9]: the range for Cuello is 1,420–860 yr b.c., for San Lorenzo, 1,430–780 yr b.c. on 14 determinations. This range also overlaps the Tlatilco 'Olmec' and the Ayotla, Bomba and Justo phases in the Valley of Mexico, where the 1σ range of 5 determinations is 1,350–850 yr b.c. (ref. 10).

In the Maya highland zone the site of Chalchuapa in El Salvador has yielded two widely spaced dates for the Early Formative Tok complex of 2,790±60 yr b.p., 840 yr b.c. (P-1551), calibrating to 1020 BC and 3,610±60 yr b.p., 1,660 yr b.c. (P-1807), calibrating to ~2050 BC[11]. The later of these overlaps the latter end of the Cuello triad at the 1σ level, whilst the earlier lies between and overlaps UCLA-1985e and UCLA-1985g on 2σ.

The earliest ceramics so far reported in Mesoamerica are from the Puerto Marquez site on the Guerrero coast[12] where a determination of 4,390±140 yr b.p., 2,440 yr b.c. (Humble Oil Co; no laboratory number quoted), calibrating to ~3160 BC was obtained for a level containing mainly unslipped pottery termed 'Pox pottery'. Similar pottery was found in the Purron phase in the Tehuacan Valley in highland Mexico and placed by interpolation of dates at ~2,300 yr b.c. (2970 BC)[13].

Earlier ceramics are known from north-western South America, from Colombia and Ecuador[14], and from Panama at 4,090 yr b.p., 2,140±75 yr b.c. (Y-585), 2750 BC[15]. This pottery includes sophisticated slipped wares, as does the Swasey complex, while the Pox and Purron ceramics are mainly unslipped; the sample of Swasey material currently available is too small for dogmatic pronouncements on its resemblance and possible relationship to either the South American or the Mexican pottery to be made. Since the dates for Pox, Purron and Swasey all overlap at the 2σ level, it is an open question as to whether the earliest ceramics in Mesoamerica come from the Pacific or Atlantic coasts, or from the intervening highlands, and whether they are autochthonous or of ultimately, and perhaps not distantly, South American inspiration.

We thank the Trustees of the British Museum, the Research Committee of the British Academy and the Leverhulme Trust Fund for funding the project, which was based at the Centre of Latin American Studies, Cambridge, and directed by N.H.

Genetic hypertension in rats is accompanied by a defect in renal prostaglandin catabolism

J. M. Armstrong, G. J. Blackwell, R. J. Flower, J. C. McGiff, K. M. Mullane & J. R. Vane

Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS, UK

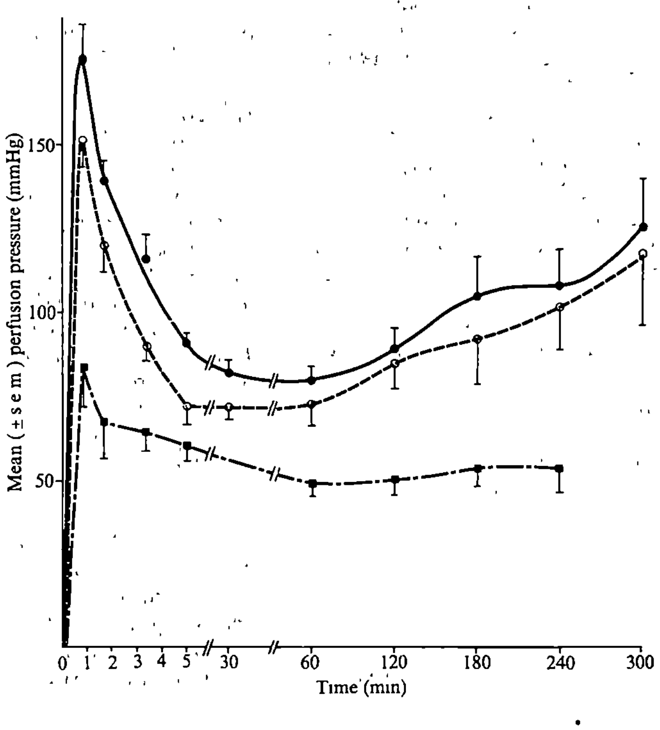
Noradrenaline releases prostaglandins in the kidney, and in rats these augment rather than reduce vasoconstriction produced by the amine. Homogenates of kidneys of New Zealand rats inbred for hypertension exhibit lower prostaglandin inactivation by 15-hydroxydehydrogenase than controls. At the same time, augmentation of noradrenaline vasoconstriction by the released prostaglandin is exaggerated. This biochemical defect could be the inherited abnormality primarily responsible for the development of hypertension in these animals.

In 1958 Smirk and Hall[1] reported that hypertension can be inherited in rats by selectively inbreeding animals with above average blood pressures. The strain which they developed, the New Zealand, genetic hypertensive (GH) rat has been studied extensively and similarities looked for between this model of the disease and essential hypertension in man[2]. The cause of hypertension is unknown in either species. Malik and McGiff[3] found that, in contrast to other species, prostaglandins of the E series cause vasoconstriction in the kidneys of rats. They also augment adrenergic transmission and potentiate the vasoconstrictor effects of noradrenaline. These results suggest that renal prostaglandins could contribute to the development of hypertension in the rat, as an increase in renal vascular resistance might be an initiating factor in the pathogenesis of the disease[4]. They also question the use of hypertensive rats as a model of human essential hypertension. Prostaglandin E_2 (PGE_2) is the principal renal prostaglandin (PG)[5,6] and is released from the kidney by pressor hormones[7,8]. We have, therefore, studied interactions of noradrenaline and PGE_2 in the renal vascular bed of normotensive and GH rats. Metabolism of PGs by kidneys from the two types of rat was also investigated to determine whether abnormal PG synthesis or degradation could contribute to the increased renal vascular reactivity which occurs in GH rats[9].

Male GH rats of the New Zealand strain of 17–19 weeks of age were used; their mean body weights (±s.e.m.) were 242.1±6.5 g and kidney weights were 1.56±0.04 g per pair. We used as control rats a Charles River strain which, like GH rats, originated from the Wistar strain. As the GH rats weighed less than normotensive control rats of the same age, kidneys were used from controls of either similar age (12 weeks) or body weight to those of GH. Systolic blood pressures, measured indirectly from the tails of rats anaesthetised lightly with ether before removal of the kidneys, were 160–190 mm Hg in GH rats and 110–130 mm Hg in normotensive rats.

Animals were anaesthetised with chloroform and the lower alimentary tract was excised after tying and severing the superior mesenteric, coeliac, spermatic and suprarenal arteries. Following intravenous heparin (100 IU per 100 g) and ligation of the aorta just below the coeliac artery stump, the kidneys were flushed with 5 ml oxygenated Krebs' solution by way of a cannula inserted into the abdominal aorta. The kidneys, attached to the cannula by the renal arteries and aorta, were rapidly transferred to the perfusion apparatus where they were hung from the aortic cannula in a covered water-jacketed glass container and perfused with oxygenated (95% O_2, 5% CO_2) Krebs' solution at 37 °C by a Watson–Marlow roller pump delivering 20 ml min^{-1}. This rate of perfusion flow, although greater than estimated by us to occur *in vivo*, has been found to prolong the useful life of similar preparations[10]. Furthermore, basal perfusion pressures were found to approximate more closely to normotensive blood pressures for rats *in vivo* (our unpublished observations). Perfusion pressure was measured by means of a Bell and Howell transducer placed proximal to the kidneys. The renal effluent was continuously assayed for PG-like activity by allowing it to superfuse in series a rat stomach strip, chick rectum and rat colon using the method of Ferreira and Vane[11]. Specificity and sensitivity of the assay tissues for PGs were increased by adding a mixture of pharmacological antagonists[12] and indomethacin (1–2 μg ml^{-1}) into the renal effluent before it superfused the tissues. Changes in length of the assay tissues were detected using Harvard transducers (type 386) and transcribed by a

Fig. 1 Graphs of mean pressures developed in the system at intervals after starting the perfusion of hypertensive or normotensive rat kidneys *in vitro*. Normotensives of body weight similar to those of GH were chosen as controls as their perfusion pressures were also similar. ——, Genetic hypertensive (n = 19); – – – –, Weight-matched normotensive (n = 12); – · – · –, Age-matched normotensive (n = 6). The number of preparations used in each group is given in parentheses.



Rikadenki KA-41 pen recorder. Drugs dissolved in saline were administered into a port situated proximal to the roller pump. Indomethacin was dissolved initially in 1 ml Tris buffer (*p*H 8) and the final concentration achieved by dilution with distilled water.

Selection of controls

Figure 1 compares changes, with time, of basal perfusion pressure of isolated kidneys of GH rats with those obtained from normotensive rats of either similar age or weight. The age-matched control group had a lower renal perfusion pressure, both at the start and at 5 h, than either the GH group or the weight-matched group. This difference could be accounted for by the differences in renal mass when identical rates of renal perfusion (20 ml min^{-1}) were used for the three groups. The kidneys obtained from GH and normotensive rats matched for body weight were comparable (1.6 g per pair), whereas those from age-matched normotensive rats weighed 2.3 g per pair, an increase in renal mass of about 40%. The heavier control kidneys had perfusion pressures which were 30–50% less than those of the other groups. Control rats were used with perfusion pressures similar to those of GH rats thus reducing the possibility that differences in vascular responsiveness between the two groups were a result of differences in basal tone of the vessels.

Release of PGs

Figure 2 is from an experiment in which different doses of noradrenaline were injected into the renal inflow. Dose-dependent increases in perfusion pressure were followed by the release of a substance which contracted the chick rectum and rat stomach strip superfused by the renal effluent. There was no effect on the rat colon. This pattern of activity could be matched by PGE$_2$ applied directly to the assay tissues. That PGs released from kidneys by noradrenaline were primarily of the E type, has been reported previously[3,13]. When indomethacin (1 μg ml^{-1}) was infused into the kidneys, the rises in perfusion pressure induced by noradrenaline were substantially reduced and there was no release of PGE-like activity[14].

Infusion of indomethacin into the kidneys of GH or control rats, although ensuring that its concentration in the superfusion fluid remained unaltered, was followed by relaxation of the assay tissues. This indicated that a resting output of PGE-like material had been abolished[15]. The level of basal release from the kidneys was estimated to be 0.1–1 ng ml^{-1} as these concentrations of PGE$_2$ were required to restore the tone of the assay tissues.

When PGE$_2$ was infused into the indomethacin-treated kidney, in amounts (100–300 pg ml^{-1}) which by themselves did not affect basal perfusion pressure, the pressor effects of noradrenaline were increased (Fig. 3*a*). This enhancement was sufficient to restore the effects of noradrenaline to pre-indomethacin levels. The potentiating effect of PGE$_2$ developed within 16–20 min and usually waned over a similar period after stopping the infusion The results of these experiments are summarised in Fig. 3*b*, *c* where changes in renal perfusion pressure produced by noradrenaline in GH and normotensive rats are shown, before and after inhibition of PG synthesis by indomethacin[14], the latter in the presence and absence of an infusion of PGE$_2$

Indomethacin usually did not affect basal renal perfusion pressure in normotensive rats, whereas in GH rats addition of indomethacin to the perfusing medium resulted in small reductions of 5–8 mmHg in perfusion pressure in 60% of these experiments. The failure of indomethacin to produce greater effects on renal perfusion pressure is consistent with the relatively small basal PG efflux from the rat kidney. Such small amounts would have marginal effects on basal tone but might still potentiate the renal vasoconstrictor activity of noradrenaline.

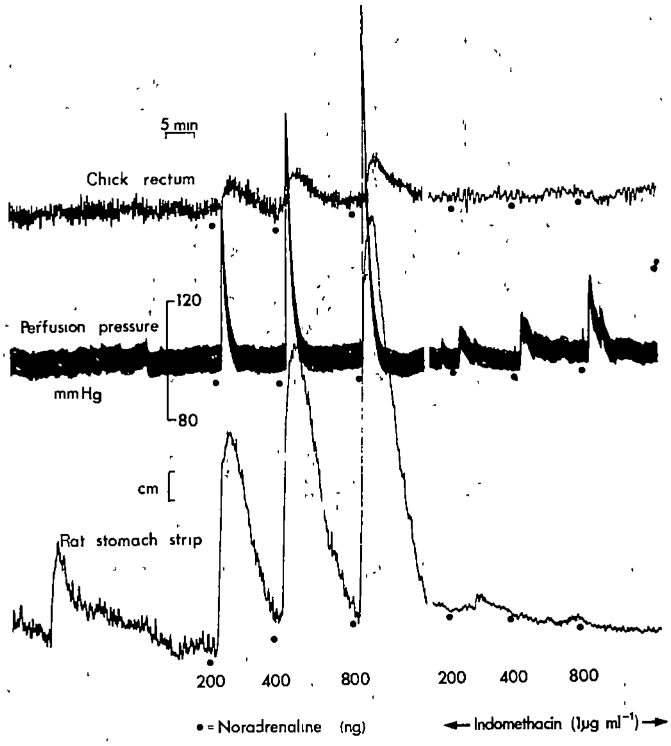


Fig. 2 The kidneys of a normotensive rat were perfused with Krebs' solution *in vitro* and the effluent allowed to superfuse assay tissues as described in the text. Indomethacin added to the perfusion fluid abolished the release of PGE-like activity, denoted by contractions of the chick rectum (top trace) and rat stomach strip (bottom trace), which normally accompanies the pressor responses (middle trace) evoked by noradrenaline. Moreover the rises in perfusion pressure produced by the amine were also markedly reduced in the presence of indomethacin.

In all these experiments we used the superfusion bioassay method to detect release of PGs by noradrenaline, to ascertain the effectiveness of indomethacin treatment in preventing release, and to determine the smallest dose of indomethacin which would achieve this effect. Since indomethacin inhibits PG dehydrogenase[16] and phosphodiesterase[17] in concentrations higher than those which affect synthetase, effects which by themselves could influence vascular reactivity, it was essential to select the minimal effective dose of indomethacin which inhibited prostaglandin synthetase. Our unpublished observations indicate that the concentration of indomethacin used (1–2 μg ml^{-1}) in this study does not substantially inhibit PG 15-hydroxydehydrogenase. These findings confirm those of Pace-Asciak[16].

Comparison of the vasoconstrictor responses to noradrenaline administered by injection in random sequence revealed that the renal vasculature of GH rats, compared with that of normotensive rats, was about 50% more sensitive to noradrenaline and was more susceptible to indomethacin-induced attenuation of the constrictor action of noradrenaline (Fig. 3*b*, *c*). In normotensive rats, PGE$_2$ (100–300 pg ml^{-1}) restored to pre-indomethacin levels the depressed renal vasoconstriction to doses of noradrenaline of 200 ng or greater, but not to low doses (50–100 ng). In contrast, similar concentrations of PGE$_2$ restored renal vascular reactivity of GH rats to low doses of noradrenaline, whereas restoration of responses to pre-indomethacin levels was incomplete to doses of the amine greater than 200 ng. The latter was related in part to the greater reduction in renal vascular responsiveness to noradrenaline produced by indomethacin in GH rats. Thus, the magnitude of PGE$_2$-induced potentiation of doses of noradrenaline greater than 100 ng in the presence of indomethacin was similar in both types of kidneys. The failure of exogenous PGE$_2$ to restore

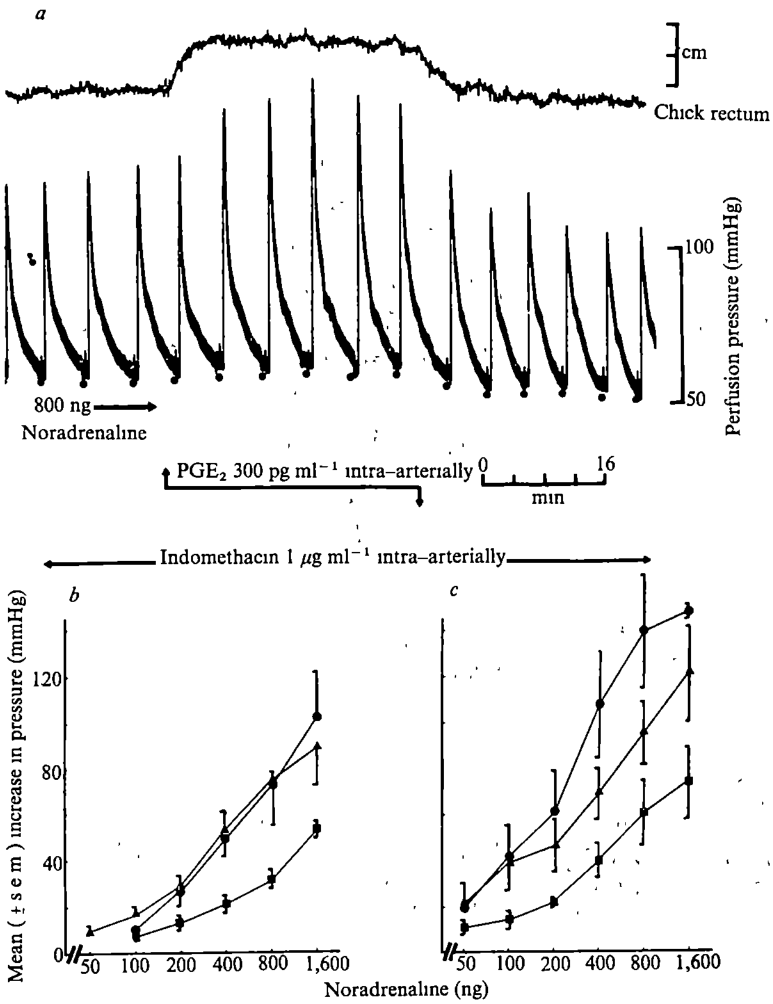

Fig. 3 *a*, Changes in perfusion pressure in response to intra-arterial noradrenaline (800 ng) injected at the dots, into the kidneys of a normotensive rat perfused *in vitro* with Krebs' solution containing indomethacin (for method see text). PGE_2, in amounts subthreshold for vasoconstriction, potentiated the vasoconstrictor responses to noradrenaline. The potentiation declined after withdrawal of the PG. *b*, *c*, Dose–response curves relating the vasoconstrictor responses to various doses of noradrenaline injected into the kidneys of normotensive (*b*, n = 7–10) or hypertensive (*c*, n = 7) rats *in vitro*. Addition of indomethacin to the perfusion fluid reduced in either group responses to each dose of the amine used. Thereafter infusion of PGE_2, in amounts subthreshold for vasoconstriction, augmented responses in either group. ●, Initial; ▲, indomethacin + PGE_2 (100–300 pg ml^{-1}); ■, indomethacin (1–2 μg ml^{-1}).

vasoconstrictor responses to noradrenaline may perhaps be a consequence of a reduced protein synthesis *in vitro* which would lead to lowered dehydrogenase concentrations[18] and thereby less potentiation than one would otherwise expect.

Of the other PGs identified in the rat kidney[5], $PGF_{2\alpha}$ in concentrations up to 10 ng ml^{-1} did not affect the renal vascular responsiveness to noradrenaline, whereas PGD_2 resembled PGE_2 in its ability to potentiate the amine.

The finding that kidneys of normotensive rats were less sensitive to inhibition by indomethacin of the vasoconstrictor action of noradrenaline could indicate that a smaller contribution was made by released PGs to the vascular effects of the amine than was the case in GH kidneys. Indomethacin caused a larger absolute reduction in vascular reactivity to noradrenaline in kidneys of GH rats than in those of normotensive rats, the renal vasoconstrictor responsiveness to noradrenaline was least in normotensive rats after indomethacin treatment. The difference which was revealed by indomethacin between the kidneys of GH and normotensive rats in their vascular responses to noradrenaline, that is, when the contribution of PGs was eliminated, is important since it indicates that other factors, such as structural changes in the vascular wall[19], also contribute to the increased vascular sensitivity to noradrenaline in GH rats.

Renal PG metabolism

Our results suggest that increased renal vascular reactivity to pressor hormones in the GH rat[20], could result partly from elevated levels of PGs Indeed, the renal vascular responsiveness to noradrenaline was reduced by indomethacin to a greater extent in the GH rat than in the normotensive rat (Fig. 3*b*, *c*). If increased levels of PGs are present, this could result from either increased synthesis or decreased degradation. Production of PGs by homogenates of kidneys of GH rats was, however, not different from normal as indicated by measurements of conversion of labelled arachidonic acid to PGs (Table 1). Moreover, no change could be detected in the pattern of production of PGs; that is, the rate of synthesis of PGE_2 was similar to that of $PGF_{2\alpha}$ in normotensive and GH rats; (PGE–PGF) ratios of 1.3 : 1 were obtained. As the activity of PGE_2 as a renal vasoconstrictor agent is considerably greater than that of $PGF_{2\alpha}$ (ref. 3), changes in patterns of synthesis of PGs without changes in their rate could influence vascular reactivity.

In contrast to the above findings, important differences were found between the kidneys of GH and normotensive rats in their abilities to degrade PGs to their 15-keto metabolites, the first and most important step in the metabolism of renal PGs[21]. This assay depends on the oxidation of ^3H-PGE_2 by an enzyme, PG 15-hydroxydehydrogenase (PGDH), the activity of which is associated with a high speed supernatant fraction obtained from renal homogenates. Blackwell, Flower and Vane[18] reported that the oxidation of ^3H-PGE_2 by the enzyme obtained from this fraction was linear for the first 5 min during which time approximately one-half of the labelled substrate was metabolised. We have confirmed these findings. A marked reduction of PGDH activity in the kidneys of GH rats was demonstrated when compared to those of normotensive rats (Fig. 4) These differences in PGDH activity were evident when kidneys of normotensive rats of either similar weight or age to those of GH rats were used. Since an age-dependent difference in PGDH activity has been described

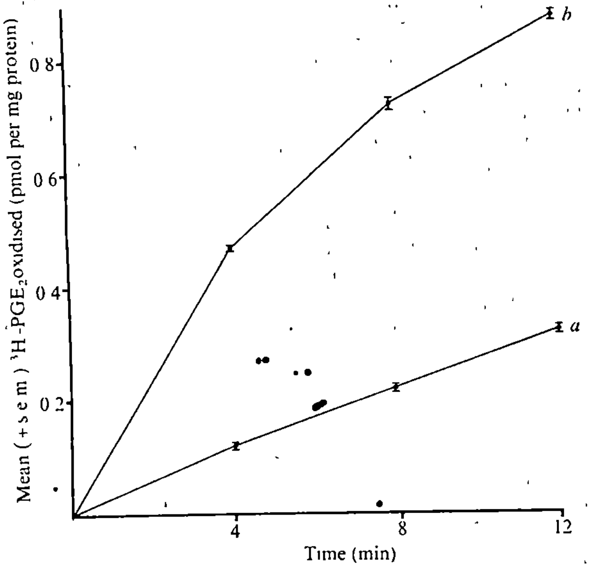

Fig. 4 Comparison of the activity of PGDH from the kidneys of GH (*a*) and normotensive (*b*) rats of similar weight ($n = 3$ for each point). Kidneys of male rats were homogenised in ice-cold 100 mM Tris buffer, *p*H 7.5. After centrifugation at 1,000*g* to remove cellular debris, the supernatant was recentrifuged at 100,000*g* for 1 h in a Beckman Spinco ultracentrifuge. Of the resultant supernatant, 1 ml containing the PGDH was added to a reaction mixture containing 280 pmol NAD^+, 0.1 µCi ^{3}H-PGE_2 and 28 pmol unlabelled PGE_2. After incubation at 37 °C for 4, 8 and 12 min the reaction was stopped by acidification to *p*H 3 with 1 N HCl. A control mixture containing boiled supernatant was similarly treated. Unreacted PGE_2 and its metabolites were extracted by mixing with 1.5 ml ethyl acetate. The phases were separated by centrifugation and 1 ml of the organic layer was removed and evaporated in a vacuum desiccator. The dried residue was then reconstituted in 30 µl of chloroform; methanol (2:1) with unlabelled PGE_2 and 15-keto PGE_2 as markers. This was then spotted quantitatively on plastic-backed silica–gel plates and developed in an ethyl acetate–water–iso-octane–acetic acid (11:10:5:2) system. The zones corresponding to the authentic prostaglandin markers were indicated by brief exposure to iodine. These zones were then cut out and placed in a scintillation vial containing 10 ml Diatol. The radioactivity in each zone was estimated by liquid scintillation counting on a Beckman LS-150 scintillation counter. c.p.m. were converted to d.p.m. using a quench correction curve and external standards. Results are expressed as the mean oxidation of PGE_2 to 15-keto PGE_2 per mg protein (± s.e.m.) with time. Protein content of the supernatant fraction was determined by the Biuret method.

by Pace-Asciak[22] it was important to use as controls age-matched kidneys to characterise changes in renal vascular reactivity. A decreased catabolism of PGs could lead to increased levels within the kidneys of GH rats, and thereby partially explain the enhanced renal vascular responsiveness to noradrenaline and the greater lowering of renal vascular sensitivity to noradrenaline produced by inhibition of PG synthesis in this species (Fig. 3*b*, *c*) PGE_2 released by noradrenaline potentiates the vascular action of the amine as well as having an additive vasoconstrictor action of its own. The latter is shown when large amounts of PGE_2 are infused in the kidney[3]. We obtained evidence supporting the uniqueness of the deficiency of PG metabolism in the GH rat by showing that another form of hereditary hypertension in the rat[23], the Japanese spontaneously hypertensive (SH) rat, was not associated with decreased renal PGDH activity (Table 1). Further, hypertension produced by constriction of one renal artery and of comparable severity to that in the GH rat, did not result in a similar derangement of PG metabolism in either the constricted or the untouched contralateral kidney. In three experiments oxidation of PGE_2 by PGDH was measured in kidney homogenates of renal hypertensive and normotensive rats. Hypertension (approximately 170 mmHg), was produced 5–7 weeks after constriction of the right renal artery using a silver clip (diameter 0.23 mm) leaving the contralateral kidney untouched. The two kidneys were assayed for PGDH activity separately. Rats, similarly treated, which had not developed hypertension were used as controls. Differences in enzyme activity observed between the two types of kidney were small relative to those of GH and normotensives. The finding that normal renal PGDH activity occurs in rats with other types of hypertension suggests that the fault occurring in GH kidneys is not secondary to the high blood pressure.

If lower than normal degradation of PGs contributes to enhanced renal vascular reactivity in the GH rat, then

Table 1 Prostaglandin metabolism in normotensive and hypertensive rats

	Catabolism			Synthesis pmol PG per min per g kidney
	fmol PGE_2 per min per mg protein			
	GH	GH	SH	GH
Hypertensive	76.2±2.9	46.0±6.0	397.3±5.7	17.29±1.26
Normotensive	*201.2±3.3	*222.3±7.1	‡378.6±1.6	17.20±1.36
		†118.3±7.1	305.3±17.9	

Kidneys of male rats were homogenised in ice-cold 100 mM Tris buffer, *p*H 7.5. To the homogenates were added 20 µg each of PGE_2 and $PGF_{2\alpha}$ to saturate the metabolising enzymes. Prostaglandin synthesis was determined using a radiochemical assay. 1 ml of the homogenate was added to the reaction mixture containing 0.1 µCi ^{14}C-arachidonic acid 33 pmol unlabelled substrate, 10 µl reduced-glutathione, 5 mM, and 10 µl (−)-adrenaline, 5 mM. The reaction mixture was then incubated at 37 °C for varying times between 2 and 10 min, and the reaction was stopped by boiling for 2 min. A sample with a boiled enzyme preparation was used as control. The mixture was then acidified and the unreacted arachidonic acid and its products extracted and chromatographed on a silica gel TLC plate (Uniplate) with unlabelled PGE_2 and $PGF_{2\alpha}$ as markers. The zones corresponding to the prostaglandins were scraped into a scintillation vial and the radioactivity determined (as for Fig. 5). The units of enzyme activity, fmol per min per mg protein or pmol per min per g kidney, were calculated from the difference in d.p.m. of each product relative to that of the control, the specific activity of the ^{14}C-arachidonic acid or the ^{3}H-PGE_2, the percentage extraction of each product, the aliquot ethyl acetate taken, the incubation time and the protein concentration or weight of the kidney.

$n = 3$–5

*Weight-matched normotensives.

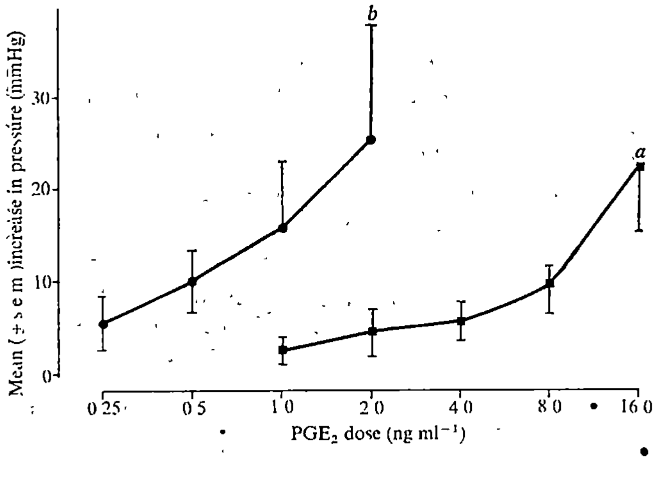
Fig. 5 Mean changes in perfusion pressure produced by PGE_2 infused for 8 min into kidneys of normotensive (a, $n = 9$) or hypertensive (b, $n = 9$) rats *in vitro*. Curves of hypertensives were found to be to the left of normotensives denoting greater vascular sensitivity to the PG.



it should be possible to show greater than normal vascular reactivity to exogenous PGE_2 in kidneys from these animals. We, therefore, infused PGE_2 in different concentrations and showed increased vascular sensitivity to PGE_2 in the kidneys of GH rats, as indicated by a lowering of the dose required to produce a threshold response (Fig. 5). There was also an approximately tenfold increase in responsiveness to its vasoconstrictor action when compared with its effects on the renal vascular bed of normotensive rats.

Prohypertensive activity

Rats with hereditary forms of hypertension have so far been considered as good animal paradigms of human essential hypertension[19]. Abnormalities of a system involved in blood pressure regulation have long been sought in genetically hypertensive rats[2]. The vasoconstrictor effects of endogenously released PGs coupled with a relative lack of the inactivating enzyme, offer a biochemical basis for hypertension in the GH rat. At the same time, the fact that PGE_2 is vasodilator in the kidneys of most other species must call into question the use of hypertensive rats as a model of human disease.

Prostaglandins as modulators

As modulators, prostaglandins may amplify or attenuate the vascular actions of other hormones or neurotransmitters in concentrations which do not affect the vasculature directly. Thus, prostaglandins have been shown to amplify the renal vascular action of kinins[24] and attenuate those of angiotensin II and noradrenaline[7,13,15]. There is an additional and less well known corollary of possible interactions between modulators and hormones, and one which has bearing on the concept that hypertension may develop in the face of normal activity of either the adrenergic nervous system or the renin–angiotensin system[25]. That is, that an abnormality of the modulator, by itself, could result in elevated blood pressure and we suggest this is the case in the GH rat. Such an explanation accounts for the demonstration that, although the adrenergic nervous system is essential for maintaining elevated blood pressure in GH rats, there is no direct evidence for its activity being increased in this species. Thus, the primary or initiating event would be increased levels of PGE_2, or a similar product of PG synthetase, which results from a deficiency of the major catabolising enzyme in the face of normal rates of prostaglandin synthesis. As emphasised above, it is likely that this disturbance need only occur in the kidney for the development of hypertension. Recent studies on other visceral vascular beds of the rat, demonstrate, however, that one or more products of prostaglandin synthesis[26,27] contributes to the vasoconstrictor actions of adrenergic stimuli The present study is the second which indicates a genetically determined defect in prostaglandin metabolism, the first being a deficiency in synthesis demonstrated in the platelets of a patient with an haemostatic defect[28].

Early Mesozoic rifting and fragmentation of the Cordilleran orogen in the western USA

Richard A. Schweickert

Department of Geological Sciences and Lamont–Doherty Geological Observatory of Columbia University, New York, New York 10964

New data make possible the precise definition of the truncated edge of the southern part of the Cordilleran orogen in California, and lead to the identification of possible 'missing pieces' removed during the early Triassic. A probable reconstruction of the Palaeozoic Cordilleran orogen involving large scale lateral transport of major tectonic units is suggested.

MANY lines of evidence indicate that only part of the Palaeozoic Cordilleran orogen is preserved intact in the western USA. An inferred south-western segment of unknown dimensions that presumably extended south-west of California has been lost. North-west-trending Mesozoic arc-trench complexes developed adjacent to the raw edge of a truncated Palaeozoic orogen[1–5]. Few people have attempted to reconstruct the ancient orogen or to identify its dispersed fragments, although studies in the Canadian and Alaskan Cordillera have begun to suggest that certain Palaeozoic terrains may have originated far to the south[6,7], perhaps even adjacent to the truncated margin of the US Cordillera[6].

Before missing parts of the Palaeozoic orogen can be identified confidently and restored to their original positions, it is necessary to bring into closer focus the truncated margin itself. Where is the edge, and what is the nature of the truncated terrains? If these questions can be resolved, it should be possible to specify the nature of the missing parts and, if they can be identified elsewhere, to outline a broad kinematic history of breakup of the orogen.

This article is composed of three parts. In the first part, I discuss current views of the relations of Palaeozoic terrains of northern California and Oregon to their counterparts in Nevada. New data from the Sierra Nevada region of California and their bearing on the location of the truncated edge of the orogen are then presented. In the second part, I present arguments concerning the identity of displaced terrains. I conclude, in the third part, with a possible tectonic reconstruction and model for the truncation and fragmentation of the orogen during early Mesozoic time.

Accepted model of late Palaeozoic orogen

Several reviews envision island arc complexes in the northern Sierra Nevada and eastern Klamath Mountains of California, together with presumably equivalent units in eastern Oregon, as having fringed the Palaeozoic North American continent much as Cainozoic island arcs in the western Pacific festoon the south-eastern margin of Asia. The volcanic archipelago was flanked to the south-east by contemporaneous deep-water chert–argillite facies with minor limestone and mafic volcanic rocks that apparently accumulated in a marginal basin which separated the arc complex from the Cordilleran miogeocline. These marginal basin rocks were thrust south-easterly over shallow-water shelf facies (Fig. 1) during periods of contraction of the marginal basin[4,5,8–10].

This model is evidently appropriate for two distinct parts of the Palaeozoic. (1) Beginning in the Devonian, an arc developed on ultramafic basement in the eastern Klamath Mountains[4,5,10] (1, Fig. 1) and on metasedimentary basement in the northern Sierra Nevada (2, Fig. 1), adjacent to what had formerly been a stable continental margin[10]. The presence of bluechist in the heart of the structurally complex north-westernmost part of the eastern Klamath Mountains[11] (3, Fig. 1), where rocks of Ordovician, Silurian and Devonian ages occur, suggests that the north-east-trending Palaeozoic arc complex (1, Fig. 1) was paralleled by a north-east-trending subduction complex, and therefore faced north-west.

Most workers have concluded that the arc terrain was flanked by a marginal basin to the south-east, but it is important to note that the marginal basin did not originate by back-arc spreading[5,8,9]. During the late Permian–early related arc magmatism, well removed from the continental edge. The sedimentary fill of this trapped marginal basin was uplifted and thrust south-eastward on to the miogeoclinal prism as the marginal basin was closed during the late Devonian–early Mississippian Antler orogeny[4,5].

(2) During Permo–Carboniferous time, an analogous arc-marginal basin system developed in nearly the same position as the earlier couplet, but this time the marginal basin grew by back-arc spreading[5,8,9]. During the late Permian–early Triassic Sonoma orogeny the sedimentary contents of the marginal basin were again uplifted and thrust on to the Antler orogenic belt[4,5,8,9].

Effects of the Antler orogeny have been obscured in places by the younger event, and evidence of a Devonian arc complex apparently exists only in northern California. The Permo–Carboniferous record is more complete, making possible more confident recognition of the various tectonic elements in Nevada, California and Oregon. In neither postulated phase of closure of the marginal basin is the fate of the presumed underlying oceanic crust known[4,5,8,9], but one hypothesis suggests that closure was accomplished by contemporaneous subduction of oceanic crust and obduction of sedimentary fill[5,12].

Sierran Palaeozoic rocks and their relation to the orogen

The foregoing model of arc-marginal basin tectonics is based almost entirely on data from north-central Nevada and northern California. A large terrain of Palaeozoic metasedimentary rocks occurs in part between these better known areas, in the western Sierra Nevada (Fig. 1), and is separated from pre-Mesozoic rocks of Nevada by the Mesozoic Sierra Nevada batholith. Although little is known of specific stratigraphic and structural relationships between Palaeozoic rocks on opposite sides of the Mesozoic batholith, there is no evidence that the batholith occupies a major tectonic boundary.

Fig. 1 Sketch map showing inferred tectonic elements of the Cordilleran orogen and specific localities, 1–18, discussed in the text; relations in eastern Oregon are uncertain in detail and highly schematic as shown. The map is modified, in part, from Fig. 1 of ref. 8 and Fig. 4 of ref. 4. GT, Golconda thrust; MFZ, Melones fault zone; TFZ, Trinity fault zone.

The Sierran Palaeozoic terrain lies at a high angle to the north-eastern tectonic trends of the Palaeozoic Cordillera, and its southern half (4, Fig. 1) occupies a "back-arc" position analogous to that of probable marginal basin rocks of north-central Nevada (5, Fig. 1; discussed below). The part of the Sierran terrain north of about latitude 39° is here considered older sedimentary basement of the above-mentioned island arc complex. Recent field studies[13–15], discussed below, have revealed major lithological and structural contrasts between the southern part of the Sierran belt (known as the Calaveras Formation) and the northern part of the belt (to which the name Shoo Fly Formation is applied).

The Calaveras Formation (4, Fig. 1) is a structurally complex assemblage of argillite, chert, subordinate quartzite and greenstone, with several large, lenticular masses of strongly recrystallised limestone. Recent work (refs 13, 14 and my unpublished data) indicates that the Calaveras Formation consists of two major units. The lower unit is a very thick, extensive mass of chaotic submarine slide deposits consisting primarily of fragments and blocks of chert in an argillaceous matrix. Most exposures can be termed diamictite, and bedding is only rarely preserved. The chaotic rocks were deposited on a structurally coherent sequence of mafic pillow lava, pyroclastic rocks, and interbedded shale. These rocks are overlain on the east by an upper sequence of quartzites (ref. 16 and my unpublished data) in which graded beds indicate tops to the east, and interbedded olistostromes. All rocks of the Calaveras Formation have been penetratively deformed, producing an east- to north-east-plunging extension lineation and a regional schistosity. The Calaveras Formation may be Permo–Carboniferous, but faunal evidence is meagre and does not preclude the existence of rocks of other ages. The penetrative deformation predates the development of Jurassic structures and the intrusion of Jurassic plutons; and may be late Palaeozoic or early Mesozoic[13,14].

As Speed suggested[17], the Calaveras Formation is probably correlative with the Havallah sequence in north-central Nevada (5, Fig. 1), which has been interpreted by other workers to have accumulated in the late Palaeozoic marginal basin[4,5,8,9]. My reconnaissance of parts of the Havallah sequence has revealed the existence of widespread submarine slide deposits consisting primarily of chert–argillite diamictite with assorted blocks of chert, sandstone, limestone and greenstone. In addition, evidence of penetrative deformation is present. The lower chert–argillite–greenstone units of the Havallah sequence are overlain by an upper quartzitic sequence[18,19]. These highly distinctive lithological and structural characteristics are identical to those of rocks of the Calaveras Formation. The Havallah sequence contains fossils of middle Pennsylvanian to early Permian age[8]. During the Sonoma orogeny, these marginal basin sedimentary and volcanic rocks were thrust south-eastward along the Golconda thrust on to rocks of the Antler orogenic belt[4,5,8,9,17].

Owing to their analogous palaeogeographic setting, remarkably similar lithology and structure, and probably similar age[17], I suggest that the chaotic chert–argillite facies and quartzites of the Calaveras formation are part of the marginal basin assemblage represented by the Havallah sequence. The chaotic nature of parts of both sequences probably resulted from repeated slumping in this tectonically unstable environment; shallow-water limestones in both areas were introduced into deep-water environments by large scale slumping. The penetrative deformation of both terrains probably represents shortening during the Sonoma orogeny when the marginal basin was partially closed. Rocks representative of the late Palaeozoic marginal basin can thus be considered to extend as far west as the Melones fault zone in the western Sierra Nevada (Fig. 1).

Like the Havallah sequence, rocks of the Calaveras Formation may be largely allochthonous; and if so they are separated from miogeoclinal Palaeozoic rocks of the eastern and southern Sierra Nevada (6, Fig. 1) by the projected Golconda thrust, whose actual trace has been obliterated by the Sierra Nevada batholith. The Golconda allochthon may in addition include part of the Garlock Formation (7, Fig. 1) as suggested by Burchfiel and Davis[4,5], requiring projection of the thrust 300 km south of its known extent in north-central Nevada.

Metasedimentary rocks in the northern half of the Sierran belt (8, Fig. 1) are known as the Shoo Fly Formation[20,21]. These rocks are considerably older than the Calaveras Formation and may be Silurian or older[15,16,21]. They are unconformably overlain by Upper Devonian volcanic rocks[22,23] (2, Fig. 1) which form the basal part of the volcanic arc discussed above[2,4,5,8–10]. The Shoo Fly is made up of slate, phyllite, graywacke and distinctive quartzose sandstone, bedded chert and rare thin limestone beds[15,21,23]. Its thickness is unknown as it is tightly folded and penetratively cleaved.

The Shoo Fly comprises a thick, deformed metasedimentary pile on which the Devonian–Permian arc complex developed[2,4,5,8–10], and thus contrasts with the ultramafic basement of the arc in the Klamath Mountains. It resembles lithologically the siliceous facies[10] of the early Palaeozoic eugeocline to the south-east. The entire northern Sierra Nevada terrain and that of the eastern Klamath Mountains, including both younger arc rocks and older metasedimentary and ultramafic basement, may have been rifted north-westerly away from the eugeocline during growth of the late Palaeozoic marginal basin to the south-east.

Widespread Permo–Triassic volcanism

Thick sequences of silicic volcanic rocks or probable Permo–Triassic age occur in many parts of the Cordilleran orogen, within both the former marginal basin and the arc complex proper.

In the eastern Sierra Nevada, the late Palaeozoic Koip sequence[24–26] (9, Fig. 1) consists of andesitic and rhyolitic lava and pyroclastic rocks[26]. Age assignment is based on two Rb–Sr whole-rock isochron ages: 240 Myr (ref. 24) and 250 Myr (ref. 25). These rocks, together with similar rocks of the Permo–Triassic(?) Excelsior Formation[26] within the Sonoma orogenic belt[19,27] (10, Fig. 1), may occupy a structural position analogous to that of the Permo–Triassic Koipato sequence of north-central Nevada (11, Fig. 1), which consists of more than 3 km of rhyolitic and andesitic lava and pyroclastic rocks[8,19]. The Koipato has yielded fission-track and lead-alpha ages that average about 250 ± 40 Myr (ref. 28). Koipato rocks were erupted and deposited on the Havallah sequence, evidently after thrusting[8,17,19]. Although precise age equivalence cannot be demonstrated, the Koip, Excelsior and Koipato collectively

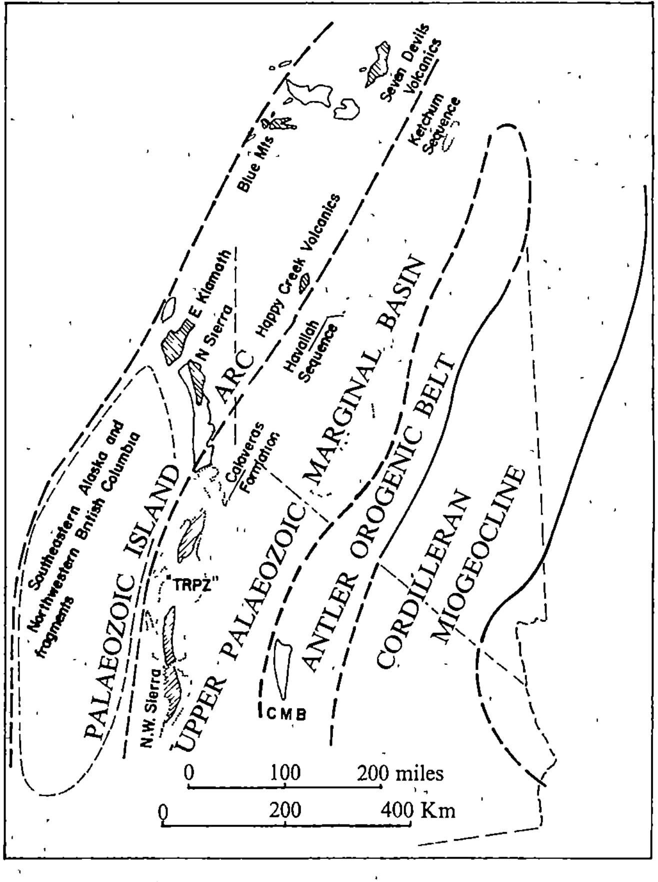

Fig. 2 Proposed tectonic reassembly of southern part of Cordilleran orogen for Permian time, before the Sonoma orogeny, which involved shortening and thrusting of marginal basin fill on to the Antler orogenic belt. Terrains north-east of the line of truncation have been shifted 50 km north-west of their present locations to eliminate effects of the Sonoma orogeny; Mesozoic and Cainozoic displacements have not been treated. Arc rocks of the eastern Klamath Mountains have been shifted 60 km closer to those of the northern Sierra Nevada[53]. The dot pattern outlines chert–argillite terrains which were once part of the marginal basin. North-east ruling marks probable remnant arcs within the marginal basin; north-west ruling marks arc volcanic sequences in the autochthonous part of the Palaeozoic island arc. TRPZ, western Palaeozoic and Triassic belt; CMB, central metamorphic belt. See text for discussion.

indicate extensive Permo–Triassic silicic volcanism within the Sonoma orogenic belt.

Notable Permo–Triassic volcanic rocks much like the above units are found, in addition, in the eastern Klamath Mountains, overlying Devonian to Permian arclike volcanic rocks discussed earlier (12, Fig. 1). These units, the Dekkas Andesite and Bully Hill Rhyolite, constitute up to 2 km of lava and pyroclastic rocks[29], and perhaps should be regarded simply as continued arc volcanism. Nevertheless, the widespread Permo-Triassic andesitic and rhyolitic volcanism within both former arc and marginal basin settings may be indicative of a transition to extensional tectonics following the Sonoma orogeny[17], preliminary to rifting within the orogen. Burchfiel and Davis[5,12], however, consider such volcanism to be arc volcanism which resulted from subduction of the oceanic crust on which the Havallah sequence was presumably deposited[8].

Truncated edge in central California

As shown here, recognisable elements of the late Palaeozoic Cordilleran marginal basin continue south-westerly across the Sierra Nevada batholith into the western Sierra Nevada. Such rocks do not extend beyond the Melones fault zone, the major tectonic boundary of the region, and which apparently represents a collision boundary between the rifted Palaeozoic margin and a Jurassic island arc[15]. The Melones fault zone has been interpreted as a high-angle reverse fault[30], strike-slip fault[31], and as a thrust fault[32]. Limited exposures of melanges with Permian limestones occur west of the Melones fault zone[33], but their Tethyan faunas[34], and tectonic setting within a Jurassic island arc[15], suggest that these rocks did not originate within the Cordilleran orogen. The Melones fault zone, whatever its detailed movement history may be, appears to mark the modified truncated edge of the Palaeozoic orogen in central California. On tectonic grounds, its probable northward extension is viewed as the Trinity fault zone[32] (Fig. 1), which, as shown here, truncates the north-east-trending arc and subduction terrains of the eastern Klamath Mountains and abruptly juxtaposes them against arcuate, northerly trending terrains to the west.

The missing pieces

Tectonic elements presumably missing from the Palaeozoic orogen are the south-western continuation of the marginal basin and the remainder of the Devonian–Permian arc complex. I assume that these missing pieces had some finite areal extent and might be recognised in some other geological setting.

Is the western Klamath terrain a marginal basin fragment? The western Palaeozoic and Triassic belt of the Klamath Mountains[35] (13, Fig. 1), like the Calaveras and Havallah terrains, is underlain largely by deformed chert–argillite, mafic volcanic rocks and lenses of limestone[35–37]. Large parts of the belt are chaotic[38,39] and closely resemble diamictite of the Calaveras Formation and Havallah sequence (my observations made in 1972–75). Most fossils from limestone lenses within the southern part of the terrain indicate Pennsylvanian to Permian ages[36], although rare Devonian and Triassic fossils have been reported[36,40]. A probable southern continuation of the Klamath terrain occurs, in addition, west of the Melones fault zone in the north-western Sierra Nevada[15,32].

Rocks of the western Palaeozoic and Triassic belt have been interpreted as part of a late Palaeozoic subduction complex related to the late Palaeozoic arc of the eastern Klamath Mountains and northern Sierra Nevada[2,4,5], invoking blueschists in two areas near the eastern edge of the belt[4,5,11,37] (14, 15, Fig. 1). For the following reasons this interpretation is considered untenable.

(1) As argued earlier, the probable north-east-trending subduction complex related to the late Palaeozoic arc (1, Fig. 1) lies in the north-western part of the eastern Klamath Mountains. (2) The structural trends of the western Palaeozoic and Triassic belt and its southern continuation parallel the Trinity and Melones fault zones which mark the truncated edge of the orogen and are highly discordant with north-east-trending arc terrains. (3) Available evidence indicates that deformation and metamorphism of the sedimentary rocks was post-Permian and pre-late Jurassic[39,41]. (4) Blueschists in the eastern part of the western palaeozoic and Triassic belt have yielded a 215-Myr K–Ar date[5], which allowing for uncertainties in the Triassic part of the time scale[42], could be as young as late Triassic. These blueschists are clearly part of an inner, early Mesozoic blueschist belt in the Cordillera, including localities in central British Columbia[43], the Northern Cascades[44], east-central Oregon[45] (16, Fig. 1), and undated lawsonite blueschist along the Melones fault zone in the northern Sierra Nevada (ref. 54) (17, Fig. 1). Published K–Ar ages on blueschists in this belt all cluster around 210–220 Myr[5,43,44]. This and the geological setting of these blueschists strongly indicates that they formed in subduction zones related to Upper Triassic and Lower Jurassic arc rocks in eastern California, western Nevada, Idaho and British Columbia[42,47–49].

I believe that the rocks of the western Palaeozoic and Triassic belt are best interpreted as part of an already chaotic terrain that originated elsewhere and may have been subducted during the early Mesozoic with the local production of blueschist. I suggest (Fig. 2) that the western Palaeozoic and Triassic belt represents part of the missing marginal basin sequence and has been shifted some 500–600 km north-west from its original position opposite the Calaveras Formation after the truncation event. This interpretation accounts for the fact that the apparently correlative rocks of the Calaveras Formation and western Palaeozoic and Triassic belt lie on opposite sides of the Trinity–Melones fault zones (Fig. 1), and also allows for the existence of blueschist in the Klamath terrain and its southern continuation and its apparent absence in the Calaveras Formation[13,14,54] (also my unpublished data).

Andesitic rocks flanked on both sides by ophiolitic rocks, recently noted in the western Palaeozoic and Triassic belt[36], may represent part of a remnant arc which became isolated by continued spreading within the marginal basin Volcanic rocks within parts of the terrain in Oregon and the north-western Sierra Nevada[50] may also represent parts of remnant arcs, and shreds of ophiolites are probably represented in these areas as well.

The north-north-west-trending central metamorphic belt (18, Fig. 1), a tectonic sliver of hornblende schist and overlying mica schist[37,51] between the western Palaeozoic and Triassic belt and the Trinity fault zone, has late Devonian to Mississippian K–Ar and Devonian Rb–Sr ages[41]. Burchfiel and Davis[4,5] regard this terrain as the subduction complex related to Devonian arc activity to the east although blueschists are lacking, and the Trinity fault zone juxtaposes the central metamorphic belt directly against the south-western part of the north-east-trending arc complex (Fig. 1). It could alternatively be an exotic fragment[2], but as Burchfiel and Davis[4,5] point out, its metamorphic ages suggest some relation to the Antler orogeny A highly speculative possibility, adopted in Fig. 3, is that rocks of the central metamorphic belt represent a deep-seated southerly portion of the Antler orogenic belt rifted away from its original position together with rocks of the western Palaeozoic and Triassic belt. The westward vergence of synmetamorphic overturned folds within the terrain[4,5,51], however, is difficult to explain unless it is attributed to eastward subduction beneath the Antler orogenic belt[5,12]. Unfortunately, blueschists are lacking. Whatever its origin, the central metamorphic belt now forms a thrust plate that has overridden the western Palaeo-

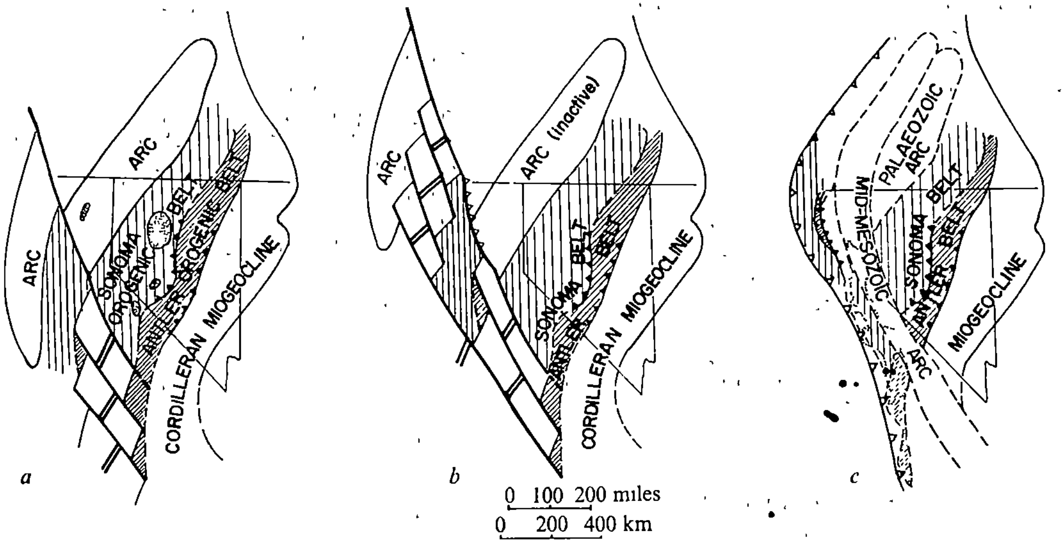

Fig. 3 Tectonic diagrams showing proposed sequence of events leading to present distribution of Palaeozoic terrains in the Cordilleran orogen. *a*, Stage of fragmentation during early Triassic. Stipple pattern shows areas of Permo–Triassic silicic volcanism. *b*, Hypothetical stage of fragmentation during middle Triassic. Arc and marginal basin fragment are separated by jump in plate boundary; marginal basin fragment begins to underthrust truncated edge of arc. *c*, Initiation of subduction along truncated margin during the late Triassic. Partial subduction of marginal basin fragment produces local blueschist metamorphism in Klamath Mountains and Northern Sierra, Nevada. Late Triassic to mid-Jurassic arc is superimposed on older tectonic elements. The dot pattern shows future site of Upper Jurassic–Upper Cretaceous Sierra Nevada batholith.

zoic and Triassic belt for 20–30 km, and has itself been overridden by rocks of the eastern Klamath belt for distances of 30 km or more[51].

I next consider a possible arc fragment in the Pacific North-West. Figure 2 depicts the original south-western extent of the late Palaeozoic volcanic arc and marginal basin which fringed North America before the truncation event. The western Palaeozoic and Triassic belt and its Sierran continuation are shown as the south-westerly part of the marginal basin. Local remnant arcs are also shown.

The remaining part of the orogen to be identified is the corresponding arc segment which must originally have lain along the north-western flank of the marginal basin. Monger and Ross[7] have suggested that Upper Palaeozoic rocks of the Coast Mountains of British Columbia and south-eastern Alaska may be far-travelled from their original sites of accumulation. Jones and others[6] argued that the Lower Palaeozoic rocks of south-eastern Alaska, at least, were derived from the truncated margin of the Cordilleran orogen, probably in northern California. Palaeozoic sequences containing volcanic rocks of basaltic to rhyolitic composition occur widely within this 1,500-km-long region and rest on a basement of metavolcanic and ultramafic rocks[6,9].

It seems likely that the Palaeozoic rocks in this region in part represent a volcanic arc complex that developed on lower Palaeozoic basement in late Palaeozoic time[7]. Much of the terrain, especially its northern part, can be viewed as the missing arc segment required by the arguments presented here, in turn satisfying the palaeontological contraints invoked by Monger and Ross[7]. If so, the puzzle is relatively complete (Fig. 2).

Possible sequence of fragmentation

Figure 3 shows hypothetical stages of fragmentation of the orogen, resulting in dispersal of its component parts Figure 3*a* shows the initiation of separation, which perhaps began in the early Triassic, after the Sonoma orogeny[4,5], when silicic volcanism was widespread within the orogen. Figure 3*a* shows a rhombochasm, like the Gulf of California, forming behind the arc and marginal basin fragment.

Figure 3*b*, approximately middle Triassic, shows two significant changes: a second rhombochasm begins to separate the arc segment from the Palaeozoic marginal basin fragment. There is no direct evidence of timing, but some such mechanism is required for the separation of the arc and marginal basin fragments. The marginal basin fragment perhaps impinged obliquely against the blunt end of the arc thus retarding its motion, and producing thrusting along its boundary.

Figure 3*c*, drawn for late Triassic to early Jurassic time, shows that the marginal basin fragment has underthrust the truncated end of the arc with the initiation of north-eastward subduction of lithosphere beneath the newly reshaped continental margin. This subduction resulted in the production of blueschists and the generation of a new magmatic arc at a high angle to the Palaeozoic trends[4,5,15,46]. The arc fragment has by this time progressed on its way to south-eastern Alaska.

Implications and conclusions

The model described here has several attractive features. It provides a plausible context for assembly of the various Palaeozoic terrains of the Klamath Mountains, one that seems more satisfactory than repeated collisions of exotic plates[2]; it is consistent with known ages of deformation and metamorphism, and it provides some insights into the basic similarities and differences between Palaeozoic terrains in the Klamath Mountains and the western Sierra Nevada of California In addition, it is consistent with tectonic inferences drawn from studies of the Canadian and Alaskan Cordillera[6,7].

If this model has any validity, it seems to imply that western North America was repeatedly subjected to major north-westerly transcurrent movements, beginning about 850 Myr ago, with north-west–south-east rifting which initiated the Cordilleran geosyncline[52], continuing with the early Mesozoic movements suggested here, and again in the Cainozoic, with slicing and north-west tectonic transport related to the San Andreas system.

Because chaotic sequences like the Calaveras, the western Palaeozoic and Triassic belt, and the Havallah sequence may have acquired their chaotic character behind island arcs, with or without subduction, it seems that the chaotic character of assemblages alone may not be sufficient for them to be labelled subduction complexes; other lines of evidence are needed.

The proposed scheme of reassembly and fragmentation is consistent with many known aspects of Cordilleran geology, but is obviously an oversimplification of complex, controversial and as yet poorly known geology. I consider the first part of this article, which locates the truncated edge of the orogen, the most certain. The second and third parts are successively more speculative, and new data will require modification or even rejection of some of the suggestions. I present this analysis as an alternative to the orthodox models of orthogonal subduction and collision tectonics currently in vogue[2,4,5,9]. As noted here, major transcurrent motions along longitudinal faults deserve as much careful consideration as simple subduction in the generation of viable models of the tectonic evolution of Cordilleran mountain belts.

I thank W. Alvarez, D. S. Cowan, I. W. D. Dalziel and W. R. Dickinson for reading the manuscript, and D. S. Cowan and W. R. Dickinson for discussions. This work was partially supported by the Department of Geological Sciences, Columbia University.

Observational tests in cosmology

It is often said that the determination of the deceleration term is one of the main aims of observational cosmology. In the following comments this view is questioned, and in a universe of indeterminate density, the third time derivative of the scaling variable is shown to be of greater fundamental importance.

Let $K(=k/R^2)$ be the curvature of a homogeneous and isotropic model of the Universe, where R is the scaling variable, and k is the curvature constant indicating whether the model is closed ($k = 1$) and space is finite, or open ($k = 0, -1$) and space is infinite. According to general relativity, the dynamic equation of a zero-pressure model is

$$K = 4\pi G\rho - H^2(q+1) \qquad (1)$$

where ρ is the average mass density. The Hubble term H and the deceleration term q are

$$H = \dot{R}/R$$

$$q = -\ddot{R}/RH^2$$

and dots denote time derivatives. The cosmological term, which at present cannot be measured independently by any known means, is

$$\Lambda = 4\pi G\rho - 3qH^2 \qquad (2)$$

The verification of the important cosmological equation (1) requires measurements of the quantities K, ρ, H, and q. When, however, (1) is assumed to be valid, the resolution of the issues as to whether the Universe is open or closed, and whether the Λ term is zero or not, requires measurements of ρ, H, and q.

In principle the quantities K, H, and q can be determined, although in practice their precise determination is exceedingly difficult[1]. The determination of the average density ρ is quite another matter—for its exact value cannot be determined, even in principle. The reason for this is obvious. We know approximately the contribution to the average density from luminous galaxies, and can even attempt with tongue in cheek to estimate the contributions from the intergalactic medium and known non-luminous objects such as stellar black holes. But we cannot, of course, include all the unknown contributions (dead galaxies? primordial black holes? . . . ?) that will be discovered in the future.

Cosmological tests of a local nature[2] concerning the sign of K and the value of ρ, based on age determinations, assume first the validity of (1) and second a zero value for the Λ term, and they must therefore be regarded as doubly uncertain.

If in principle the density is indeterminate, then, like the Λ term, it must be removed from (1). In a form analogous to the deceleration term, let

$$Q = \dddot{R}/RH^3$$

be a dimensionless third-order time derivative. The differentiation of equation (1), with ρR^3 kept constant, gives

$$K = H^2(Q-1) \qquad (3)$$

with the auxiliary relationships

$$\Lambda = H^2(Q-2q) \quad (4)$$

$$4\pi G\rho = H^2(Q+q) \quad (5)$$

Thus the removal of ρ also eliminates q from the cosmological equation (3), and the deceleration term is reduced to a subordinate role in equations (4) and (5).

From equation (3) it is seen that verification of general relativity on cosmic scales requires measurements of K, H, and Q, and the Universe is closed (open) when Q is $>$ ($<$) 1. Weinberg[3] has drawn attention to the problem of extracting separately the values of K and q from observational data. Attention is now drawn to an additional problem: until the density is known with greater precision than is possible at present, the value of q is irrelevant for testing the validity of general relativity. Moreover, when general relativity is assumed to be valid on cosmic scales, the traditional observational parameters H and q are inadequate for deciding such questions as: (1) is the Universe open or closed? (2) is the Λ term zero? and (3) is there 'missing mass'? Verification, and the resolution of these issues, depends on the value of Q and therefore $\dot{R}$, and at present, unfortunately, we have no knowledge of this value.

The assumption that the Λ term is zero greatly simplifies the problems of observational cosmology. In this case, $Q = 2q$, and

$$K = H^2(2q-1) \quad (6)$$

and verification requires measurements of K, H, and q, and the Universe is closed (open) when q is $>$ ($<$) 0.5.

Reasons for rejecting or retaining the Λ term are still of a philosophical flavour. A particularly appealing argument proposes that Λ is retained provisionally as a reminder of the possibility of undiscovered cosmic complexity. As an illustration, the Universe consists perhaps mainly of matter and relatively little antimatter[4]. Does this cosmic predilection for matter arise from some quirk in the properties of elementary particles, or does it come in some unknown way from the Λ term and hidden richness in the properties of space-time?

Of the physical systems that range in size from atoms ($\sim 10^{-8}$ cm) to galaxies ($\sim 10^{23}$ cm), electromagnetic interactions dominate on the atomic scale at one extreme, and gravitational interactions dominate on the galactic scale at the other extreme. It is found, on going down five orders of magnitude in size from atoms to elementary particles, that electromagnetic theory is inadequate and is supplemented by weak and strong interactions. Why then, in the absence of observational proof, should we assume that gravitational theory remains unmodified on going up five orders of magnitude in size from galaxies to the Universe? A universe that contains everything is surely as complex as an elementary particle? Considerations of this kind again suggest that the Λ term should be provisionally retained, even though at present we are not aware of its purpose in the cosmic design.

Most observational work in general relativity has in the past been devoted to testing the Einstein equation within stellar-like systems. But we must not forget that confirmation of general relativity in the Solar System and on the scale of stellar systems does not automatically guarantee that the theory is unassailable on the cosmic scale. The Riemannian metric is the most appealing feature of general relativity when applied to cosmology. The identification, however, of the coupled 'matter' tensor solely with energy and momentum has not been submitted to tests on the cosmic scale, and here again is reason for retaining the Λ term until verification is forthcoming. On this subject it is worth recalling Einstein's[5] words: "The right side [the 'matter' tensor] is a formal condensation of all things whose comprehension in the sense of a field theory is still problematic. Not for a moment, of course, did I doubt that this formulation was merely a makeshift in order to give the general principle of relativity a preliminary closed form."

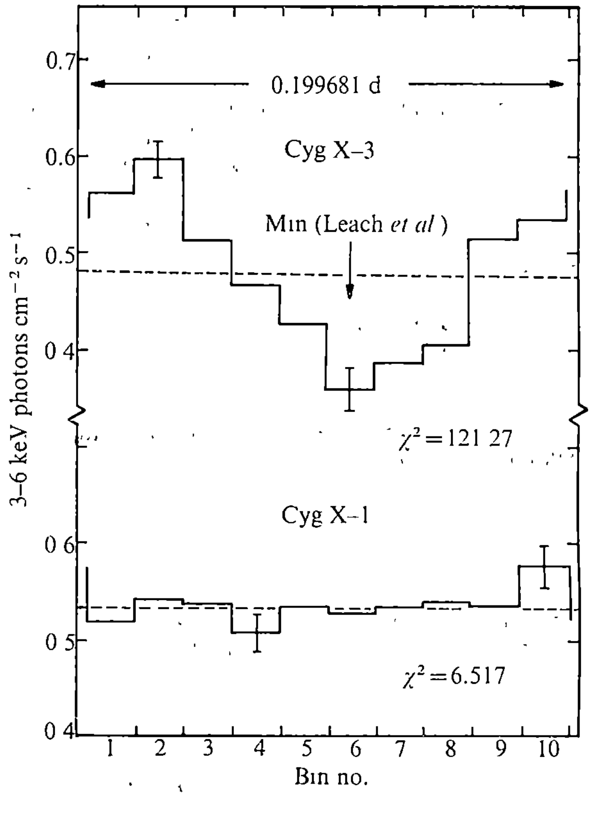
Evidence for a 17-d periodicity from Cyg X-3

Cyg X-3 (3U2030+40) has exhibited phenomena which are observationally unique among identified X-ray sources. The giant radio flare of 1972 is, perhaps, the most spectacular such anomaly, but there are others no less unusual. A wide variation in X-ray spectra has been observed, including the identification of X-ray emission lines at some times, and consistency with a black body at others[1]. The approximately sinusoidal 4.8-h variation[2] is at a period far in excess of any rotation period which has been ascribed to the compact members of other binary sources, and at least four times shorter than any comparable orbital period. Models have been constructed which identify the 4.8-h variation with orbital period[3-5], acknowledging the peculiar geometries which could give rise to a smooth 4.8-h effect in observed X rays. We here present data indicating that a much longer periodicity of ~17 d is also characteristic of Cyg X-3.

The Ariel-V All-Sky Monitor (ASM), from which most of our data are taken, has been described in detail elsewhere[6]. The

Fig. 1 Approximately 100 d of single-orbit Cyg X-3 and Cyg X-1 ASM data obtained between December 1974 and March 1975 folded at the Cyg X-3 period (with indicated phase) of ref 7. The indicated χ^2 values are for 10-bin folds (9 degrees of freedom) against the hypothesis of a constant source intensity.



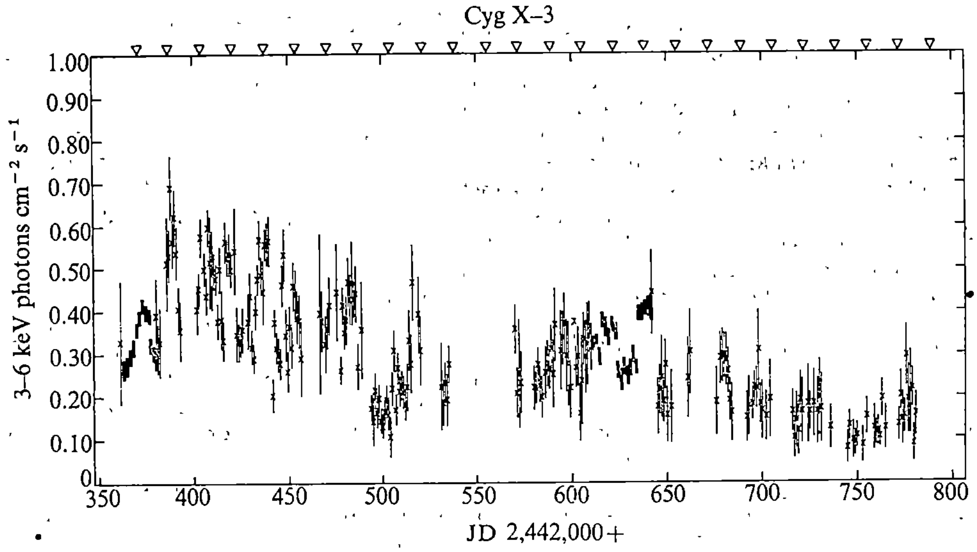


Fig. 2 Continuous record of Cyg X-3. The data points are daily averages of ASM data, with ±1-σ error bars. The solid bars are ±1-σ thick, 1.6-d averages of SSE data. The latter are 2–18 keV measurements which are normalised to the natural ASM ordinate with the response of both instruments to the Crab Nebula. The grid above the data indicates the positions of expected maxima with the best fold values of period (16.75 d) and maximum (JD 2,442,522).

important parameters are an effective pinhole area of 0.6 cm^2 in the energy band 3–6 keV, an average duty cycle for source observation of ~1%, and no temporal resolution finer than 100 min. Typically, ~10 Cyg X-3 counts are accumulated each 100-min orbit in a resolution element of spatial dimensions ~10°×10°, with a background of ~2 counts.

Figure 1 is a useful verification of experiment performance on Cyg X-3. Single-orbit data from ~100 d are plotted |4.8 h| from Cyg X-3 and, as a control, Cyg X-1 (with which it might conceivably be confused with resolution elements centred ~10° apart). Data points are accepted only if they represent an unambiguous determination of source intensity (the possible contribution from other sources is <10%, and the intensity is at least twice the estimated 1-σ error after all corrections have been applied). In folding, the data from each 100-min accumulation are tagged with the orbit midtime. Each bin in Fig. 1 is statistically independent of the others, as an orbit contributes only to the bin that contains its midtime (even though the data are accumulated over the equivalent of 3–4 bins). Both the shape (and phase) are in excellent agreement with the results of ref. 7, indicating that the present measurements are consistent with their period (and error) of 0.1996811±0.0000016 d.

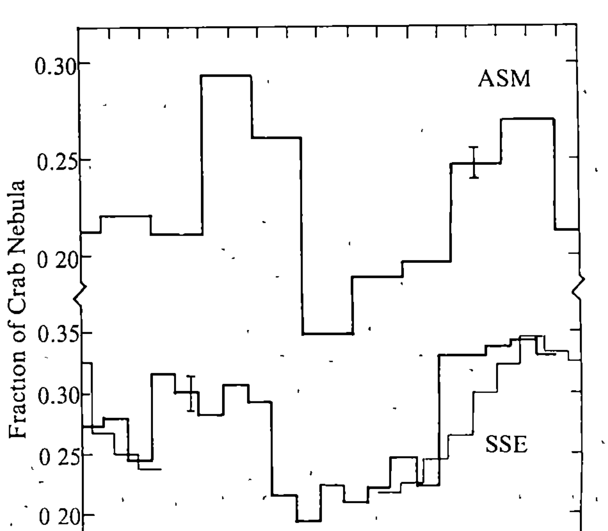
Additionally there is considerable variability in the day-to-day intensity of Cyg X-3, as shown in Fig. 2. This behaviour is in marked contrast to the constant (within the relatively poor statistics) day to day nature of low-state Cyg X-1 data measured simultaneously with the same experiment[8]. There is, however, some indication of regularity in the Cyg X-3 variations on time scales ≳1 week. As the Cyg X-3 data from individual orbits do not always satisfy the 2-σ condition, the ASM data used in Fig. 2 are derived from ~½-d accumulations which are then analysed in exactly the same way as are the individual orbits (they are treated as single long duration orbits). It is not possible unambiguously to compensate completely for the 4.8-h variation, so no attempt has been made to do so. This variation, as well as gaps in the finite data string and an apparently erratic source behaviour, result in many periods in excess of a few days which give relative χ^2 maxima. The effect near 17 d is not only the most significant statistically, but also exhibits a roughly symmetrical χ^2 distribution which has a width commensurate with the length of the data sample. For more than one year's data folded in this way, the best period is 16.75±0.25 d with a phase at maximum of JD 2,442,522±2 (as determined from the folded data, not an individual peak) near the midpoint of the data accumulation interval.

Figure 2 also contains data from the Ariel V Sky Survey Experiment (SSE) against which the 17-d hypothesis may be tested. It is important to note that the latter measurements are obtained in the gaps of the ASM coverage, as the two experiments possess mutually exclusive fields of view. The data are generally consistent with the displayed grid of 16.75 d, but it is clear that the effect is not completely reproducible (as the apparent maxima are not always clearly defined, and are sometimes absent). Nevertheless, the general agreement of the SSE data with the ASM grid is independent evidence for the reality of the candidate period.

Figure 3 contains the same ASM data folded |33.5 d|, or precisely twice the best value of period. The lower trace is the SSE data plotted in phase with the upper trace. Attempts to test the 16.75-d hypothesis with older data in the literature are inconclusive (as these are essentially point measurements), but it is interesting to note that the highest intensity value of Cyg X-3 reported from Uhuru in ref. 7 is in phase with the ASM maxima.

In ref. 1, the authors pointed out that the "high intensity state" of Cyg X-3 is relatively well fitted by a structureless black body, in contrast to the considerably more complex spectra observed in lower intensity states. They further suggest that the total source luminosity is close to the Eddington limit, and approximately constant, regardless of spectral form. This interpretation of the "high intensity state" is, therefore, a manifestation of the relatively better efficiency of contemporary experiments near the black-body peak than at higher energies. We are assuming here that this interpretation is correct, and

Fig. 3 ASM data for >1 yr folded at 33.5 d (upper trace), and SSE data plotted in phase (lower trace). Both are normalised with their respective responses to the Crab Nebula.



that the times of Cyg X-3 maximum correspond to increased electron scattering in the source.

One possible explanation would arise naturally if the 17-d effect was the orbital period of the binary system containing Cyg X-3. In this case, however, the stability of the 4.8-h variation (which would now be interpreted as a slow source rotation) would seem to constrain this hypothesis severely. No apparent 17-d Doppler variation in the 4.8-h modulation is detectable in our data ($v_x \sin i < 300\ \mathrm{km\ s^{-1}}$) and it is difficult to account for the long term stability of this period unless the surface field is much lower than that expected if the observed 4.8-h modulation arises from rotation.

A less drastic suggestion (one which does not alter the identification of 4.8 h with the orbital period) is that the 17-d effect is analogous to the 35-d variation in Her X-1 (see ref. 9). The consistency of both Cyg X-3 and Her X-1 with contact-binary models (in contrast to the supergiant–stellar-wind models reconcilable with the mass source in other identified X-ray binaries) makes this conjecture attractive. It is interesting to note that the interpretation of this effect in terms of free precession[10,11] does not necessarily require a neutron-star source for Cyg X-3 just because the 17-d and 35-d time scales are comparable. A precession period of 17 d is entirely consistent with either a neutron star with rotation period ~1 s, or a white dwarf having a rotation period of the order of minutes. Its interpretation in terms of the precession of the primary member of the binary system (compare ref. 12) is likewise insensitive to the nature of the secondary. While it does not appear that the 17-d effect can unambiguously distinguish between a white dwarf and a neutron star, the inferred high luminosity and relatively hard spectrum out to ~40 keV would seem to favour the latter.

Satellite observations of planetary waves in the mesosphere

The pressure modulator radiometer (PMR) is one of the instruments carried by the Nimbus 6 observatory satellite launched on June 12, 1975 into a near polar circular orbit at an altitude of ~ 1,000 km. The PMR sounds atmospheric temperature in the upper stratosphere and mesosphere (the 40–95 km height range) by measuring infrared emission from atmospheric carbon dioxide in its 15-μm band[1]. With this instrument measurements of mesospheric temperature with global coverage are being made for the first time. Here we present some of the first results from the PMR, which show, in particular, the propagation of a planetary wave from the troposphere up to the mesopause.

The radiation to be detected is passed through a cell of carbon dioxide which acts as a filter and in which the cell pressure is varied sinusoidally at ~ 15 Hz. The amplitude of the resulting signal selected at this frequency is a measure of the intensity of incident radiation from very narrow spectral intervals near each line centre. This radiation originates in the mesosphere, so the PMR provides a method of measuring the temperature at mesospheric levels. This basic technique[2,3] has been used in the Nimbus 4 and 5 selective chopper radiometers (SCR)[4,5] which measure emission up to ~ 55-km altitude by chopping between different cells of carbon dioxide. By varying the pressure in a single cell, problems of mismatch between cells are avoided and temperature can be sounded to much higher levels.

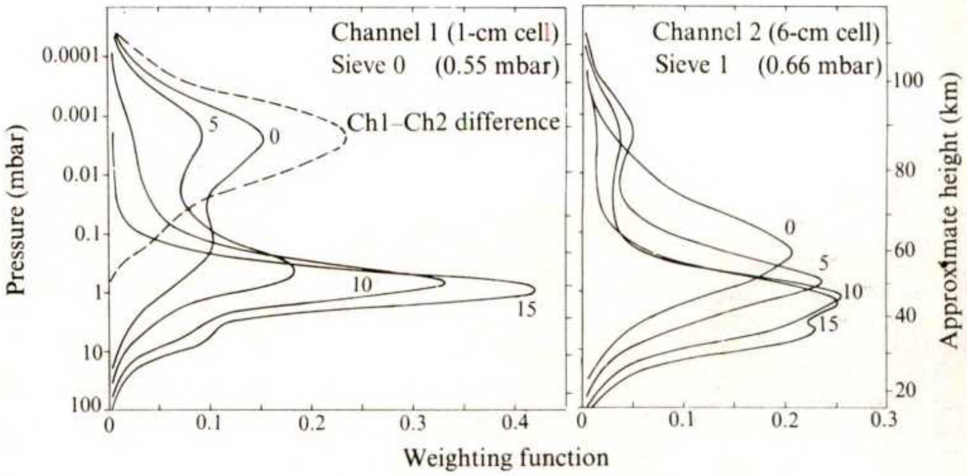
The Nimbus 6 PMR has two modulators called channels 1 and 2 which have cells of path length 1 and 6 cm respectively. Two different methods are used to vary the altitude range being sounded. The first is to vary the mean pressure in a modulator cell between 0.5 mbar and 4 mbar by altering the temperature of some molecular-sieve contained in a thimble attached to the cell (and hence the amount of gas adsorbed on it).

The second method uses Doppler scanning. Observing at a few degrees from the nadir along the direction of flight causes a Doppler shift of the incident radiation because of the velocity of the satellite. The CO_2 emission lines from the atmosphere are moved relative to the CO_2 absorption lines in the cell by an amount comparable with the width of the spectral lines in the mesosphere. With this spectral shift the pressure modulators select from narrow spectral intervals in the wings of the lines which originate from lower altitudes. Figure 1 shows a selection of weighting functions (the functions which describe the region of the atmosphere from which the radiation detected by the PMR originates) for different cell pressures and angles of view, showing that the altitude range 40–90 km can be well covered by such a combination. The field of view of the radiometer is 4° (full angle) along the direction of flight and 20° perpendicular to the flight direction, corresponding to a rectangle in the atmosphere of horizontal dimensions 70×350 km. Doppler scanning is arranged in flight by tilting the primary mirror of the optical system so that the direction of view moves from +15° to −15° with respect to the nadir along the direction of flight. One scan takes 88 s, the rate of scan being arranged so that during the scan the same part of atmosphere is being viewed.

The PMR has functioned continuously since June 20, 1975. From each day's data, hemispheric maps have been drawn for each of the channels of the radiance at the centre and end of the scan respectivey. Examples are shown in Fig. 2 for the Southern Hemisphere, for August 25, 1975, a day on which there was considerable planetary wave activity. For the lowest level shown (~45 km) notice the warm region at ~90° longitude and 65°S latitude. The wave amplitude is higher at ~ 50 km and the warm region has shifted westward to ~ 15° longitude. The westward shift continues with increasing altitudes to ~ 65 km but the wave amplitude decreases. Notice that the wave can still be identified at the highest level (~ 85 km altitude). A westward tilt of geopotential height is well known[6] to be associated with waves in which the energy is propagating upwards. A considerable amplitude of wave number two (two maxima round the pole) is evident at the lower levels, but has not penetrated far into the mesosphere.

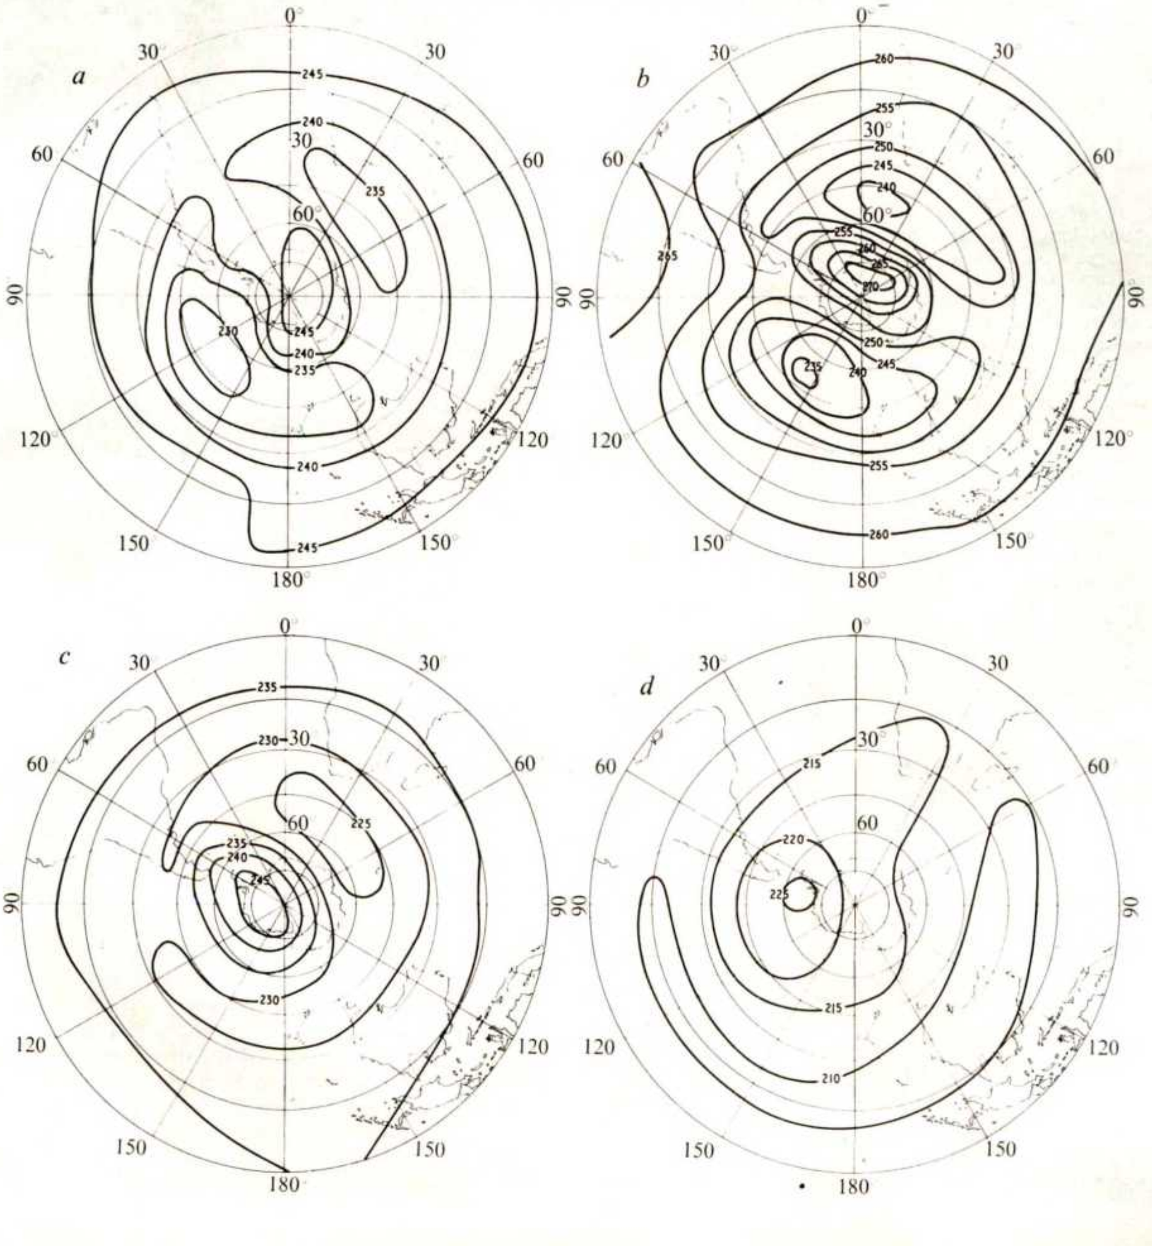
The radiance field of the top PMR channel (Fig. 2*d*) seems at first sight to be surprisingly flat, and does not

Fig. 1 Weighting functions for the 2 channels of the PMR for their lowest cell pressures for different angles of view from the nadir. The dashed weighting function in *a* is the weighting function applicable to the nadir view for 1.67 × (channel 1) − 0.67 × (channel 2).



indicate the presence of large amplitude gravity waves often observed by meteorological rockets. This is because the vertical wavelengths of such disturbances are short compared with the vertical averaging of ~ 20 km produced by the PMR. It is likely also that they possess horizontal distance scales which are short compared with the size of the field of view. The day-to-day consistency of the radiance fields at the top level demonstrates that there is little

Fig. 2 Polar stereographic maps of the Southern Hemisphere radiance (expressed as equivalent temperature) for August 24, 1975 for *a*, channel 2, 0.66 mbar, 15° from nadir; *b*, channel 1, 0.55 mbar, 15° from nadir; *c*, channel 2, 0.66 mbar, nadir view; *d*, 1.67 × (channel 1) − 0.67 × (channel 2) nadir view, cell pressures as in *a*–*c*. The appropriate weighting functions are shown in Fig. 1; they peak at ~40 km (*a*), 48 km (*b*), 61 km (*c*), 87 km (*d*).



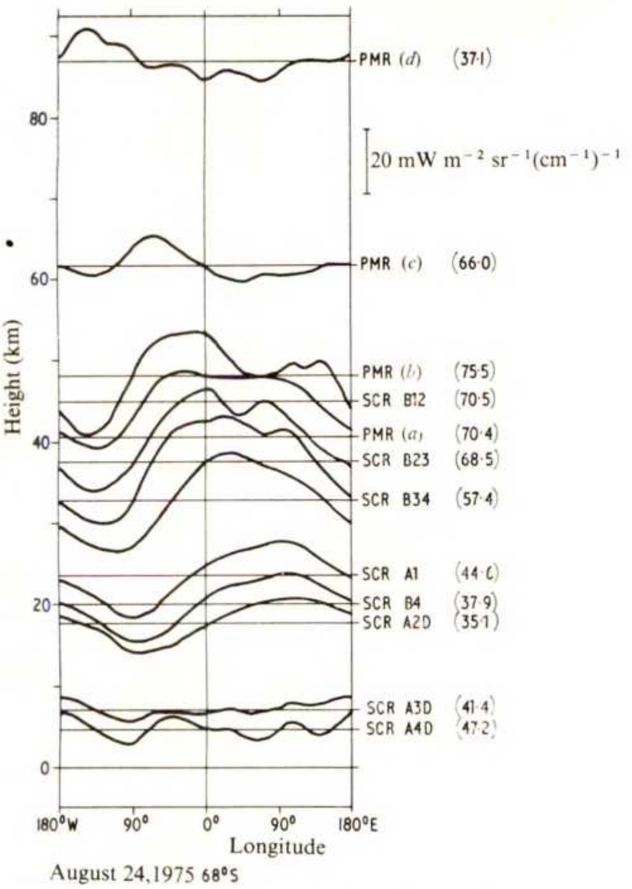


Fig. 3 Height–longitude cross section around the 68° S latitude circle for August 24, 1975. For each PMR and SCR channel the mean radiance is shown in brackets near the centre of the weighting function peak, and the deviation from the mean radiance is plotted as the ordinate at each of the levels. The PMR channels are labelled (*a*), (*b*), (*c*) and (*d*) corresponding to the key of Fig. 2.

residual atmospheric noise left after this averaging process.

Figure 3 gives more details of the wave. The PMR and Nimbus 5 SCR (which has functioned continuously for 3 yr) are in excellent agreement in the region where they overlap. The same planetary wave can be identified from the troposphere up to the mesopause, over which altitude range it shows a consistent westward tilt with altitude—the longitude of the maximum changing by nearly 360° from the bottom to the top.

Construction of the PMR involved a large number of personnel at Oxford University, the Rutherford Laboratory, Marconi's Space and Weapons Laboratory at Frimley, and the Department of Applied Physics, Reading University. The project was supported by the SRC. We also acknowledge the cooperation of the Nimbus Project, NASA.

Ball lightning

A DRAMATIC and characteristic ball lightning event, important because it may reveal details of the energetics of the phenomenon, was reported by a housewife to have occurred during a vigorous thunderstorm in the Midlands area of England on August 8, 1975. During this storm, a number of houses in the area were struck by lightning.

The witness was in the kitchen of her house in Smethwick, Warley, at about 1945, when a sphere of light appeared over the cooker. The ball was ~ 10 cm across and surrounded by a flame-coloured halo; its colour was bright blue to purple. The ball moved straight towards the witness at an estimated height of 95 cm from the ground. Burning heat was felt, and there was a singeing smell. A sound something like a rattle was heard. The ball was in sight for only a second or so because its lifetime was cut short:

"The ball seemed to hit me below the belt, as it were, and I automatically brushed it from me and it just disappeared. Where I brushed it away there appeared a redness and swelling on my left hand. It seemed as if my gold wedding ring was burning into my finger."

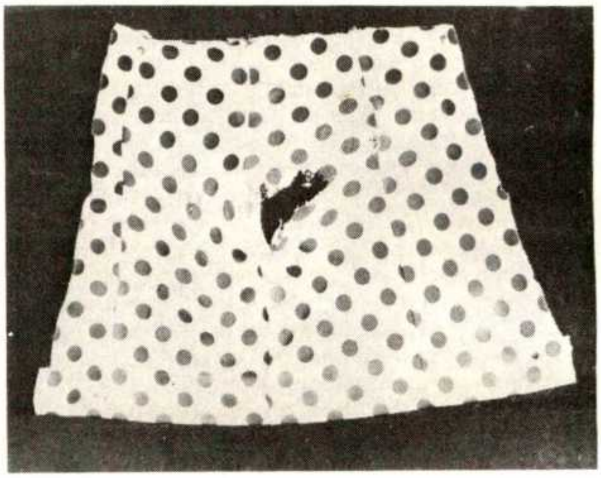

Fig. 1 Part of the dress alleged to have been damaged by "ball lightning", showing area and extent of damage. Scale: average diameter of spots in pattern is 19 mm.

Where the ball struck her, the clothing of the witness was damaged. A hole was produced in her dress and her tights. Her legs were not actually burned, however, but became red and numb. The dress has been secured for examination, and tests are currently being carried out to try to establish the nature of the damage. There is a central area (Fig. 1) where the synthetic fibre of the dress has disappeared altogether, and the shape of the hole is in agreement with the witness' statement that she brushed the ball downward a couple of inches. The hole is ~ 11×4 cm. Around its perimeter, the material has shrivelled, but is not charred. In addition, there is a secondary area where the fibre has shrivelled, and the pattern printed on the fabric has faded noticeably. The position of the primary damage is ~ 20 cm from the hem of the dress, so it is estimated that the ball struck at ~ 95 cm from the ground.

Although thunder and lightning were going on at the time, the witness is not sure whether or not the manifestation was associated with a thunderclap. The ball exploded with a bang, but she is not certain whether it exploded at the exact time at which she touched it; she felt this to be the case, however. Before my contacting her, the witness had had no acquaintance with the phenomenon of ball lightning.

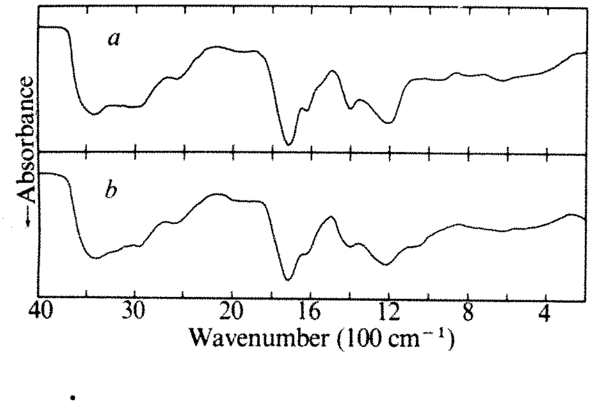
Possible relationship between soil fulvic acid and polymaleic acid

In the course of structural investigations into the organic matter component of soil, it became clear that the fulvic acid solutions[1] (the alkali-soluble fractions of humus not precipitated by acid) contained a high proportion of their soluble organic matter as a polymer, consisting of a carbon skeleton highly substituted by carboxyl groups. The solutions also normally contained peptide and polysaccharide mixtures or complexes which could be removed almost entirely by fractionation on charcoal[2], a technique which allowed the isolation of the polycarboxylic acid. Brown acidic polymers virtually identical with those found in the fulvic acid solution were recovered from podzol B_h horizon humus by extraction of the soil with dilute mineral acid or trisodium citrate solutions (*p*H 7.0) followed by dialysis.

Infrared spectroscopy, elemental analysis and a study of the degradation products of these polymers and their derivatives suggested that the polymers had an aliphatic or alicyclic backbone substituted predominantly by vicinal carboxyl groups. The soil polymers still contained polysaccharide, phenolic derivatives and nitrogen, but in low amounts, the last being accountable as amino acid residues and the ammonium ion. The product arising from the hydrolysis of pyridine-catalysed homopolymerised maleic anhydride[3] was found to be chemically and structurally related to the natural polymers, as shown by the similarities between their infrared absorption spectra (Fig. 1), their analysis (polymaleic acid: C 48.76, H 3.30, N 0.82%; B_h citrate-soluble humus: C 47.62, H 3.39, N 0.86%; for comparison, fulvic acid polymer: C 46.18, H 2.68, N 0.95%) and certain of their acid-hydrolysis products (Fig. 2). The dissimilar hydrolysis products, levulinic acid and the phenolic acids, could arise from species adsorbed on to or incorporated into the natural polymer, and this was demonstrated with the synthetic polymer. Slight differences between the potentiometric titration curve of the polymaleic acid[4] and that of the soil polymer were similarly explicable, while the solution-*p*H visible absorption spectra relationships were identical.

Fig. 1 Infrared spectra of *a*, polymaleic acid, *b*, fulvic acid in KBr pressed disks (1-mg sample and 170-mg KBr in a 12-mm diameter disk). Absorption in (*b*) near 1,000–1,100 cm⁻¹ is from carbohydrate.



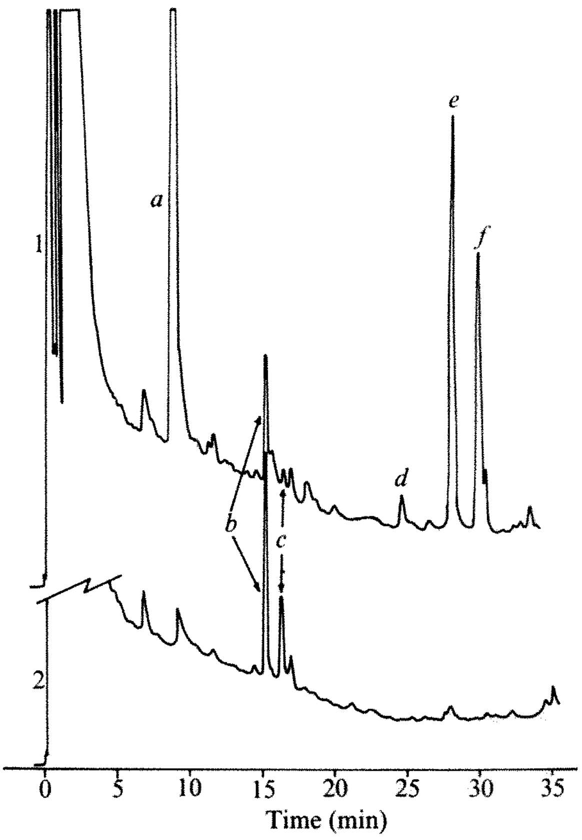


Fig. 2 Gas chromatography curves of trimethylsilyl derivatives of ether-soluble products from 6 M HCl hydrolysis of (1) Humus podzol Bh citrate-soluble humus, (2) Polymaleic acid. Products identified by gas chromatography–mass spectrometry: *a*, Levulinic acid TMS; *b*, Succinic acid di-TMS; *c*, Fumaric acid di-TMS; *d*, 4-Hydroxybenzoic acid di-TMS; *e*, Vanillic acid di-TMS; *f*, 3,4-Dihydroxybenzoic acid tri-TMS. GC conditions: 3% OV-1 on AW silanised Diatomite C (1.5 × 0.006 m); 15 cm³ min⁻¹ nitrogen carrier gas; temperature programme 100 °C isothermal for 5 min, 4 °C min⁻¹ to 250 °C, isothermal at 250 °C for 10 min.

Although the complete structure of polymaleic acid has yet to be elucidated, certain aspects of the structure are known, for example, the existence of vicinal carboxyl groups readily dehydrating to yield anhydride, a property shown spectroscopically by fulvic acid, and unsaturation which accounts for an absorption band near 1,620 cm⁻¹ in the infrared spectrum of fulvic acid. It is these features that make this polymer attractive as a model for fulvic acid. Structures already proposed[5] for fulvic acid are based on aromatic residues that have been assumed to arise partly from lignin- and/or tannin-derived material. Previous unpublished work by H.A.A. and A. Hepburn has shown that the yields of aromatic molecules from degradations are sufficiently low for these compounds to be considered of minor importance in the structure. Further structural investigations of fulvic and polymaleic acids are in progress.

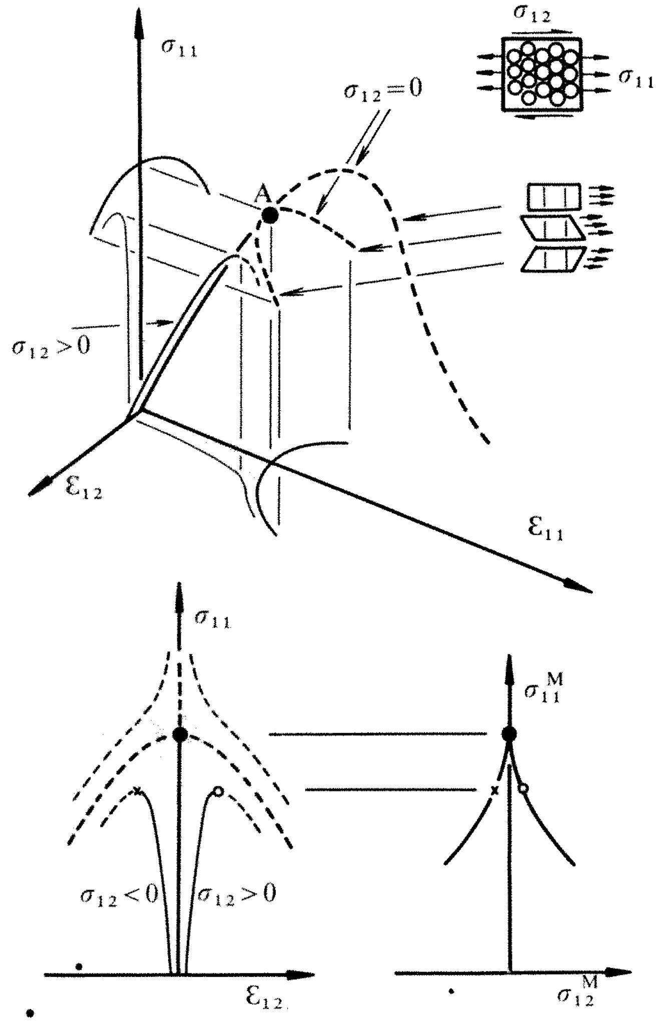
Hyperbolic umbilic catastrophe in crystal fracture

WE have demonstrated the existence of a cusp catastrophe in a symmetry-breaking mechanical instability of a close packed atomic lattice[1,2], and in an extension of this work we demonstrate here the existence of the more complex hyperbolic umbilic catastrophe[3-5] in a three-dimensional failure-stress locus.

The original cusp was associated with an unstable symmetric point of bifurcation[6] encountered by a close packed crystal with Lennard-Jones interatomic potentials subjected to a uniaxial tensile stress σ_{11}. Under this stress the lattice follows a primary equilibrium path involving a direct strain ε_{11}, and we showed that this path becomes unstable at the critical point A of Fig. 1. At this bifurcation point an unexpected symmetry-breaking shearing strain ε_{12} would develop explosively in the presence of even an infinitesimal disturbance, leading to a violent fracture of the crystal.

In this situation a corresponding small shearing stress σ_{12} acts as an 'imperfection' rounding off the bifurcation as shown by the lighter lines and giving rise to a sharp two-thirds power law cusp in the failure-stress locus represented by the plot of the peak stresses $\sigma_{11}{}^{M}$ and $\sigma_{12}{}^{M}$. This locus corresponds to the well known imperfection-sensitivity curves in the buckling of engineering structures[6-8].

Fig. 1 The upper picture shows the equilibrium paths of the atomic lattice when $\sigma_{22} = 0$, while the lower left-hand picture shows the projection of these paths into the (σ_{11}, ε_{12}) plane where we see the well known unstable-symmetric point of bifurcation or cusp catastrophe[6]. In general, stable regions of paths are drawn as solid lines while unstable regions of paths are drawn as broken lines. The lower right-hand picture shows the corresponding stability or catastrophe boundary as a failure-stress locus with the predicted two-thirds power law sensitivity.



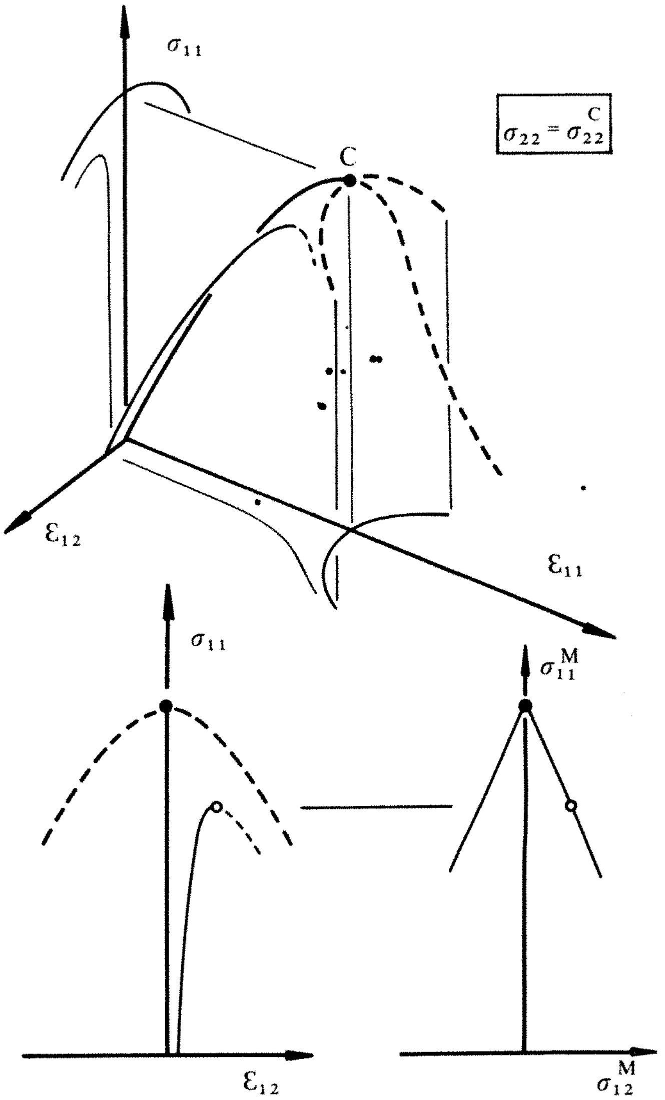


Fig. 2 This shows how Fig. 1 is modified by the addition of the direct stress $\sigma_{22} = \sigma_{22}{}^{C}$ which has shifted the point of bifurcation to the maximum of the primary stress–strain curve. The failure locus is now locally bilinear.

We have now extended this study by adding additionally a second direct tensile stress σ_{22} on the horizontal faces of the lattice. Within our approximations[2], which include an assumption that the vertical close packed columns undergo a negligible change in length, this direct stress has no effect on the primary equilibrium path lying in the plane of σ_{11} and ε_{11}. It does, however, influence the stability of this path, and has the effect of displacing the critical branching point A along the path. As we would expect, a negative (compressive) stress displaces A towards the unloaded state while a positive (tensile) stress has a stabilising action and displaces A in the direction of positive ε_{11}.

We have evaluated the magnitude of this stress, $\sigma_{22}{}^{C}$, that is necessary to shift the point A precisely to the maximum of the primary equilibrium path to give the situation shown in Fig. 2. In the presence of this small tensile stress $\sigma_{22}{}^{C}$ the crystal loaded by σ_{11} will thus encounter a hill-top branching point[2] at which the two-thirds power law cusp is replaced by a bilinear failure locus as shown in the plot of the peak stresses $\sigma_{11}{}^{M}$ and $\sigma_{12}{}^{M}$.

Inspecting our equations and the form of the equilibrium paths it is easy to see that this hill-top branching point is in fact

Thom's hyperbolic umbilic catastrophe[3–5], so that the full three dimensional failure locus in the space of the planar stresses $\sigma_{11}{}^M$, $\sigma_{12}{}^M$ and $\sigma_{22}{}^M$ must have the form of Fig. 3. Here we see that on the crest defined by $\sigma_{12}{}^M = 0$ the sharp cusp degenerates at the singularity corresponding to $\sigma_{22}{}^M = \sigma_{22}{}^C$ into two straight lines and thereafter the curve has a parabolic form. This crest is curved between A and C where it corresponds to failure at a branching point, but it is straight and parallel to the σ_{22} axis between C and B where failure is associated simply with the maximum of the primary equilibrium path: in this latter range the bifurcation has moved beyond this maximum and therefore no longer initiates the failure of the crystal. The failure surface has the characteristic form of the stability boundary of the hyperbolic umbilic catastrophe[9] which has often been likened to a breaking wave.

This attractive and concrete example of the hyperbolic umbilic catastrophe can now be added to the imperfection-sensitivity curve determined by G. W. Hunt[1,6] for the buckling of a stiffened panel as a second illustration of this catastrophe in nonlinear elasticity[10].

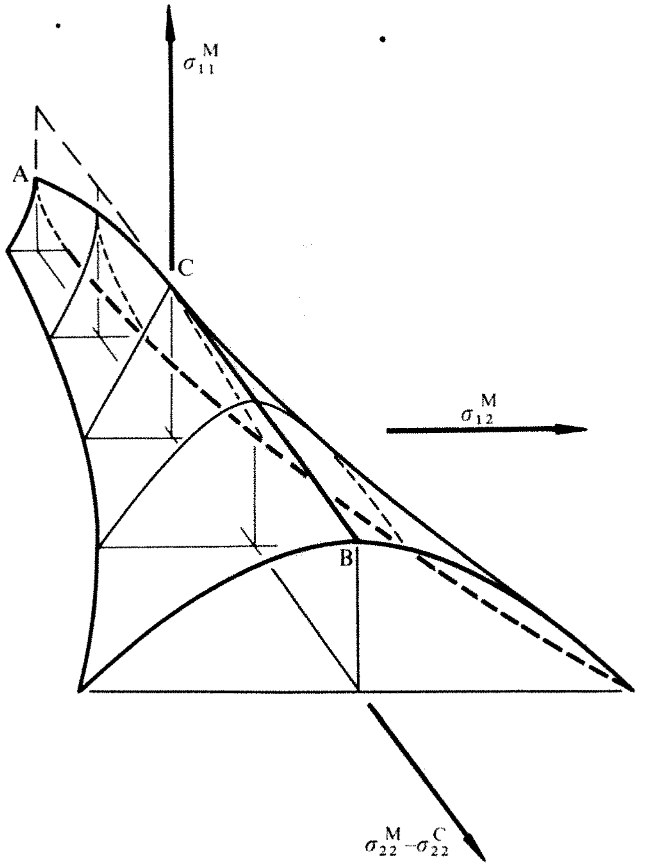

Fig. 3 The stability boundary in the space of the failure stresses corresponding to the catastrophe boundary of the hyperbolic umbilic catastrophe.

We feel that our demonstration of this new instability phenomenon for a fairly idealised, perfect and dislocation-free lattice is of some fundamental importance and is a useful complement to the numerical studies of Macmillan and Kelly[11] and the theoretical work of Hill[12]. Some further details of our cusp analysis have been published[13], and details of the present extension will be presented shortly.

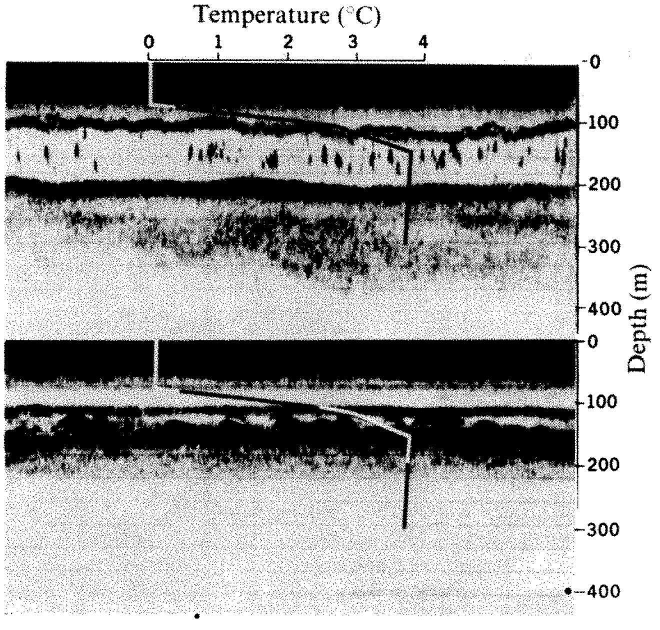
Arrest of deep scattering layer migration by a positive thermal gradient

LIGHT and temperature are considered to be the factors that influence diel vertical migrations of populations of biological sound scatterers (deep scattering layers) in the sea[1–3]. While light is probably the most important, temperatures which surpass the physiological tolerances of the organisms should play a major role in setting vertical limits. With positive thermal gradients (temperature increasing with depth) as are found in arctic and sub-arctic seas, sufficiently low temperatures near the surface could limit the evening ascent. This situation was observed in March, 1966 over the Kurile Trench along the eastern coast of the Kamchatka Peninsula (50°30′N, 162°30′E), an area influenced by the Oya Shio current system. Data were collected from USNS Charles Davis; acoustic records were made on a Westrex MK 10A Precision Depth Recorder using a Gifft transceiver to drive a hull-mounted UQN transducer at 12 kHz. The records were made on the 1.5-s sweep scale of the recorder.

Day and night acoustic scattering profiles are shown in Fig. 1. The day record was made between 1430 and 1530, March 5 while the ship was underway at 10 knots. The night record was made between 2330, March 5 and 0030, March 6 while the ship was drifting. Both records were made on the same station, however, and within a distance of ten nautical miles. The sea floor was at ~ 6,500 m. A 1,000-m hydrographic cast was taken at 2000, March 5 and

Fig. 1 Acoustic scattering profiles recorded over the Kurile Trench in March 1966. The upper record was made between 1430 and 1530 with the ship underway at 10 knots; the lower between 2330 and 0030 with the ship drifting. Temperature profile data from a hydrographic cast is superimposed.



the temperature structure is superimposed. Seven expendable bathythermographs taken within a ten-mile radius of the station show a similar profile. Salinity was ~ 33.2 ‰ from the surface to 100 m; at 200 m it had increased slightly to > 34 ‰.

The first well defined scattering feature below the outgoing pulse and surface scattering was a 20-m wide layer which oscillated between 90 and 130 m, the depth of the thermocline. The layer did not migrate, but seemed permanently associated with the thermocline on both day and night records. This phenomenon has been previously reported, and it has been demonstrated that the density gradient of the thermocline could not itself be the scattering factor for frequencies as high as 12 kHz (refs 5 and 6). Oscillations of the layer are suggestive of internal waves on the thermocline.

Between the thermocline layer and the main scattering layer were many discrete reflectors. Little is known of the composition of these targets over the deep sea, but their recordings are similar to acoustic signatures of fish schools in coastal waters[6]. The spatial relationship between these targets and the layers was maintained on both the day and night recordings. Like the main scattering layer beneath them, their upward migration was apparently arrested by the low temperature.

Maximum depth to the top of the main scattering layer was 255 m at 1000, March 5. Below the dense upper component of the layer, diffuse scattering was present to 350 m. Upward migration began at 1300 and a very gradual ascent (~ 20 m h^{-1}) progressed through the afternoon. The ascent was terminated at 1800 at a depth of 145 m.

A- and *B*-type hydrogen bond modifications of potassium hydrogen tartronate

ACCORDING to Speakman[1] two types of intermolecular hydrogen bonds between carboxyl groups can be discerned in the crystal structures of acid salts of carboxylic acids. The first, type *B*, occurs when two carboxyl groups are not symmetry related, and have structural differences sufficient to characterise them, separately, as unionised ($-CO_2H$) and ionised ($-CO_2^-$). Thus, any hydrogen bond between these groups must be asymmetric. The second, type *A*, occurs when two carboxyl groups are related by a symmetry element of the crystal, so that they are effectively equivalent. Thus any hydrogen bond between the groups must be, at least formally, symmetrical.

A reliable tool for establishing the type of hydrogen bond present in crystals of acid salts is infrared spectroscopy, which can be used to examine the region of the stretch vibration of the hydroxyl group[2]. Also, geometric evidence from X-ray data on a number of acid salts unambiguously reveals the existence of the two types of hydrogen bonds. The difference in symmetry brings about a significant difference in the geometry of the carboxyl groups involved in hydrogen bonding[1].

Moreover, there is also a difference in the O···O distance: in the *A* type it seems to be at least 0.05 Å shorter than the *B* type. It has been argued that the symmetry in the *A* type could be only apparent, and attributable to a 1:1 disordering of the hydrogen atom in an asymmetric hydrogen bond[3]. But it seems from infrared and X-ray studies that *A*- and *B*-type hydrogen bonds do differ. It is intriguing to identify the factors that determine whether a compound crystallises either as an *A*- or *B*-type salt. It is of interest to note that in the crystal of potassium hydrogen *meso*-tartrate both types of bond are present[4,5]. The *A* type relates to one *meso*-tartrate carboxyl group, and the *B* type relates to the second, which is inequivalent to the first because of molecular asymmetry.

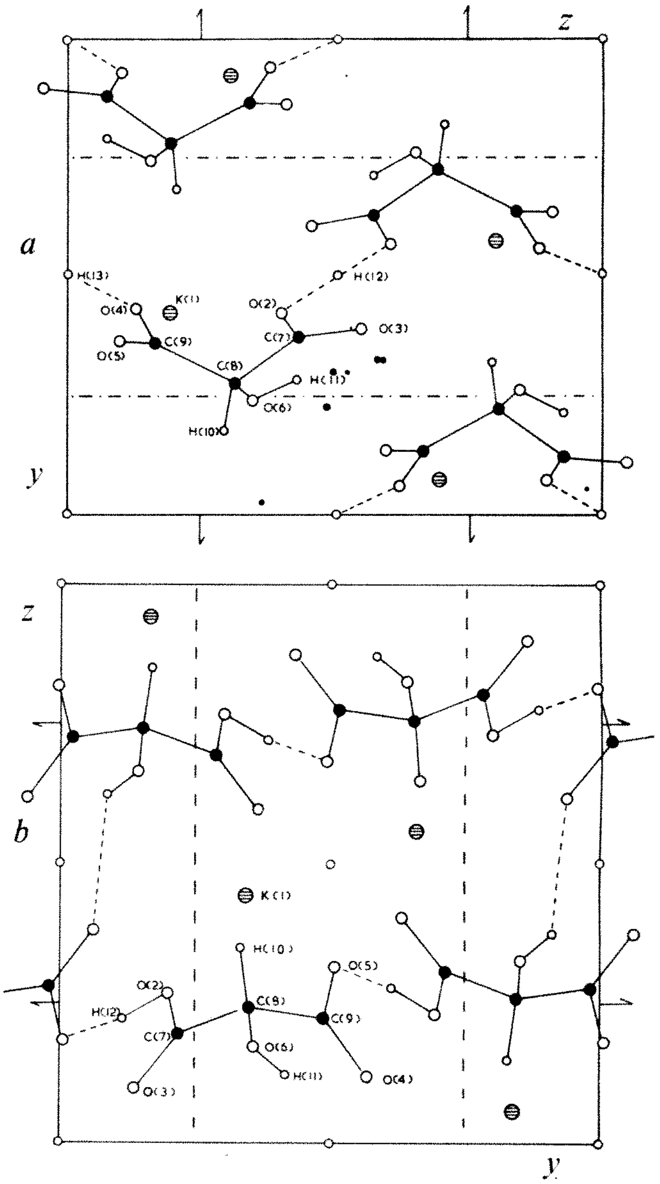

Fig. 1 Projections along the *a* axis of the crystal structures of potassium hydrogen tartronate: *a*, α form; *b*, β form. Dashed lines, hydrogen bonds.

The study of the *A*- and *B*-type hydrogen bonds found in the acid potassium salt of tartronic acid seems to be more promising in studies of the problem. That compound crystallises in two forms, the α form having an *A*-type and the β form having a *B*-type hydrogen bond. Experimental data of the modifications are summarised in Table 1, and relevant structural data are given in Table 2.

The *A*- and *B*-type hydrogen bonds are easily recognised from projections along the *a* axis (Fig. 1). The tartronic acid anions in both structures are linked by hydrogen bonds forming infinite chains. In the α form, the chains are generated by centres of inversion lying along the [101] direction with O···O

distances of 2.433 and 2.435 Å, respectively. In the β form the O···O distance in the hydrogen bond propagating along the screw axis is 2.485 Å. Glide planes interrelate the anion chains in both types. The aliphatic hydroxyl group interaction is very different in the two forms. In view of its geometry (Table 2), it is highly questionable whether the O-H···O contact in the α form should be considered as a hydrogen bond. In this respect we refer to the crystal structure of tartronic acid itself[6], in which the aliphatic hydroxyl group is free[7]: (O···O, 3.02 Å; H···O, 2.24 Å; O-H···O angle, 142°).

In contrast, the OH group in the β form participates in a hydrogen bond of normal geometry (Table 2). The molecular geometry and conformation in the anion part of the α form differs significantly from that of the β form. In the former the conformation of one of the carboxyl groups with respect to the C(α)-hydroxyl group is antiplanar, which is quite exceptional[8]. The observed geometry of the carboxyl group reflects the schematical classification in *A* and *B* types: the *A*-type carboxyl groups are half ionised, whereas in the *B*-type anion one carboxyl group is neutral and the other is completely ionic (Table 2). The potassium coordination is eightfold and, as usual, irregular.

From the shorter O···O distances in *A*-type hydrogen bonds it looks as though such a symmetrical bond is more favourable than an asymmetric one. We feel that the comparison of the crystal structures of the two modifications of potassium hydrogen tartronate provides new evidence for this. The energetically unfavourable molecular conformation and the weaker O(6)-H(11)···O(5′) hydrogen bond may compensate for the stronger *A*-type hydrogen bonding in the α form, and thus account for the dimorphism.

Speed of podzolisation

THE coastal sand dunes of eastern Australia are being mined extensively for heavy minerals. After mining, the replaced sand is subject to soil-forming processes. On such sites we have observed the formation of podzol profiles after 4.5 yr, with the development of bleached A_2 'pipes' up to 45 cm deep after 9 yr, indicating the extreme rapidity of soil-forming processes in suitable conditions.

Only a few estimates have been made of the time required for a podzol profile to develop because the time of initiation of soil-forming processes cannot usually be determined precisely. Chandler[1] used the known retreat pattern of the Medenhall glacier in Alaska and by comparing the degree of podzol development in materials of different ages, estimated that a mature profile would require 1,000–1,500 yr to form. Tamm (quoted by Russell[2]) used the drainage of Lake Ragunda in 1796 as the beginning of soil development and also estimated a time of from 1,000–1,500 yr for the development of a mature podzol. In Australia, Burges and Drover[3] examined soil development on a sequence of beach ridges just north of Sydney, and estimated that a period of 1,000 yr is required to develop a distinct B horizon in an iron podzol. The basis of this estimate was not the soil profile itself, but the supposed age of the beach ridges in which the podzols are developed.

On a more restricted time scale, Crompton[4] demonstrated that thin iron pan podzols, not more than 8 cm in total thickness have developed in less than a century. Muir[5]

reported that on formerly cultivated land overgrown with Scots pine in Scotland a bleached A$_2$, 0.5 cm thick, developed in 20 yr.

The example we have studied is in the Myall Lakes area, 290 km north of Sydney (Portion 19, Parish of Fens, New South Wales, Private Mining Lease 2, 32°39′S 150°11′E). Here, before mining, well developed podzols supporting dry heath or woodland occurred in low relief quartz sand dunes. The heath vegetation was similar to that described by Clark[6] and included shrubs such as *Banksia, Leptospermum, Casuarina* and *Persoonia,* up to 3 m high. The original profile was: dark grey A$_1$ 0–30 cm; bleached A$_2$ 30–150 cm, sharply demarcated across a highly convoluted boundary from the B$_2$ which had a marked colour contrast but only slight and sporadic induration developed in several metres of sand.

The oldest site examined supported heath and was mined in September 1966. During this process the podzol was completely destroyed, since mining involves the stripping and stockpiling of the topsoil (largely A$_1$), and complete homogenisation of all remaining sand to depths greater than 5 m by the dredging and mineral separation processes. The pale brown (10 YR 6/3 moist 7/3 dry) homogenised sand was reformed to a similar topography as the original and covered by the stockpiled topsoil during March 1967. The area was planted with rye (*Secale cereale*), West Australian blue lupin (*Lupinus angustifolius*) and fertilised with Shirleys No. 17 fertiliser (9.2% N, 4.3% P, and 4.6% K) at the rate of 517 kg ha^{-1}, during September 1967. Aerial fertilisation with Nitram (34% N) at the rate of 129 kg ha^{-1} was carried out in April and September 1972. Regrowth of native species occurred from seed in the replaced topsoil. The present vegetation on the mined site is 0.5–1.5 m high, covers 50% of the ground surface (visual estimate) and is made up of shrubs which occur on adjacent unmined areas but in different proportions.

Figure 1 is a section through the sand 9 yr after mining. Below the abrupt lower boundary of the replaced topsoil, the underlying homogenised sand has a zone of bleaching with an extremely convolute lower margin marked by a thin zone of dark yellowish brown (10 YR 4/4 moist and dry) sand. On examination under a binocular microscope the surface organic-rich material (replaced A$_1$) is seen to consist of clean quartz sand grains with interstitial organic matter. The homogenised unbleached sand is made up of approximately 80% clean quartz grains and 20% of grains with reddish (probably ferric oxide) skins on their surface, giving the overall pale brown colour. Within the bleached zone the surfaces of the quartz grains are completely clean and there is no interstitial organic matter. Bleaching of the pale brown homogenised sand is associated with a reduction of the iron content of the sand from about 1,150 p.p.m. (w/w) to about 250 p.p.m. Iron was extracted from ashed samples in hot concentrated hydrochloric acid and concentrations were determined by atomic absorption spectrophotometry. Dissection of Kubiena tin samples shows the bleached zone to be planar immediately beneath the replaced topsoil, to average 1–2 cm in thickness and to extend up to 45 cm deep as scattered roughly circular pipes. On a microscale this is an exact replica of the convoluted relationship seen between the A$_1$ and B$_2$ horizons of the podzols in unmined sand. It would seem to result from percolating solutions removing surface coverings of ferric oxides from quartz sand grains and depositing them again within a short distance, that is, in a typical podzolising process. The rapidity of this process in producing features of the dimensions shown in Fig. 1, in 9 yr is probably due to the absence of finer grained materials to inhibit the throughflow of solutions or to inactivate the molecules responsible for the podzolisation. It is not certain whether the active organic molecules originate from the present vegetation or from organic matter in the replaced topsoil. The pipe-like areas of bleached sand were also found on mined sand under *Imperata cylindrica* and in an area of sparse vegetation on a former *Ammophila arenaria* nursery. They were not, however, present under this vegetation where the organic content of the replaced topsoil was low.

The speed with which the pale brown quartz sand can be bleached has been demonstrated in the laboratory. Aqueous extracts from fresh leaves of *Angophora costata* and *Eucalyptus gummifera* growing on a podzol site were prepared using the method of Bloomfield[7]. These species are common in woodland on podzols at Myall Lakes. The 5% extract was dripped at 1–2 cm^3 h^{-1} into the top of a glass tube (0.3 cm internal diameter) packed with the homogenised mined sand. Continuous flow produced visible bleaching to a depth of a least 1 cm in the first hour. This extended to the bottom of the column (25 cm) after about 7 h. With interrupted flow but without drying out of the column, a bleached layer 2 cm deep formed above a dark brown band 0.1 cm thick within 18 h. Water or acetate buffer (*p*H 4) did not duplicate these effects. These experiments reproduce within hours aspects of the podzol morphology. They are being continued in an effort to determine the conditions for iron redeposition and the relative importance of vegetation species and soil organic matter in the genesis of these profiles.

Two points requiring evaluation arise from these observations; pedological and geomorphic ages based on the degree of development of podzol profiles, especially in sand dune areas, may have been overestimated and the speed of pedological processes, especially in disturbed systems, may have been underestimated.

Transfer of mildew resistance from the wild oat *Avena barbata* into the cultivated oat

MILDEW (*Erysiphe graminis*, F.sp. *avenae*) can reduce the yield of cultivated oats by 30% (ref. 1) and is the most important disease of the crop in the UK. The ability of the pathogen to change either by mutation or recombination, giving rise to strains which can effectively attack previously resistant cultivars, leads to a continuous search for further sources of resistance. Genotypes of related weed species of *Avena* have been isolated that are completely resistant to mildew. A genotype of the tetraploid species *Avena barbata* ($2n = 28$) collected in Algeria is resistant to all the prevalent races of mildew and would form a valuable source of resistance to the pathogen. We now report the successful transfer of this source of mildew resistance into the cultivated oat. This provides the oat breeder with a new source of mildew resistance to use in breeding programmes.

The cultivated oat *Avena sativa* is a hexaploid species ($2n = 42$) and probably combines three distinct diploid sets of chromosomes. *A. barbata* can be crossed readily with the cultivated oat, but the hybrid is sterile. It is possible to obtain the occasional viable seed when the sterile hybrid is backcrossed to *A. sativa* and some success has been achieved in transferring genes for crown rust resistance from diploid and tetraploid weed species to *A. sativa* by continuous backcrossing[2,3]. But the genetic control of chromosome pairing in *A. sativa*[4,5], which restricts pairing to homologous chromosomes, minimises the amount of interspecific chromosome pairing that takes place in hybrids and derivatives. Consequently, plants resistant to crown rust isolated in later generations of interspecific hybrids have often proved to be chromosome substitution or addition lines, and not the products of natural recombinations[6–8].

The amphiploid *A. barbata* × *A. sativa* was produced at the Welsh Plant Breeding Station and backcrossed twice to *A. sativa*. Selection for mildew resistance was practised at each generation and a resistant plant with 44 chromosomes was isolated from the selfed progeny of the second backcross generation[9]. This disomic addition line combines the full complement of the recurrent *A. sativa* parent Manod and a pair of *A. barbata* chromosomes. The monosomic addition line ($2n = 43$) is also resistant. When the selfed progenies of the monosomic addition line were tested for mildew reaction to race 2 all the resistant plants were found to contain the *A. barbata* chromosome, confirming that resistance is due to the presence of the *A. barbata* chromosome. No recombinants were found in the progeny (5,649 seedlings tested) of the monosomic addition line.

Seeds of the disomic addition line ($2n = 44$) were irradiated at doses of 10,000 and 15,000 rad using a ^{60}Co source. The screening procedure for translocations was that used successfully in wheat-rye studies[10]. If translocations between the *A. barbata* and *A. sativa* chromosomes were achieved, the formation of a multivalent or incompletely homologous bivalents would give rise to gametes deficient for the *A. barbata* gene for resistance. When the I_1 plants (originating from the irradiated seeds) are selfed fusion of gametes which do not have the resistant gene should result in some susceptible progeny in the I_2 populations. Nineteen I_2 families out of 391 did segregate a proportion of susceptible progeny but the rest produced only resistant seedlings, as expected from a normal disomic addition line. The resistant plants from the 19 I_2 families were grown to maturity to produce I_3 seeds. As a result of further tests for mildew reaction in the I_3 and I_4 generations, lines were isolated which segregated three resistant: one susceptible seedlings. All these segregating lines had 44 chromosomes, which shows that the susceptible seedlings were not the result of the complete loss of the *A. barbata* chromosome.

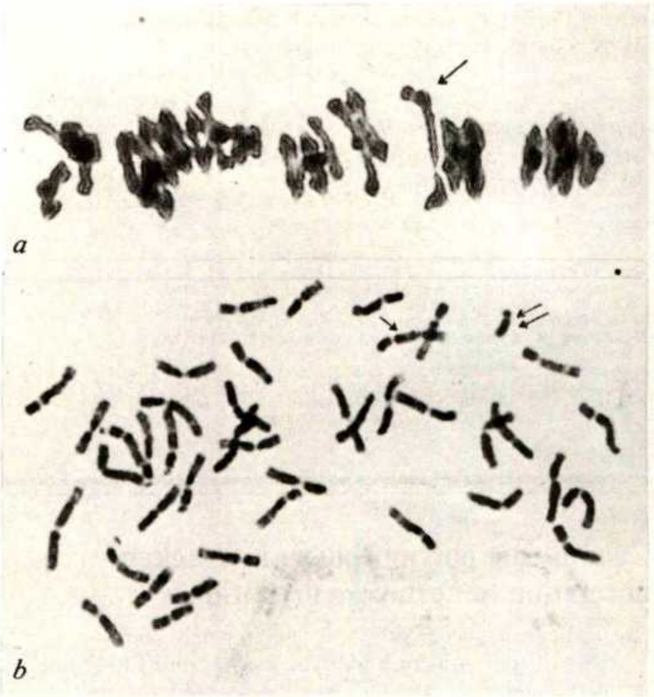

Fig. 1 *a*, Metaphase 1 in I_3 plant of B.133 with 22 bivalents, one of which is a distinct heteromorphic bivalent. *b*, Somatic chromosomes of a euploid plant heterozygous for the translocated chromosome. Two arrows indicate natural chromosome 21 and a single arrow the translocated chromosome.

One of these particular lines, B.133, was studied in detail to assess the potential of the translocation stock as breeding material. Meiotic analysis was made difficult by clumping and stickiness of chromosomes, but in some cells a distinct heteromorphic bivalent (Fig. 1*a*) was observed. Resistant plants were crossed with the susceptible cultivar Manod to produce 43-chromosome hybrids. The F_2 families again segregated in a 3 : 1 ratio, the pooled data being 361 resistant : 120 susceptible seedlings. Counting the chromosomes of the resistant seedlings revealed that with the exception of the occasional seedling with 43 chromosomes the resistant progeny had the euploid number of 42 chromosomes. The *A. barbata* gene had been incorporated into the *A. sativa* genome and behaved normally, producing a monofactorial ratio.

Some of the chromosomes of *A. sativa* can be identified readily according to shape and size[11]. Chromosome 21, the smallest of the complement, can be identified easily. In the F_2 families which segregate three resistant : one susceptible we found that in the resistant seedlings chromosome 21 was either absent or only present as a single chromosome. In the susceptible seedlings the pair of chromosomes 21 was always present. Because all the seedlings had the euploid number of 42 chromosomes the fact that chromosome 21 was either absent or present single in the resistant seedlings shows that it is involved in the translocation. Resistant seedlings lacking chromosome 21 are homozygous for the translocated chromosome and those containing only a single chromosome 21 are heterozygous for the translocated chromosome. It has already been established that the gene for mildew resistance is located on the short arm of the *A. barbata* chromosome[9]. The morphology of the translocated chromosome (Fig. 1*b*) suggests that it involves the short arm, the centromere and a portion of the long arm of the *A. barbata* chromosome and the long arm of chromosome 21 of *A. sativa*.

Plants homozygous for the translocation are vigorous and fertile, the deletion of a part of chromosome 21 and the duplication arising from the *A. barbata* segment are readily tolerated. In the euploid lines which were heterozygous for the translocation 21 bivalents were regularly formed, one of which was heteromorphic. The regular monofactorial segregation observed when the heterozygous translocation stock is selfed shows that the translocated chromosome can compete effectively with the intact chromosome 21. It should thus be possible to transfer the mildew resistance to other cultivars of the cultivated oat by a simple backcrossing programme.

Cyanogenic polymorphism in bracken in relation to herbivore predation

THE ecological success of bracken is partly a result of its extensive rhizome system, and because of its ability to synthesise various secondary compounds which deter predators and phytopathogens[1–3]. These compounds include the cyanogenic glycoside, prunasin[4], toxic because on enzymatic hydrolysis HCN is released. Although present in only 5% of ferns[5], cyanogenic glycosides are ecologically significant in other plant species; they deter both molluscs and voles from grazing on *Lotus corniculatus*[6], and rabbits from eating *Trifolium repens*[7]. As in these two species, we have found that cyanogenesis is also polymorphic in bracken.

Our aim was to correlate herbivore predation with changes in cyanogenesis and phenolic content of bracken throughout the growing season (G.A.C.-D., E. Bernays, S. Finch and T.S., unpublished). We examined bracken from several randomly chosen sites in Richmond Park, Surrey, These comprised open and shady areas, and involved both inter- and intra-population studies. Our results showed that in most populations 96% of individuals contained both prunasin and the corresponding hydrolase and were therefore cyanogenic, but in a few populations, 98% of individuals were acyanogenic. Of these, 85% lacked both enzyme and substrate, whereas 15% contained prunasin without enzyme. We found that the bracken fronds from such areas were heavily grazed by deer and sheep, as examination of animal droppings in the area and observations by the gamekeeper showed. Examination of other widely separated patches of bracken confirmed that only fronds from acyanogenic plants were eaten.

To establish whether it is the production of HCN or merely the possession of prunasin which is the predator deterrent, we fed disks of bracken fronds to the phytophagous locust, *Schistocerca gregaria*. The results of our experiments showed that when both prunasin and enzyme were present only 4% of fronds were eaten, whereas when only the substrate was present the insects consumed 52% of the test meal, which was nearly the same as when both substrate and enzyme were absent (48%). It seems, therefore, that the production of HCN (or benzaldehyde) acts as the deterrent. Young fronds of bracken were more cyanogenic than older fronds, whether sampled throughout the season, or as young and spore-bearing fronds of a single plant. We found that *S. gregaria* consumed the minimum amount of bracken in test meals during late May to early June, coinciding with the greatest intensity of cyanogenesis[8].

We conclude that cyanogenic polymorphism in bracken has a positive role in determining the degree of herbivore predation and that there is selectivity for acyanogenic forms in natural conditions.

We thank Dr E. Bernays, C.O.P.R., Mr S. Finch, Brunel University, and Mr Brown, gamekeeper of Richmond Park, for their assistance. This work was supported by the ARC.

Inhibitory binocular interaction in human vision and a possible mechanism subserving stereoscopic fusion

IN the human visual system, pathways from the two eyes converge anatomically by partial crossing over of the optic nerve fibres at the optic chiasma. Neurophysiological studies of the primary visual cortex of primates have established that these converging pathways carry signals from both eyes to the same cortical neurones[1]. In normal viewing conditions, each eye forms an image of the external visual field, the point of attention in the field being centrally fixated in both eyes. There is a small difference in the relative positions of non-central image points formed on the two retinae because the eyes view the visual field from slightly different positions. The ability of the primate visual system to extract information about the depth of a focused object in the visual field apparently rests on the convergence on to single cortical neurones of signals arising from the slightly displaced images in the two eyes[2]. If each eye perceives a totally different visual stimulus, however, the visual signals arising from the two stimuli are perceptually antagonistic and, in this situation, an observer usually detects only one stimulus at a time. This phenomenon is referred to as binocular rivalry. We have investigated interactions between visual signals produced by two different stimuli when presented one to each eye.
